ADVANCING EMERGENCY CARE

Tintinalli's Emergency Medicine

A Comprehensive Study Guide

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the clinical practices accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Tintinalli's Emergency Medicine

A Comprehensive Study Guide

Eighth Edition

Editor-in-Chief

Judith E. Tintinalli, MD, MS
Professor and Chair Emeritus
Department of Emergency Medicine
Adjunct Professor
Department of Health Policy and Administration
University of North Carolina
Chapel Hill, North Carolina

Co-Editors

J. Stephan Stapczynski, MD
Professor, Department of Emergency Medicine
University of Arizona College of Medicine - Phoenix
Phoenix, Arizona

O. John Ma, MD
Professor and Chair
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Donald M. Yealy, MD
Chair, Department of Emergency Medicine
University of Pittsburgh/University of Pittsburgh Physicians
Senior Medical Director, Health Services Division, UPMC
Professor of Emergency Medicine, Medicine, and Clinical and Translational Sciences
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Garth D. Meckler, MD, MSHS
Associate Professor and Division Head
Pediatric Emergency Medicine
University of British Columbia/BC Children's Hospital
Vancouver, British Columbia

David M. Cline, MD
Professor and Director of Departmental Research
Department of Emergency Medicine
Wake Forest School of Medicine
Winston-Salem, North Carolina

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

To the clinicians, residents, medical students, NPs, PAs, EMTs, and paramedics who provide emergency care around the world.

Judith E. Tintinalli, MD, MS

Co-Editors

Dedicated with love and respect to my father and father-in-law, two veterans from the Greatest Generation, on the 70th anniversary of the end of World War II.

J. Stephan Stapczynski, MD

For my parents: my mother, Simone, for her continued love and support, and in loving memory of my father, Mark.

O. John Ma, MD

I thank: My family, who always believe in me and make this all possible; my partners, who bring excellence to my eyes each day; and those seeking emergency care, trusting that all will be well.

Donald M. Yealy, MD

To the patients, nurses, students, and mentors who teach me every day, and to my family and partner for their love and support.

Garth D. Meckler, MD, MSHS

To my family, mentors, residents, and students who continue to give meaning to this work.

David M. Cline, MD

About the Video . . . . . *xv*

Contributors . . . . . *xvii*

Pharmacy Reviewers . . . . . *xli*

Preface . . . . . *xliii*

SECTION 1 Prehospital Care 01

1 **Emergency Medical Services** 01
C. Crawford Mechem

2 **Prehospital Equipment** 04
Andy Boggust

3 **Air Medical Transport** 10
C. Keith Stone, Stephen H. Thomas

4 **Mass Gatherings** 14
Michael G. Millin

SECTION 2 Disaster Management 23

5 **Disaster Preparedness** 23
Robert G. Hendrickson, B. Zane Horowitz

6 **Natural Disasters** 30
Lisa D. Mills, Trevor J. Mills

7 **Bomb, Blast, and Crush Injuries** 34
Michael J. Bono, Pinchas Halpern

8 **Chemical Disasters** 39
B. Zane Horowitz, Robert G. Hendrickson

9 **Bioterrorism** 46
Anthony G. Macintyre, Joseph A. Barbera

10 **Radiation Injuries** 51
Annette M. Lopez, Jennifer A. Stephani

SECTION 3 Resuscitation 59

11 **Sudden Cardiac Death** 59
Joseph P. Ornato

12 **Approach to Shock** 63
Bret A. Nicks, John Gaillard

13 **Fluid and Blood Resuscitation in Traumatic Shock** 69
David M. Somand, Kevin R. Ward

14 **Anaphylaxis, Allergies, and Angioedema** 74
Brian H. Rowe, Theodore J. Gaeta

15 **Acid-Base Disorders** 79
Gabor D. Kelen, David D. Nicolaou, David M. Cline

16 **Blood Gases** 89
Casey Glass

17 **Fluids and Electrolytes** 92
Roberta Petrino, Roberta Marino

18 **Cardiac Rhythm Disturbances** 112
William J. Brady, Thomas S. Laughrey, Chris A. Ghaemmaghami

19 **Pharmacology of Antiarrhythmics and Antihypertensives** 135
Sara H. Shields, Rachel M. Holland, R. Dustin Pippin, Benjamin Small

20 **Pharmacology of Vasopressors and Inotropes** 143
Sara H. Shields, Rachel M. Holland

21 **Hyperbaric Oxygen Therapy** 146
David S. Lambert, Stephen R. Thom

SECTION 4 Resuscitative Procedures 151

22 **Basic Cardiopulmonary Resuscitation** 151
Adam D. Friedlander, Jon Mark Hirshon

23 **Defibrillation and Cardioversion** 157
Marcus E. H. Ong, Swee Han Lim, Anantharaman Venkataraman

24 **Advanced Cardiac Life Support** 160
Anantharaman Venkataraman, Swee Han Lim,
Marcus E. H. Ong, Kenneth B. K. Tan

25 **Resuscitation in Pregnancy** 168
Boyd Burns

26 **Post-Cardiac Arrest Syndrome** 174
Benjamin S. Abella, Bentley J. Bobrow

27 **Ethical Issues of Resuscitation** 176
Catherine A. Marco

28 **Noninvasive Airway Management** 178
Jestin N. Carlson, Henry E. Wang

29 **Intubation and Mechanical Ventilation** 183
Robert J. Vissers, Daniel F. Danzl

30 **Surgical Airways** 192
Michael D. Smith, Donald M. Yealy

31 **Vascular Access** 198
Chris Wyatt

32 **Hemodynamic Monitoring** 209
H. Bryant Nguyen, David T. Huang, Michael R. Pinsky

33 **Cardiac Pacing and Implanted Defibrillation** 216
Swee Han Lim, Wee Siong Teo, Anantharaman Venkataraman

34 **Pericardiocentesis** 223
Carolyn K. Synovitz, Eric J. Brown

SECTION 5 Analgesia, Anesthesia, and Procedural Sedation 231

35 **Acute Pain Management** 231
James Ducharme

36 **Local and Regional Anesthesia** 238
Douglas C. Dillon, Michael A. Gibbs

37 **Procedural Sedation** . . . 249
Chris Weaver

38 **Chronic Pain** . . . 256
David M. Cline

SECTION 6 Wound Management . . . 263

39 **Wound Evaluation** . . . 263
Adam J. Singer, Judd E. Hollander

40 **Wound Preparation** . . . 265
Aleksandr M. Tichter, Wallace A. Carter, Susan C. Stone

41 **Wound Closure** . . . 268
Adam J. Singer, Judd E. Hollander

42 **Face and Scalp Lacerations** . . . 281
Wendy C. Coates

43 **Arm and Hand Lacerations** . . . 288
Moira Davenport

44 **Leg and Foot Lacerations** . . . 296
Annabella Salvador-Kelly, Nancy Kwon

45 **Soft Tissue Foreign Bodies** . . . 302
Richard L. Lammers

46 **Puncture Wounds and Bites** . . . 313
James Quinn

47 **Postrepair Wound Care** . . . 320
Adam J. Singer, Judd E. Hollander

SECTION 7 Cardiovascular Disease . . . 325

48 **Chest Pain** . . . 325
Simon A. Mahler

49 **Acute Coronary Syndromes** . . . 332
Judd E. Hollander, Deborah B. Diercks

50 **Cardiogenic Shock** . . . 349
Casey Glass, David Manthey

51 **Low-Probability Acute Coronary Syndrome** . . . 353
Kathleen A. Hosmer, Chadwick D. Miller

52 **Syncope** . . . 360
James Quinn

53 **Acute Heart Failure** . . . 366
Sean P. Collins, Alan B. Storrow

54 **Valvular Emergencies** . . . 373
William D. Alley, Simon A. Mahler

55 **Cardiomyopathies and Pericardial Disease** . . . 380
James T. Niemann

56 **Venous Thromboembolism** . . . 388
Jeffrey A. Kline

57 **Systemic Hypertension** . . . 399
Brigitte M. Baumann

58 **Pulmonary Hypertension** . . . 409
Michael E. Winters

59 **Aortic Dissection and Related Aortic Syndromes** . . . 412
Gary A. Johnson, Louise A. Prince

60 **Aneurysmal Disease** . . . 416
Louise A. Prince, Gary A. Johnson

61 **Arterial Occlusion** . . . 420
Anil Chopra, David Carr

SECTION 8 Pulmonary Disorders . . . 427

62 **Respiratory Distress** . . . 427
John Sarko, J. Stephan Stapczynski

63 **Hemoptysis** . . . 436
Troy Sims

64 **Acute Bronchitis and Upper Respiratory Tract Infections** . . . 440
Cedric W. Lefebvre

65 **Pneumonia and Pulmonary Infiltrates** . . . 445
Gerald Maloney, Eric Anderson, Donald M. Yealy

66 **Lung Empyema and Abscess** . . . 456
Eric Anderson, Sharon E. Mace

67 **Tuberculosis** . . . 459
Vu D. Phan, Janet M. Poponick

68 **Pneumothorax** . . . 464
Bret A. Nicks, David Manthey

69 **Acute Asthma** . . . 468
Rita K. Cydulka

70 **Chronic Obstructive Pulmonary Disease** . . . 475
Rita K. Cydulka, Craig G. Bates

SECTION 9 Gastrointestinal Disorders . . . 481

71 **Acute Abdominal Pain** . . . 481
Mary Claire O'Brien

72 **Nausea and Vomiting** . . . 489
Bophal Sarha Hang, Susan Bork, Jeff Ditkoff

73 **Disorders Presenting Primarily With Diarrhea** . . . 492
Nicholas E. Kman, Howard A. Werman

74 **Constipation** . . . 500
Vito Rocco, Arash Armin

75 **Upper Gastrointestinal Bleeding** . . . 503
Christopher M. Ziebell, Andy Kitlowski, Janna M. Welch, Phillip A. Friesen

76 **Lower Gastrointestinal Bleeding** . . . 506
Bruce M. Lo

77 **Esophageal Emergencies** . . . 508
Moss Mendelson

78 **Peptic Ulcer Disease and Gastritis** . . . 514
Matthew C. Gratton, Angela Bogle

79 **Pancreatitis and Cholecystitis** . . . 517
Bart Besinger, Christine R. Stehman

80 **Hepatic Disorders** . . . 525
Susan R. O'Mara, Kulleni Gebreyes

81 **Acute Appendicitis** . . . 532
E. Paul DeKoning

82 **Diverticulitis** . . . 536
Autumn Graham

83 **Bowel Obstruction** . . . 538
Timothy G. Price, Raymond J. Orthober

84 **Hernias** . . . 541
Donald Byars, Turan Kayagil

85 **Anorectal Disorders** . . . 545
Brian E. Burgess

86 **Gastrointestinal Procedures and Devices** . . . 563
Michael D. Witting

87 **Complications of General Surgical Procedures** . . . 567
Edmond A. Hooker

SECTION 10 Renal and Genitourinary Disorders . . . 575

88 **Acute Kidney Injury** . . . 575
Richard Sinert, Peter R. Peacock, Jr.

89 **Rhabdomyolysis** . . . 581
Francis L. Counselman, Bruce M. Lo

90 **End-Stage Renal Disease** . . . 584
Mathew Foley, Ninfa Mehta, Richard Sinert

91 **Urinary Tract Infections and Hematuria** . . . 589
Kim Askew

92 **Acute Urinary Retention** . . . 597
David Hung-Tsang Yen, Chen-Hsen Lee

93 **Male Genital Problems** . . . 601
Jonathan E. Davis

94 **Urologic Stone Disease** . . . 609
David E. Manthey, Bret A. Nicks

95 **Complications of Urologic Procedures and Devices** . . . 613
Elaine B. Josephson

SECTION 11 Obstetrics and Gynecology . . . 619

96 **Abnormal Uterine Bleeding** . . . 619
Bophal Sarha Hang

97 **Abdominal and Pelvic Pain in the Nonpregnant Female** . . . 625
Melanie Heniff, Heather R.B. Fleming

98 **Ectopic Pregnancy and Emergencies in the First 20 Weeks of Pregnancy** . . . 628
Heather A. Heaton

99 **Comorbid Disorders in Pregnancy** . . . 636
Lori J. Whelan

100 **Maternal Emergencies After 20 Weeks of Pregnancy and in the Postpartum Period** . . . 644
Janet Simmons Young

101 **Emergency Delivery** . . . 652
Sarah Elisabeth Frasure

102 **Vulvovaginitis** . . . 661
Ciara J. Barclay-Buchanan, Melissa A. Barton

103 **Pelvic Inflammatory Disease** . . . 668
Suzanne M. Shepherd, Brian Weiss, William H. Shoff

104 **Breast Disorders** . . . 672
Bophal Sarha Hang

105 **Complications of Gynecologic Procedures** . . . 676
Nikki Waller

SECTION 12 Pediatrics . . . 681

106 **Emergency Care of Children** . . . 681
Garth Meckler

107 **Neonatal and Pediatric Transport** . . . 684
Samuel J. Prater, Manish Shah

108 **Resuscitation of Neonates** . . . 689
Marc F. Collin

109 **Resuscitation of Children** . . . 695
William E. Hauda, II

110 **Pediatric Trauma** . . . 706
Camilo E. Gutiérrez

111 **Intubation and Ventilation in Infants and Children** . . . 714
Robert J. Vissers, Nathan W. Mick

112 **Intravenous and Intraosseous Access in Infants and Children** . . . 722
Matthew Hansen

113 **Pain Management and Procedural Sedation in Infants and Children** . . . 727
Peter S. Auerbach

114 **Neonatal Emergencies and Common Neonatal Problems** . . . 734
Quynh H. Doan, Niranjan Kissoon

115 **Sudden Infant Death Syndrome and Apparent Life-Threatening Event** . . . 741
Ilene Claudius, Joel S. Tieder

116 **Fever and Serious Bacterial Illness in Infants and Children** . . . 747
Vincent F. Wang

117 **Meningitis in Infants and Children** . . . 754
Amy Levine

118 **Ear and Mastoid Disorders in Infants and Children** . . . 757
Carmen Coombs

119 **Eye Emergencies in Infants and Children** . . . 764
Janeva Kircher, Andrew Dixon

120 **Nose and Sinus Disorders in Infants and Children** . . . 775
Joanna S. Cohen, Dewesh Agrawal

121 **Mouth and Throat Disorders in Infants and Children** . . . 779
Derya Caglar, Richard Kwun, Abigail Schuh

122 **Neck Masses in Infants and Children** . . . 786
Charles E. A. Stringer, Vikram Sabhaney

123 **Stridor and Drooling in Infants and Children** . . . 793
Elisa Mapelli, Vikram Sabhaney

124 **Wheezing in Infants and Children** . . . 802
Allan Shefrin, Alia Busuttil, Roger Zemek

125 **Pneumonia in Infants and Children** . . . 814
Joseph E. Copeland

126 **Congenital and Acquired Pediatric Heart Disease** . . . 822
Esther L. Yue, Garth D. Meckler

127 **Syncope, Dysrhythmias, and ECG Interpretation in Children** . . . 835
Andrew C. Dixon

128 **Vomiting, Diarrhea, and Dehydration in Infants and Children** . . . 843
Stephen B. Freedman, Jennifer D. Thull-Freedman

129 **Fluid and Electrolyte Therapy in Infants and Children** . . . 852
Melissa Chan, Paul Enarson

130 **Acute Abdominal Pain in Infants and Children** . . . 857
Ross J. Fleischman

131 **Gastrointestinal Bleeding in Infants and Children** . . . 864
Sarah M. Reid

132 **Urinary Tract Infection in Infants and Children** . . . 871
Justin W. Sales

133 **Pediatric Urologic and Gynecologic Disorders** . . . 875
Deborah R. Liu

134 **Renal Emergencies in Children** . . . 881
Andrew Dixon, Brandy Stauffer

135 **Seizures in Infants and Children** . . . 888
Maija Holsti

136 **Headache in Children** . . . 895
David C. Sheridan, Garth Meckler

137 **Altered Mental Status in Children** . . . 901
Sarah Mellion, Kathleen Adelgais

138 **Head Injury in Infants and Children** . . . 903
Alessandra Conforto, Ilene Claudius

139 **Cervical Spine Injury in Infants and Children** . . . 910
Solomon Behar

140 **Musculoskeletal Disorders in Children** . . . 915
Karen J.L. Black, Catherine Duffy, Courtney Hopkins-Mann, Demilola Ogunnaiki-Joseph, Donna Moro-Sutherland

141 **Rashes in Infants and Children** . . . 934
Gary Bonfante, Amy Dunn

142 **Sickle Cell Disease In Children** . . . 953
John Marshall

143 **Oncologic and Hematologic Emergencies in Children** . . . 958
Megan E. Mickley, Camilo Gutierrez, Michele Carney

144 **Metabolic Emergencies in Infants and Children** . . . 977
Garth Meckler, Nadeemuddin Quereshi, Mohammed Al-Mogbil, Osama Y. Kentab

145 **Diabetes In Children** . . . 983
Adam Vella

146 **The Child With Special Healthcare Needs** . . . 987
Lila O'Mahony

147 **Behavioral Disorders in Children** . . . 994
Quynh Doan, Tyler R. Black

148 **Child Abuse and Neglect** . . . 999
Margaret Colbourne, Michelle S. Clarke

172 **Acute Peripheral Neurologic Disorders** . . . 1178
Phillip Andrus, J. Michael Guthrie

173 **Chronic Neurologic Disorders** . . . 1185
Daniel A. Handel, Sarah Andrus Gaines

174 **Central Nervous System and Spinal Infections** . . . 1192
Mary Tanski, O. John Ma

175 **Central Nervous System Procedures and Devices** . . . 1199
Jay G. Ladde

SECTION 15 Toxicology . . . 1207

176 **General Management of Poisoned Patients** . . . 1207
Shaun Greene

177 **Cyclic Antidepressants** . . . 1213
Frank LoVecchio

178 **Atypical and Serotonergic Antidepressants** . . . 1219
Frank LoVecchio, Erik Mattison

179 **Monoamine Oxidase Inhibitors** . . . 1224
Frank LoVecchio

180 **Antipsychotics** . . . 1228
Michael Levine, Frank LoVecchio

181 **Lithium** . . . 1232
Sandra M. Schneider, Daniel J. Cobaugh, Benjamin D. Kessler

182 **Barbiturates** . . . 1235
Chip Gresham, Frank LoVecchio

183 **Benzodiazepines** . . . 1237
Dan Quan

184 **Nonbenzodiazepine Sedatives** . . . 1240
Michael Levine, Dan Quan

185 **Alcohols** . . . 1243
Jennifer P. Cohen, Dan Quan

186 **Opioids** . . . 1251
Guillermo Burillo-Putze, Oscar Miro

187 **Cocaine and Amphetamines** . . . 1256
Jane M. Prosser, Jeanmarie Perrone

188 **Hallucinogens** . . . 1260
Katherine M. Prybys, Karen N. Hansen

189 **Salicylates** . . . 1265
Rachel Levitan, Frank LoVecchio

190 **Acetaminophen** . . . 1269
Oliver L. Hung, Lewis S. Nelson

191 **Nonsteroidal Anti-Inflammatory Drugs** . . . 1276
Joseph G. Rella, Wallace A. Carter

192 **Methylxanthines and Nicotine** . . . 1280
Chip Gresham, Daniel E. Brooks

193 **Digitalis Glycosides** . . . 1284
Michael Levine, Aaron B. Skolnik

194 **Beta-Blockers** . . . 1288
Jennifer L. Englund, William P. Kerns II

195 **Calcium Channel Blockers** . . . 1292
Alicia B. Minns, Christian Tomaszewski

196 **Antihypertensives** . . . 1297
Frank LoVecchio, Dan Quan

197 **Anticonvulsants** . . . 1301
Frank LoVecchio

198 **Iron** . . . 1307
Stephanie H. Hernandez, Lewis S. Nelson

199 **Hydrocarbons and Volatile Substances** . . . 1310
C. William Heise, Frank LoVecchio

200 **Caustic Ingestions** . . . 1314
Nicole C. Bouchard, Wallace A. Carter

201 **Pesticides** . . . 1318
Guillermo Burillo-Putze, Santiago Nogue Xarau

202 **Anticholinergics** . . . 1326
Dan Quan, Frank LoVecchio

203 **Metals and Metalloids** . . . 1329
Heather Long, Lewis S. Nelson

204 **Industrial Toxins** . . . 1336
Chip Gresham, Frank LoVecchio

205 **Vitamins and Herbals** . . . 1341
Rick Tovar

206 **Antimicrobials** . . . 1345
Joseph G. Rella, Wallace A. Carter

207 **Dyshemoglobinemias** . . . 1348
Brenna M. Farmer, Lewis S. Nelson

SECTION 16 Environmental Injuries . . . 1353

208 **Cold Injuries** . . . 1353
Michael T. Paddock

209 **Hypothermia** . . . 1357
Doug Brown

210 **Heat Emergencies** . . . 1365
Frank LoVecchio

211 **Bites and Stings** . . . 1371
Aaron Schneir, Richard F. Clark

212 **Reptile Bites** . . . 1379
Richard C. Dart, Julian White

213 **Marine Trauma and Envenomation** . . . 1383
John J. Devlin, Kevin Knoop

214 **Diving Disorders** . . . 1390
Brian Snyder, Tom Neuman

215 **Drowning** . . . 1395
Stephen John Cico, Linda Quan

216 **Thermal Burns** . . . 1398
E. Paul DeKoning

217 **Chemical Burns** . . . 1405
Anthony F. Pizon, Michael J. Lynch

218 **Electrical and Lightning Injuries** . . . 1411
Caitlin Bailey

219 **Mushroom Poisoning** . . . 1419
Anne F. Brayer, Lynette Froula

220 **Poisonous Plants** . . . 1424
Betty C. Chen, Lewis S. Nelson

221 **High-Altitude Disorders** . . . 1429
Peter H. Hackett, Christopher B. Davis

222 **Carbon Monoxide** . . . 1437
Gerald Maloney

SECTION 17 Endocrine Disorders . . . 1441

223 **Type 1 Diabetes Mellitus** . . . 1441
Nikhil Goyal, Adam B. Schlichting

224 **Type 2 Diabetes Mellitus** . . . 1445
Mohammad Jalili, Mahtab Niroomand

225 **Diabetic Ketoacidosis** . . . 1457
Andrew L. Nyce, Cary L. Lubkin, Michael E. Chansky

226 **Alcoholic Ketoacidosis** . . . 1464
William A. Woods, Debra G. Perina

227 **Hyperosmolar Hyperglycemic State** . . . 1466
Charles S. Graffeo

228 **Hypothyroidism** . . . 1469
Alzamani Mohammad Idrose

229 **Hyperthyroidism** . . . 1472
Alzamani Mohammad Idrose

230 **Adrenal Insufficiency** . . . 1479
Alzamani Mohammad Idrose

SECTION 18 Hematologic and Oncologic Disorders . . . 1483

231 **Anemia** . . . 1483
John C. Ray, Robin R. Hemphill

232 **Tests of Hemostasis** . . . 1486
Stephen John Cico, Robin R. Hemphill

233 **Acquired Bleeding Disorders** . . . 1491
Robert W. Shaffer, Sally A. Santen

234 **Clotting Disorders** . . . 1496
Jessie G. Nelson, Robin R. Hemphill

235 **Hemophilias and von Willebrand's Disease** . . . 1500
Robin R. Hemphill

236 **Sickle Cell Disease and Hereditary Hemolytic Anemias** . . . 1504
Jean Williams-Johnson, Eric Williams

237 **Acquired Hemolytic Anemia** . . . 1513
Laurie Ann Dixon, Robin R. Hemphill

238 **Transfusion Therapy** . . . 1518
Clinton J. Coil, Sally A. Santen

239 **Thrombotics and Antithrombotics** . . . 1524
David E. Slattery, Charles V. Pollack, Jr.

240 **Emergency Complications of Malignancy** . . . 1535
J. Stephan Stapczynski

SECTION 19 Eye, Ear, Nose, Throat, and Oral Disorders . . . 1543

241 **Eye Emergencies** . . . 1543
Richard A. Walker, Srikar Adhikari

242 **Ear Disorders** . . . 1579
Kathleen Hosmer

243 **Face and Jaw Emergencies** . . . 1585
Stephanie A. Lareau, Corey R. Heitz

244 **Nose and Sinuses** . . . 1591
Henderson D. McGinnis

245 **Oral and Dental Emergencies** . . . 1598
Ronald W. Beaudreau

246 **Neck and Upper Airway** . . . 1613
Nicholas D. Hartman

247 **Complications of Airway Devices** . . . 1619
John P. Gaillard

SECTION 20 Dermatology . . . 1625

248 **Initial Evaluation and Management of Skin Disorders** . . . 1625
William Rushton, Joseph M. Grover, William J. Brady

249 **Generalized Skin Disorders** . . . 1642
Mark Sochor, Amit Pandit, William J. Brady

250 **Skin Disorders: Face and Scalp** . . . 1646
Dean S. Morrell, Kevin W. Dahle

251 **Skin Disorders: Trunk** . . . 1652
Dean S. Morrell, Kara Luersen Brooks

252 **Skin Disorders: Groin and Skinfolds** . . . 1666
Dean S. Morrell, Edith V. Bowers

253 **Skin Disorders: Extremities** . . . 1670
Rachna A. Bhandari, Dean S. Morrell

SECTION 21 Trauma . . . 1681

254 **Trauma in Adults** . . . 1681
Peter Cameron, Barry J. Knapp

255 **Trauma in the Elderly** . . . 1688
Ross J. Fleischman, O. John Ma

256 **Trauma in Pregnancy** . . . 1692
Nicole M. Delorio

257 **Head Trauma** . . . 1695
David W. Wright, Lisa H. Merck

258 **Spine Trauma** . . . 1708
Steven Go

259 **Trauma to the Face** . . . 1724
John Bailitz, Tarlan Hedayati

260 **Trauma to the Neck** . . . 1733
Ashley S. Bean

261 **Pulmonary Trauma** . . . 1740
David Jones, Anna Nelson, O. John Ma

262 **Cardiac Trauma** . . . 1752
Christopher Ross, Theresa Schwab

263 **Abdominal Trauma** . . . 1761
L. Keith French, Stephanie Gordy, O. John Ma

264 **Trauma to the Flank and Buttocks** . . . 1765
Alicia Devine

265 **Genitourinary Trauma** . . . 1767
Matthew C. Gratton, L. Keith French

266 **Trauma to the Extremities** . . . 1772
James Heilman

SECTION 22 Injuries to Bones and Joints 1777

267 **Initial Evaluation and Management of Orthopedic Injuries** 1777
Jeffrey S. Menkes

268 **Injuries to the Hand and Digits** 1791
Moira Davenport, Peter Tang

269 **Wrist Injuries** 1801
Robert Escarza, Maurice F. Loeffel, III, Dennis T. Uehara

270 **Elbow and Forearm Injuries** 1816
Yvonne C. Chow

271 **Shoulder and Humerus Injuries** 1828
Lars Petter Bjoernsen, Alexander Ebinger

272 **Pelvis Injuries** 1842
Melissa A. Barton, H. Scott Derstine, Ciara J. Barclay-Buchanan

273 **Hip and Femur Injuries** 1848
Mark Steele, Amy M. Stubbs

274 **Knee Injuries** 1857
Rachel R. Bengtzen, Jeffrey N. Glaspy, Mark T. Steele

275 **Leg Injuries** 1865
Paul R. Haller

276 **Ankle Injuries** 1868
Daniel A. Handel, Sarah Andrus Gaines

277 **Foot Injuries** 1876
Sarah Andrus Gaines, Daniel A. Handel

278 **Compartment Syndrome** 1883
Paul R. Haller

SECTION 23 Musculoskeletal Disorders 1887

279 **Neck and Back Pain** 1887
David Della-Giustina, Jeffrey S. Dubin, William Frohna

280 **Shoulder Pain** 1894
David Della-Giustina, David Hile

281 **Hip and Knee Pain** 1900
Kelly P. O'Keefe, Tracy G. Sanson

282 **Systemic Rheumatic Diseases** 1911
R. Darrell Nelson

283 **Nontraumatic Disorders of the Hand** 1921
Carl A. Germann

284 **Joints and Bursae** 1927
John H. Burton, Timothy J. Fortuna

285 **Soft Tissue Problems of the Foot** 1936
Mitchell C. Sokolosky

SECTION 24 Psychosocial Disorders 1941

286 **Mental Health Disorders: ED Evaluation and Disposition** 1941
Leslie Zun

287 **Acute Agitation** 1952
Shauna Garris, Caitlin Hughes

288 **Mental Health Disorders of the Elderly** 1958
Kristen Barrio, Kevin Biese

289 **Mood and Anxiety Disorders** 1963
Tracy M. DeSelm

290 **Psychoses** 1969
Adam Z. Tobias

291 **Eating Disorders** 1973
Gemma C. Lewis

292 **Substance Use Disorders** 1976
Edward Bernstein, Judith A. Bernstein, Scott G. Weiner, Gail D'Onofrio

SECTION 25 Abuse and Assault 1983

293 **Female and Male Sexual Assault** 1983
Lisa Moreno-Walton

294 **Intimate Partner Violence and Abuse** 1988
Mary Hancock

295 **Abuse of the Elderly and Impaired** 1991
Jonathan Glauser, Frederic M. Hustey

SECTION 26 Special Situations 1997

296 **Injection Drug Users** 1997
Thomas Grosheider, Suzanne M. Shepherd

297 **The Transplant Patient** 2002
J. Hayes Calvert

298 **The Patient With Morbid Obesity** 2010
Joanne Williams

299 **Palliative Care** 2013
Robert J. Zalenski, Erin Zimny

300 **Death Notification and Advance Directives** 2017
Lindsay Weaver, Cherri Hobgood

301 **Prison Medicine** 2020
Stephen H. Boyce, Richard J. Stevenson

302 **Military Medicine** 2023
Ricardo C. Ong, Sean W. Mulvaney, Robert H. Lutz, Gerald W. Surrett, Andre M. Pennardt, Ian S. Wedmore

303 **Legal Issues in Emergency Medicine** 2030
Jonathan E. Siff

Consultant in Emergency Medicine, Glasgow Royal Infirmary
Glasgow, Scotland

William J. Brady, MD [18, 248, 249]
Professor of Emergency Medicine & the David A. Harrison Distinguished Educator
Medical Director, Emergency Preparedness and Response
University of Virginia School of Medicine
Operational Medical Director, Albemarle County Fire Rescue
Charlottesville, Virginia

Anne F. Brayer, MD [219]
Professor of Emergency Medicine and Pediatrics
University of Rochester School of Medicine
Rochester, New York

Daniel E. Brooks, MD [192]
Associate Professor
Departments of Internal Medicine and Emergency Medicine,
University of Arizona College of Medicine – Phoenix
Phoenix, Arizona

Kara Luersen Brooks, MD [251]
University of North Carolina
Department of Dermatology
University of North Carolina
Chapel Hill, North Carolina

Eric J. Brown, MD, MS [34]
Staff Physician
Department of Emergency Medicine
St. John Medical Center
Tulsa, Oklahoma

Doug Brown, MD, FRCPC [209]
Emergency Physician
Royal Columbian Hospital
Clinical Instructor
UBC Department of Emergency Medicine
Vancouver, British Columbia

Brian E. Burgess, PT, MD, FACEP, FAAEM [85]
Assistant Professor of Emergency Medicine
Jefferson Medical College
Philadelphia, Pennsylvania
Assistant Residency Director
Emergency Medicine Residency Program
Christiana Care Health System
Wilmington, Delaware

Guillermo Burillo-Putze, MD, PhD [192, 207]
Emergency Department
Hospital Universitario de Canarias and Associated Professor
Department of Pharmacology, Universidad de La Laguna
Tenerife, Spain

Boyd Burns, DO, FACEP, FAAEM [25]
Assistant Professor
Department of Emergency Medicine
University of Oklahoma School of Community Medicine
Tulsa, Oklahoma

John Burton, MD [284]
Chair
Department of Emergency Medicine
Carilion Clinic
Virginia Tech Carilion School of Medicine
Roanoke, Virginia

Alia Busuttil [124]
Queen's School of Medicine
Kingston, Ontario

Donald Byars, MD [84]
Associate Professor
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

Derya Caglar, MD [121]
Assistant Professor
Department of Pediatrics
University of Washington, School of Medicine
Attending Physician
Division of Emergency Medicine, Seattle Children's Hospital
Seattle, Washington

J. Hayes Calvert, MD [297]
Clinical Affiliate
Wake Forest School of Medicine
Winston-Salem, North Carolina

Peter Cameron, MBBS, MD, FACEM, FIFEM [254]
Professor Emergency and Trauma Centre
The Alfred Hospital
Melbourne, Australia

Donna L. Carden, MD [156]
Professor
Director of Faculty Development
Department of Emergency Medicine
University of Florida College of Medicine
Gainesville, Florida

Jestin N. Carlson, MD [28]
Department of Emergency Medicine Saint Vincent Health System
Erie, Pennsylvania
Department of Emergency Medicine, University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Michele Carney, MD [143]
Assistant Professor, Pediatric Emergency Medicine
Director, Pediatric Emergency Medicine Fellowship
Department of Emergency Medicine
Children's Emergency Services
Ann Arbor, Michigan

David Carr, MD, CCFP, EM [61]
Assistant Director of Risk Management and Faculty Development
University Health Network
Assistant Professor
Department of Family and Community Medicine
Toronto, Ontario

Wallace A. Carter, MD [40, 191, 200, 206]
Program Director, Emergency Medicine Residency
Senior Associate Medical Director, Emergency Medical Services
New York Presbyterian
White Plains, New York
Associate Professor of Emergency Medicine in Medicine
Weill Cornell Medical College
Associate Professor of Clinical Medicine
Columbia University College of Physicians & Surgeons
New York City, New York

Melissa Chan, MD, FRCPC (PEM) [129]
Division of Pediatric Emergency Medicine
Department of Pediatrics
University of Alberta
Edmonton, Alberta

Michael E. Chansky, MD [225]
Chair
Department of Emergency Medicine
Associate Professor of Emergency Medicine and Internal Medicine
Cooper Medical School of Rowan University
Adjunct Associate Professor of Emergency Medicine and Internal Medicine
UMDNJ/Robert Wood Johnson Medical School
Cooper University Hospital
Camden, New Jersey

Betty C. Chen, MD [220]
Acting Instructor, Division of Emergency Medicine, University of Washington School of Medicine
Attending Physician, Harborview Medical Center
Seattle, Washington

Anil Chopra, MD, FRCP, DABEM [61]
Head and Medical Director, Emergency Medicine
University Health Network
Associate Professor, Department of Medicine
Toronto, Ontario

Yvonne C. Chow, MD [270]
Assistant Professor of Emergency Medicine and Internal Medicine
Associate Residency Program Director
Department of Emergency Medicine
Albany Medical College
Albany, New York

Stephen John Cico, MD, MEd, FAAEM, FAAP [215, 232]
Associate Professor of Pediatrics
University of South Dakota Sanford School of Medicine
Attending Physician, Pediatric Emergency Medicine
Sanford USD Medical Center and Sanford Children's Hospital
Sioux Falls, South Dakota

Richard F. Clark, MD [211]
Professor of Emergency Medicine
Director, Division of Medical Toxicology
UCSD School of Medicine
San Diego, California

Michelle S. Clarke, MD, FRCP(C) [148]
Clinical Instructor
Division of Emergency Medicine, Department of Pediatrics, University of British Columbia
Child Protection Service Unit, British Columbia Children's Hospital
Vancouver, British Columbia

Ilene Claudius, MD [115, 138, 142]
Associate Professor
Emergency Medicine
USC, Keck School of Medicine
Los Angeles, California

David M. Cline, MD [15]
Professor and Director of Departmental Research
Department of Emergency Medicine
Wake Forest School of Medicine
Winston-Salem, North Carolina

Wendy C. Coates, MD [42]
Professor of Medicine
UCLA David Geffen School of Medicine
Senior Education Specialist
Harbor-UCLA Emergency Medicine
Torrance, California

Daniel J. Cobaugh, Pharm D, DABAT, FAACT [181]
Vice President
ASHP Research and Education Foundation
Bethesda, Maryland

Joanna S. Cohen, MD [120]
Assistant Professor of Pediatrics and Emergency Medicine
George Washington University School of Medicine
Children's National Medical Center
Washington, DC

Jennifer P. Cohen, MD [185]
Attending Emergency Physician
Mt Graham Regional Medical Center
Safford, Arizona
Attending Toxicologist
Banner-University Medical Center
Tucson, Arizona

Clinton J. Coil, MD, MPH, FACEP [238]
Assistant Clinical Professor of Medicine
Patient Safety Officer
Harbor-UCLA Medical Center
Torrance, California

Margaret Colbourne, MD, FRCP(C) [148]
Clinical Associate Professor
Department of Pediatrics, University of British Columbia
Director, Child Protection Service Unit, British Columbia Children's Hospital
Vancouver, British Columbia

Marc F. Collin, MD [109]
Associate Professor of Pediatrics
Medical Director, Neonatal Intensive Care Unit
MetroHealth Medical Center
Case Western Reserve University
Cleveland, Ohio

Sean P. Collins, MD, MSc [53]
Associate Vice Chair for Research
Department of Emergency Medicine
Vanderbilt University
Nashville, Tennessee

Alessandra Conforto, MD [138, 142]
Assistant Professor of Clinical Emergency Medicine
Keck School of Medicine of USC
University of Southern California
Los Angeles, California

Carmen Coombs, MD, MPH [118]
Assistant Clinical Professor
Division of Emergency Medicine
Seattle Children's Hospital
Seattle, Washington

Joseph Copeland, MD, CCFP-EM, FCFP [125]
Clinical Assistant Professor
Department of Emergency Medicine
University of British Columbia/BC Children's Hospital
Vancouver, British Columbia

Francis L. Counselman, MD, FACEP [89]
Distinguished Professor of Emergency Medicine
Department of Emergency Medicine
Eastern Virginia Medical School
Emergency Physicians of Tidewater
Norfolk, Virginia

Rita K. Cydulka, MD, MS, FACEP [69,70]
Professor, Emergency Medicine
Case Western Reserve University School of Medicine
Faculty, Department of Emergency Medicine
MetroHealth Medical Center
Cleveland, Ohio

Shawn M. D'Andrea, MD, MPH [161]
Instructor of Emergency Medicine
Harvard Medical School
Attending Physician
Brigham and Women's Hospital
Boston, Massachusetts

Kevin W. Dahle, MD [250]
Department of Dermatology
University of North Carolina
Chapel Hill, North Carolina

Dan Danzl, MD, FACEP [29]
Professor and Chair
Department of Emergency Medicine
University of Louisville
Louisville, Kentucky

Richard C. Dart, MD, PhD [212]
Director, Rocky Mountain Poison and Drug Center
Denver Health and Hospital Authority
Denver, Colorado

Moira Davenport, MD [43, 268]
Associate Professor of Emergency Medicine, Associate Emergency Medicine Residency Director
Allegheny General Hospital
Temple University School of Medicine
Pittsburgh, Pennsylvania

Jonathan E. Davis, MD [93]
Program Director
Georgetown University Hospital/Washington Hospital Center Emergency Medicine Residency
Associate Professor
Department of Emergency Medicine
Georgetown University School of Medicine
Washington, DC

Christopher B. Davis [221]
Assistant Professor of Emergency Medicine
University of Colorado School of Medicine
Aurora, Colorado

E. Paul DeKoning, MD, MS [81, 216]
Assistant Residency Director
Assistant Professor of Emergency Medicine
Dartmouth-Hitchcock Medical Center
The Geisel School of Medicine at Dartmouth
Lebanon, New Hampshire

David Della-Giustina, MD, FACEP, FAWM [279, 280]
Associate Professor of Emergency Medicine
Program Director of Emergency Medicine Residency
Chief of Education Section
Department of Emergency Medicine
Yale School of Medicine
New Haven, Connecticut

Nicole M. Delorio, MD [256]
Professor and Co-chief, Education Section, Department of Emergency Medicine
Assistant Dean, Student Affairs, Undergraduate Medical Education
Oregon Health and Science University
Portland, Oregon

H. Scott Derstine, MD [272]
Clinical Assistant Professor, Wayne State University
Assistant Program Director, Emergency Medicine Residency Program
Sinai-Grace Hospital/Detroit Medical Center
Tenet Health System
Detroit, Michigan

Tracy M. DeSelm, MD [289]
Assistant Professor
Department of Emergency Medicine
UNC School of Medicine Academic Advisor
University of North Carolina
Chapel Hill, North Carolina

Alicia Devine, MD [264]
Assistant Professor
Eastern Virginia Medical School
Norfolk, Virginia

John J. Devlin, MD [213]
Emergency Medicine, Naval Medical Center
Emergency Physicians of Tidewater
Virginia Beach, Virginia

Deborah B. Diercks, MD, MSc [49]
Professor and Chair, Department of Emergency Medicine
University of Texas Southwestern Medical Center

Douglas Dillon, MD [36]
Associate Professor Emergency Medicine
University of Utah
Park City, Utah

Jeffrey Ditkoff, MD [72]
Director of Operations
Department of Emergency Medicine
William Beaumont Hospital
Royal Oak, Michigan

Laurie Ann Dixon, MD, MPH [237]
Emergency Medicine
Emergency Physicians Medical Group
St. Joseph Mercy Hospital Ann Arbor/Livingston
Ann Arbor, Michigan

Andrew Dixon, MD, FRCPC [119, 127, 134]
Program Director-Pediatric Emergency Medicine Residency, Assistant Professor Division of Pediatric Emergency Medicine Department of Pediatrics, University of Alberta
Edmonton, Alberta

Quynh H. Doan, MDCM, MHSc, FRCPC [114, 147]
Clinical Assistant Professor
UBC Pediatrics, Division of Pediatric Emergency,
Clinician Scientist Child and Family Research Institute,
University of British Columbia
Vancouver, British Columbia

Gail D'Onofrio, MD, MS [292]
Professor of Emergency Medicine; and Chair, Department of Emergency Medicine
Yale School of Medicine
New Haven, Connecticut

Jeffrey S. Dubin, MD, MBA [279]
Associate Professor of Clinical Emergency Medicine
Vice-Chair, Department of Emergency Medicine
Washington Hospital Center
Washington, DC

James Ducharme, MD, CM, FRCP [35]
Clinical Professor
Department of Medicine
McMaster University
Hamilton, Ontario

Catherine Duffy, MD, FRCS [140]
Belfast Health and Social Care Trust
Musgrave Park Hospital
Belfast, Northern Ireland

Amy Lewis Dunn, DO, MPH [141]
Attending Physician, Department of Emergency Medicine
Section of Pediatric Emergency Medicine
Lehigh Valley Health Network
Allentown, Pennsylvania

Alexander Ebinger, MD [271]
Assistant Professor, Emergency Medicine, University of Colorado School of Medicine
Aurora, Colorado

Paul Enarson, MD, PhD, FRCPC (PEM) [129]
Division of Emergency Medicine, Department of Pediatrics
University of British Columbia
Vancouver, British Columbia

Jennifer L. Englund, MD [200]
Attending Physician, Department of Emergency Medicine
HealthEast Care System
Maplewood, Minnesota
Toxicology Consultant, Minnesota Poison Control System
Minneapolis, Minnesota

Robert Escarza, MD [269]
Associate Clinical Professor
Department of Surgery
University of Illinois College of Medicine at Rockford
Rockford Memorial Hospital
Rockford, Illinois

Brenna M. Farmer, MD [207]
Assistant Professor of Medicine
Attending Physician
Division of Emergency Medicine
Weill-Cornell College of Medicine/New York Presbyterian Hospital
New York City, New York

Ana Felix, MD [165]
Assistant Professor, Adult Neurology
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Ross J. Fleischman, MD [130, 255]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Heather Miller Fleming, MD [97]
Assistant Professor of Clinical Emergency Medicine and Pediatrics
Assistant Program Director
Indiana University
Indianapolis, Indiana

Ninfa Mehta, MD [90]
Associate Medical Director SUNY Downstate
Ultrasound Fellowship Director SUNY Downstate/Kings County Hospital
Emergency Department
SUNY Downstate Hospital, Kings County Emergency Department
Brooklyn, New York

Timothy J. Fortuna, DO [284]
Assistant Professor
Associate Program Director, Emergency Medicine
Virginia Tech Carilion School of Medicine
Roanoke, Virginia

Sarah Elisabeth Frasure, MD [100]
Department of Emergency Medicine
Brigham and Women's Hospital
Boston, Massachusetts

Stephen Freedman, MDCM, MSc, FAAP, FRCPC [128]
Alberta Children's Hospital Foundation Professor in Child Health and Wellness
Associate Professor of Pediatrics
Department of Pediatrics
Sections of Pediatric Emergency Medicine and Gastroenterology
Alberta Children's Hospital
Alberta Children's Hospital Research Institute
Cumming School of Medicine, University of Calgary
Calgary, Alberta

Loren K. French, MD [263, 265]
Assistant Professor
Emergency Department
Oregon Health & Science University
Portland, Oregon

Adam D. Friedlander, MD [22]
Chief Resident, Combined Residency in Emergency Medicine and Pediatrics
Department of Emergency Medicine
Department of Pediatrics
University of Maryland School of Medicine
Baltimore, Maryland

Phillip A. Friesen, DO [75]
Pediatric Emergency Medicine Fellow, The University of Texas at Austin, Dell Medical School
Austin, Texas

William Frohna, MD [279]
Professor of Clinical Emergency Medicine
Chairman, MedStar Emergency Physicians
Chairman, Department of Emergency Medicine
Washington Hospital Center
Washington, DC

Lynette Froula, MD [219]
Department of Emergency Medicine
University of Rochester Medical Center
Rochester, New York

Theodore J. Gaeta, DO, MPH [14]
Vice-chair and Program Director in Emergency Medicine
New York Methodist Hospital
Associate Professor of Emergency Medicine, in Medicine
Weill Cornell School of Medicine
West Harrison, New York

John P. Gaillard, MD [12, 247]
Assistant Professor
Department of Anesthesiology-Critical Care
Department of Emergency Medicine
Department of Internal Medicine-Pulmonary/Critical Care Wake Forest Baptist Health
Winston-Salem, North Carolina

Sarah Andrus Gaines, MD [173]
Assistant Professor
Department of Emergency Medicine
Brown University
Providence, Rhode Island

Shauna S. Garris, PharmD, BCPP, BCPS [287]
Pharmacy Clinical Specialist, Psychiatry/Neurology
UNC Healthcare
Adjunct Assistant Professor
Division of Practice Advancement and Experiential Education
UNC Eshelman School of Pharmacy
Chapel Hill, North Carolina

Kulleni Gebreyes, MD, MBA [80]
Physician Executive
Washington, DC

Carl A. Germann, MD [283]
Assistant Professor, Tufts University School of Medicine
Maine Medical Center
Portland, Maine

Chris A. Ghaemmaghami, MD [18]
Associate Professor of Emergency Medicine and Medicine
Medical Director & Vice Chair for Academics
Department of Emergency Medicine
Chief Medical Officer and Senior Associate Dean
University of Virginia School of Medicine
University of Virginia Health System
Charlottesville, Virginia

Jaylaine Ghoubrial, MD [25]
OB/GYN
Reading Hospital
West Reading, Pennsylvania

Michael A. Gibbs, MD [36]
Professor, Department of Emergency Medicine
Tufts University School of Medicine
Chief of Emergency Medicine
Department of Emergency Medicine, Maine Medical Center
Portland, Maine

Jeffrey N. Glaspy, MD [274]
Department Chief Emergency Medicine
Aurora West Allis Medical Center
ERMED, SC
Milwaukee, Wisconsin

Casey Glass, MD [16, 50]
Assistant Professor, Department of Emergency Medicine
Director of Community Emergency Ultrasound Programs
Wake Forest School of Medicine
Winston Salem, North Carolina

Jonathan Glauser, MD, MBA, FACEP [295]
Professor, Emergency Medicine
Case Western Reserve University School of Medicine
Faculty MetroHealth Medical Center
Residency Program Emergency Medicine
Cleveland, Ohio

Steven Go, MD [167, 258]
Associate Professor of Emergency Medicine
Department of Emergency Medicine
University of Missouri—Kansas City School of Medicine
Kansas City, Missouri

H. Brian Goldman, MD, FACEP, FCFP [170]
Staff Emergency Physician, Schwartz Reisman Emergency Centre
Mount Sinai Hospital
Assistant Professor, Department of Family and Community Medicine
University of Toronto
Toronto, Ontario

Stephanie Gordy, MD, FACS [263]
Assistant Professor of Surgery
Ben Taub Hospital
Baylor College of Medicine
Michael E. DeBakey Department of Surgery
Houston, Texas

Nikhil Goyal, MD [223]
EM/IM Combined Residency Director
Transitional Year Residency Director
Henry Ford Hospital
Clinical Assistant Professor, Wayne State University
Detroit, Michigan

Charles S. Graffeo, MD, ABEM-UHM [227]
Professor and Assistant Residency Director
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

Autumn Graham, MD [82]
Associate Program Director
Medstar Georgetown University Hospital/Medstar Washington Hospital Center
Washington, DC

Matthew C. Gratton, MD [78]
Professor and Chair, Emergency Medicine
University of Missouri, Kansas City School of Medicine
Truman Medical Center
Kansas City, Missouri

Matthew C. Gratton, MD [265]
Professor and Chair, Emergency Medicine
University of Missouri, Kansas City School of Medicine
Truman Medical Center
Kansas City, Missouri

Shaun Greene, FACEM [176]
Emergency Physician and Clinical Toxicologist
Austin Health
Melbourne, Australia

Chip Gresham, MD [182, 192, 204]
Director of Education
Department of Emergency Medicine
Middlemore Hospital
Auckland, New Zealand

Thomas Grosheider, MD [296]
Attending Physician
Tuba City Regional Care
Tuba City, Arizona

Joseph M. Grover, MD [248]
Clinical Instructor and EMS Fellow
Department of Emergency Medicine
University of North Carolina
Chapel Hill, North Carolina

Camilo E. Gutiérrez, MD [110, 143]
Assistant Professor of Pediatrics / Pediatric Emergency Medicine
Boston University School of Medicine
Boston Medical Center
Boston, Massachusetts

Peter H. Hackett, MD [221]
Clinical Professor
Department of Emergency Medicine
University of Colorado Denver School of Medicine
Aurora, Colorado
Founder and Director, Institute for Altitude Medicine
Telluride, Colorado

Jeffrey L. Hackman, MD [166]
Assistant Professor
Department of Emergency Medicine
University of Missouri-Kansas City School of Medicine
Truman Medical Center
Kansas City, Missouri

Paul Haller, MD [275, 278]
HealthPartners Medical Group
Assistant Professor
Department of Emergency Medicine
University of Minnesota
Minneapolis, Minnesota

Pinchas Halpern, MD [7]
Associate Professor of Emergency Medicine
Tel Aviv University Faculty of Medicine
Chair, Emergency Department
Tel Aviv Medical Center
Tel Aviv, Israel

Mary Hancock, MD [294]
Attending Physician
Emergency Services Institute
Cleveland Clinic
Cleveland, Ohio

Daniel A. Handel, MD, MPH [173]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Bophal Sarha Hang, MD [72, 96, 104]
Department of Emergency Medicine
William Beaumont Oakland University, School of Medicine
Rochester, Michigan

Matthew Hansen, MD [113, 188]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Michael Harrigan, MD, FACEP [165]
Assistant Professor
Department of Emergency Medicine
UNC Chapel Hill School of Medicine
Chapel Hill, North Carolina

Nicholas D. Hartman, MD, MPH [246]
Assistant Professor
Department of Emergency Medicine
Wake Forest School of Medicine
Winston-Salem, North Carolina

William E. Hauda II, MD [110]
Associate Professor of Emergency Medicine
Virginia Commonwealth University School of Medicine—Inova Campus
Assistant Professor of Pediatrics
University of Virginia School of Medicine
Falls Church, Virginia

Heather A. Heaton, MD [98]
Instructor of Emergency Medicine, Mayo Clinic College of Medicine
Department of Emergency Medicine
Mayo Clinic
Rochester, Minnesota

Tarlan Hedayati, MD [259]
Associate Program Director
Emergency Medicine Residency Program
Cook County (Stroger) Hospital
Assistant Professor
Department of Emergency Medicine
Rush University Medical Center
Chicago, Illinois

James Heilman, MD [266]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

C. William Heise, MD [199]
Assistant Professor, University of Arizona College of Medicine—Phoenix Center for Toxicology and Pharmacology Education and Research Department of Medical Toxicology, Banner—University Medical Center
Phoenix, Arizona

Corey R. Heitz, MD [243]
Virginia Tech Carilion School of Medicine, Carilion Clinic Department of Emergency Medicine
Roanoke, Virginia

Robin R. Hemphill, MD [231, 232, 233, 234, 235, 237]
Veterans Health Administration
Chief Patient Safety and Risk Awareness Officer
Director, VA National Center for Patient Safety
Ann Arbor, Michigan

Robert G. Hendrickson, MD [5, 8]
Medical Director, Emergency Management
Associate Professor
Department of Emergency Medicine
Program Director, Fellowship in Medical Toxicology
Oregon Health & Science University
Associate Medical Director, Oregon Poison Center
Portland, Oregon

Melanie Heniff, MD, FACEP, FAAEM, FAAP [97]
Assistant Professor Clinical Emergency Medicine
Indiana University
Indianapolis, Indiana

Stephanie H. Hernandez, MD [198]
Icahn School of Medicine at Mount Sinai
Department of Emergency Medicine
New York City, New York

David Hile, MD [280]
Assistant Professor of Emergency Medicine
Associate Program Director of Emergency Medicine Residency
Department of Emergency Medicine
Yale School of Medicine
New Haven, Connecticut

Jon Mark Hirshon, MD [22]
Associate Professor
Department of Emergency Medicine
University of Maryland School of Medicine
University of Maryland Medical Center
Baltimore, Maryland

Cherri Hobgood, MD, FACEP [300]
Chair and Rolly McGrath Professor
Department of Emergency Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Rachel Holland, PharmD, BCPS [19, 20]
Pharmacist
Emergency Department
Wake Forest Baptist Health
Department of Pharmacy
Winston-Salem, North Carolina

Judd E. Hollander, MD [39, 41, 47, 49]
Associate Dean for Strategic Health Initiatives
Vice Chair, Finance and Healthcare Enterprises
Department of Emergency Medicine
Sidney Kimmel Medical College of Thomas Jefferson University
Philadelphia, Pennsylvania

Maija Holsti, MD, MPH [135]
Associate Professor
Division of Pediatric Emergency Medicine
Department of Pediatrics
University of Utah
Salt Lake City, Utah

Edmond A. Hooker, MD [87]
Assistant Professor and Resident Research Director
Department of Emergency Medicine
University of Cincinnati
Cincinnati, Ohio

Courtney Hopkins-Mann, MD [140]
Medical Director
Children's Emergency Department
Wake Medical Center
University of North Carolina, Chapel Hill
Chapel Hill, North Carolina

B. Zane Horowitz, MD, FACMT [5, 8]
Professor
Department of Emergency Medicine
Oregon Health & Science University
Medical Director, Oregon Poison Center
Portland, Oregon

Kathleen Hosmer, MD, FACEP [51, 242]
Assistant Professor
Department of Emergency Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

David T. Huang, MD, MPH [32]
Associate Professor, Critical Care Medicine, Emergency Medicine, Clinical and Translational Science
Director, Multidisciplinary Acute Care Research Organization (MACRO)
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

J. Stephen Huff, MD [164, 168 , 169]
Associate Professor
Emergency Medicine and Neurology
Department of Emergency Medicine
University of Virginia
Charlottesville, Virginia

Caitlin M. Hughes, PharmD [287]
Assistant Professor
Department of Clinical & Administrative Sciences
Notre Dame of Maryland University School of Pharmacy
Baltimore, Maryland

Oliver L. Hung, MD [190]
Attending Physician
Department of Emergency Medicine
Morristown Memorial Hospital
Morristown, New Jersey

Fredric M. Hustey, MD [295]
Staff Physician, Emergency Services Institute
Cleveland Clinic
Cleveland, Ohio

Alzamani Mohammad Idrose, MBBS, MMed(Emergency), MITM, EMDM [228, 229, 230]
Consultant Emergency Physician
Emergency & Trauma Department
Hospital Kuala Lumpur, Kuala Lumpur, Malaysia

Andy Jagoda, MD [172]
Professor and Chair
Department of Emergency Medicine
Mount Sinai School of Medicine
New York City, New York

Mohammad Jalili, MD [224]
Associate Professor of Emergency Medicine
Tehran University of Medical Sciences
Tehran, Iran

Gary A. Johnson, MD, FACEP [59,60]
Associate Professor and Chair, Department of Emergency Medicine
Upstate Medical University
Syracuse, New York

Alan E. Jones, MD [151]
Professor and Chair of Emergency Medicine, University of Mississippi Medical Center
Jackson, Mississippi

David Jones, MD [261]
Department of Emergency Medicine
Oregon Health and Science University
Portland, Oregon

Elaine B. Josephson, MD [95]
Assistant Professor of Emergency Medicine in Clinical Medicine
Weill Cornell Medical College of Cornell University
Program Director, Emergency Medicine Residency Department of Emergency Medicine
Lincoln Medical and Mental Health Center Bronx
New York City, New York

Turan Kayagil, MD [84]
EVMS Emergency Medicine
Norfolk, Virginia

Gabor D. Kelen, MD, FRCP(C), FACEP, FAAEM [15]
Professor and Chair, Department of Emergency Medicine
Johns Hopkins University
Director, Johns Hopkins Office of Critical Event Preparedness and Response
The Johns Hopkins Institutions
Baltimore, Maryland

Elizabeth W. Kelly, MD [152]
Assistant Professor
Department of Emergency Medicine
Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

Osama Kentab, MD, FAAP, FACEP [144]
Assistant Professor Emergency Medicine—KSAU
Clinical Assistant Professor of Pediatrics—KSU
Consultant Pediatric Emergency Medicine
Department of Emergency Medicine
King Abdulaziz Medical City
Riyadh, Kingdom of Saudi Arabia

William P. Kerns II, MD, FACEP, FACMT [194]
Professor of Emergency Medicine
Program Director, Medical Toxicology Fellowship
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

Benjamin D. Kessler, MD [181]
Medical Toxicology Fellow
North Shore University Hospital
Manhasset, New York

Janeva Kircher, MD [119]
Pediatric Emergency Medicine Fellow
Department of Peditatrics and Department of Emergency Medicine
University of Alberta
Edmonton, Alberta

Niranjan Kissoon, MD [114]
Associate Head and Professor
Division of Critical Care,
Department of Pediatrics, University of British Columbia
Vice-President, Medical Affairs, BC Children's Hospital
Vancouver, British Columbia

Bryan B. Kitch, MD [160]
Clinical Instructor

Brody School of Medicine at East Carolina University
Greenville, North Carolina

Andy Kitlowski, MD [75]
Emergency Medicine
University of Texas at Austin
Dell Medical School
Austin, Texas

Jeffrey A. Kline, MD [56]
Vice Chair of Research
Department of Emergency Medicine
Professor, Department of Cellular and Integrative Physiology
Indiana University School of Medicine
Indianapolis, Indiana

Nicholas E. Kman, MD, FACEP [73]
Associate Professor
Department of Emergency Medicine
The Ohio State University
Columbus, Ohio

Barry J. Knapp, MD [254]
Residency Program Director
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

Kevin J. Knoop, MD, MS [213]
Staff Physician
Naval Medical Center, Portsmouth, Virginia
Assistant Professor of Military and Emergency Medicine
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Joshua G. Kornegay, MD [171]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Nancy S. Kwon, MD, MPA [44]
Associate Chair of Academics and Research
Department of Emergency Medicine
Long Island Jewish Medical Center
Assistant Professor of Emergency Medicine
Hofstra North Shore-LIJ School of Medicine at Hofstra University
Hempstead, New York

Richard Kwun, MD [121]
Attending Physician
Department of Emergency Medicine
Swedish Medical Center
Issaquah, Washington

Jay G. Ladde, MD, FACEP, FAAEM [175]
Associate Program Director, Orlando Health EM Residency
Orlando, Florida
Associate Professor, University of Central Florida College of Medicine
Assistant Professor, University of Florida College of Medicine
Assistant Professor, Florida State University School of Medicine

David S. Lambert, MD [21]
Associate Professor
Department of Emergency Medicine
Associate Medical Director
Hospital of the University of Pennsylvania
PennStar Life Flight Medical Command Physician
Undersea and Hyperbaric Medicine Physician

Richard L. Lammers, MD [45]
Assistant Dean for Simulation
Professor of Emergency Medicine
Western Michigan University Homer Stryker, MD School of Medicine
Kalamazoo, Michigan

Stephanie A. Lareau, MD, FAWM [243]
Assistant Professor Emergency Medicine
Emergency Physician Carilion Clinic
Virginia Tech-Carilion School of Medicine
Roanoke, Virginia
Carilion Franklin Memorial Hospital
Rocky Mount, Virginia

Thomas S. Laughrey, MD [18]
Chief Resident
Department of Emergency Medicine
University of Virginia Health System
Charlottesville, Virginia

Chen-Hsen Lee, MD [92]
Professor
Department of Surgery
Taipei Veterans General Hospital
Institute of Emergency and Critical Care Medicine
National Yang-Ming University
Taipei, Taiwan

Cedric W. Lefebvre, MD [64]
Assistant Professor
Department of Emergency Medicine
Wake Forest School of Medicine
Medical Center Blvd
Winston-Salem, North Carolina

Amy Levine, MD [117]
Associate Professor
Pediatrics and Emergency Medicine
Department of Pediatrics
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Michael Levine, MD [180, 184]
Department of Emergency Medicine, Section of Medical Toxicology
University of Southern California.
Los Angeles, California

Rachel Levitan, MD [189]
Emergency Department
Flagstaff Medical Center
Flagstaff, Arizona

Gemma C. Lewis, MD [291]
Emergency Medicine—BayCare Clinics, LLP
Adjunct Assistant Clinical Professor
Department of Medicine
University of Wisconsin
Madison, Wisconsin

Stephen Y. Liang, MD [150]
Instructor of Medicine
Divisions of Emergency Medicine & Infectious Diseases
Washington University School of Medicine
Saint Louis, Missouri

Swee Han Lim, MBBS, FRCS Edin (A&E), FRCP Edin, FAMS [23, 24, 33]
Senior Consultant, Department of Emergency Medicine, Singapore General Hospital
Outram Road, Singapore
Clinical Associate Professor, Yong Loo Lin School of Medicine, National University of Singapore
Adjunct Associate Professor, Duke-NUS Graduate Medical School Singapore

Deborah R. Liu, MD [133]
Faculty, Division of Emergency and Transport Medicine
Children's Hospital Los Angeles
Assistant Professor of Pediatrics
USC Keck School of Medicine
Los Angeles, California

Bruce M. Lo, MD, RDMS [76,89]
Assistant Professor of Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

Maurice F. Loeffel III, MD [269]
Assistant Clinical Professor
Department of Emergency Medicine
Rockford Memorial Hospital
Rockford, Illinois

Heather Long, MD [203]
Director, Medical Toxicology
Albany Medical College
Albany, New York

Annette M. Lopez, MD [10]
Clinical Instructor, Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Frank LoVecchio, DO, MPH, FACEP, ABMT [177, 178, 179, 180, 182, 189, 196, 197, 199, 202, 204, 210]
Vice Chair of Research, Department of Emergency Medicine, Maricopa Medical Center
Banner Poison Drug and Information Center, BUMC-PHX
Professor of Emergency Medicine, Research Scholar, University of Arizona College of Medicine
Phoenix, Arizona

Emeritus Professor of Emergency Medicine
University of California
San Diego, California

H. Bryant Nguyen, MD [32]
Professor of Emergency Medicine
Medicine-Critical Care, and Basic Sciences
Vice-Chair, Medicine Research
Director, Center for Comparative Effectiveness and Outcomes Research
Loma Linda University
Loma Linda, California

Bret A. Nicks, MD, MHA, FACEP [12, 68, 94]
Associate Professor, Emergency Medicine
Associate Dean, Global Health
Wake Forest School of Medicine
Winston-Salem, North Carolina

David D. Nicolaou, MD, MS, FACEP [16]
Clinical Assistant Professor
Department of Emergency Medicine
Michigan State University College of Human Medicine
Attending Physician
Munson Medical Center
Traverse City, Michigan

James T. Niemann, MD [55]
Professor of Medicine
Department of Emergency Medicine
Harbor-UCLA Medical Center
Torrance, California

Mahtab Niroomand, MD [224]
Assistant Professor of Endocrinology
Shahid Beheshti University of Medical Sciences
Tehran, Iran

Flavia Nobay, MD [149]
Associate Professor and Associate Chair for Education
Director, Emergency Medicine Residency Program
Department of Emergency Medicine
University of Rochester Medical Center
School of Medicine and Dentistry
Rochester, New York

Andrew L. Nyce, MD [225]
Assistant Professor of Emergency Medicine
Cooper Medical School of Rowan University
Adjunct Assistant Professor of Emergency Medicine
UMDNJ/Robert Wood Johnson Medical School
Cooper University Hospital
New Brunswick, New Jersey

Mary Claire O'Brien, MD [71]
Associate Professor
Department of Emergency Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Damilola Ogunnaike-Joseph, MD [140]
Wake Emergency Physicians
Raleigh, North Carolina

Kelly Patrick O'Keefe, MD [281]
Associate Professor, University of South Florida Morsani College of Medicine
Program Director, Emergency Medicine Residency
University of South Florida and Tampa General Hospital
Tampa, Florida

Lila O'Mahony, MD [146]
Departments of Emergency Medicine and Pediatrics
Pediatric Emergency Medicine Fellow,
University of Washington and Seattle Children's Hospital
Seattle, Washington

Susan R. O'Mara, MD, FAAEM [80]
Washington Hospital Center
Department of Emergency Medicine
Washington, DC

Ricardo C. Ong, MD, DiMM [302]
Command Surgeon
1st Special Forces Command (Airborne)
Fort Bragg, North Carolina

Marcus E. H. Ong, MBBS, MPH, FAMS [23, 24]
Associate Professor
Office of Clinical Sciences
Duke-National University of Singapore Graduate Medical School
Senior Consultant and Clinician Scientist
Department of Emergency Medicine
Singapore General Hospital
Outram Road, Singapore

Joseph P. Ornato, MD, FACP, FACC, FACEP [11]
Professor and Chairman
Department of Emergency Medicine
Virginia Commonwealth University
Medical College of Virginia Hospitals
Virginia Commonwealth University
Richmond, Virginia

Raymond J. Orthober, MD [83]
Assistant Professor
Department of Emergency Medicine
School of Medicine
University of Louisville
Louisville, Kentucky

Charissa B. Pacella, MD [162]
Associate Professor, University of Pittsburgh Department of Emergency Medicine
Vice Chair of Operations, UPMC Department of Emergency Medicine
Pittsburgh, Pennsylvania

Michael T. Paddock, DO, MS [208]
Clinical Associate, Section of Emergency Medicine
University of Chicago Medicine
Chicago, Illinois

Amit Pandit, MD [249]
Critical Care Medicine Fellow Memorial Sloan Kettering
New York City, New York

Peter Peacock, MD [88]
Assistant Professor, Emergency Medicine
State University of New York, Downstate
Chief Medical Informatics Officer
Kings County and Woodhull Hospital Centers
Brooklyn, New York

Andre M. Pennardt, MD, FAWM, FACEP, DiMM [302]
Professor of Emergency Medicine & Hospitalist Services
Medical College of Georgia, Georgia Regents University
Augusta, Georgia

Debra G. Perina, MD [226]
Associate Professor
Department of Emergency Medicine
Quality Director, Prehospital Division Director,
EMS Fellowship Director
Department of Emergency Medicine
University of Virginia Hospital
Charlottesville, Virginia

Andrew D. Perron, MD, FACEP, FACSM [164]
Professor and Residency Program Director
Department of Emergency Medicine
Maine Medical Center
Portland, Maine

Jeanmarie Perrone, MD [187]
Professor, Emergency Medicine Director, Division of Medical Toxicology, Department of Emergency Medicine
Perelman School of Medicine, University of Pennsylvania
Philadelphia, Pennsylvania

Roberta Petrino, MD [17]
President Elect of the European Society for Emergency Medicine
Chair Emergency Medicine Unit
S. Andrea Hospital
Vercelli, Italy

Vu D. Phan, MD [67]
Staff Physician
Emergency Department
Aultman Hospital
Canton, Ohio

Michael R. Pinsky, MD, CM, Dr hc [32]
Professor of Critical Care Medicine, Bioengineering, Anesthesiology, Cardiovascular Diseases, and Clinical & Translational Sciences
Vice-Chair, Academic Affairs
Department of Critical Care Medicine
University of Pittsburgh School of Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania

R. Dustin Pippin, PharmD [19]
Pharmacist
Emergency Department
Wake Forest Baptist Health
Department of Pharmacy
Winston-Salem, North Carolina

Anthony F. Pizon, MD [217]
Chief, Medical Toxicology
Department of Emergency Medicine
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Charles V. Pollack, Jr., MA, MD [239]
Professor of Emergency Medicine
Chairman, Department of Emergency Medicine
Pennsylvania Hospital
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Janet Poponick, MD [67]
Assistant Professor
Department of Emergency Medicine
Metro Health Medical Center
Case Western Reserve University
Cleveland, Ohio

Samuel Josiah Prater, MD [107]
Fellow
Pediatric Emergency Medicine
Baylor College of Medicine
Houston, Texas
Texas Children's Hospital
Houston, Texas

Timothy G. Price, MD [83]
Associate Professor
Department of Emergency Medicine
School of Medicine
University of Louisville
Louisville, Kentucky

Louise A. Prince, MD, FACEP [59,60]
Associate Professor, Department of Emergency Medicine
Upstate Medical University
Syracuse, New York

Susan B. Promes, MD [149]
Chairman and Professor
Department of Emergency Medicine
Pennsylvania State University School of Medicine
Hershey, Pennsylvania

Jane M. Prosser, MD [187]
Assistant Professor, Medicine Division of Emergency Medicine, Weill Cornell Medical School
New York City, New York

Katherine M. Prybys, DO [188]
Assistant Professor
Department of Emergency Medicine
University of Maryland School of Medicine
Baltimore, Maryland

Michael A. Puskarich, MD [151]
Assistant Professor of Emergency Medicine
University of Mississippi Medical Center
Jackson, Mississippi

Linda Quan, MD [215]
Professor of Pediatrics
Seattle Children's Hospital
Seattle, Washington

Dan Quan, DO [183, 184, 185, 196, 202]
Associate Professor
Department of Emergency Medicine,
University of Arizona College of Medicine – Phoenix
Phoenix, Arizona

Nadeemuddin Quereshi, MD, FAAP, FCCM [144]
Consultant Pediatric Emergency Medicine
Department of Emergency Medicine
King Faisal Specialist Hospital and Research Centre
Riyadh, Kingdom of Saudi Arabia

James Quinn, MD, MS [44, 50]
Associate Professor of Surgery/Emergency Medicine
Stanford University
Stanford, California

Ralph H. Raasch, PharmD [163]
Associate Professor of Pharmacy (retired)
Division of Practice Advancement and Clinical Education,
Eshelman School of Pharmacy
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

John C. Ray, MD [231]
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

Sarah M. Reid, MD, FRCPC [131]
Assistant Professor, Departments of Pediatrics and Emergency
Medicine, University of Ottawa
Children's Hospital of Eastern Ontario
Ottawa, Ontario

Joseph G. Rella, MD [191, 206]
Assistant Professor
Emergency Medicine
Weill Cornell Medical College
New York City, New York

Vito Rocco, MD, FACE [74]
Vice chief
Emergency medicine
St. John hospital Macomb-Oakland
Warren, Michigan

Christopher Ross, MD, FRCPC, FACEP, FAAEM [262]
Associate Professor of Emergency Medicine
Associate Chair of Professional Education
Attending Physician Emergency Medicine
Cook County (Stroger) Hospital
Department of Emergency Medicine
Chicago, Illinois

Richard Rothman, MD, PhD [154, 155]
Professor
Johns Hopkins University, School of Medicine
Baltimore, Maryland

Brian H. Rowe, MD, MSc, CCFP(EM), FCCP [14]
Tier I Canada Research Chair in Evidence-Based Emergency
Medicine
Scientific Director, Emergency Strategic Clinical Network
Professor, Department of Emergency Medicine
University of Alberta
Edmonton, Alberta

William Rushton, MD [248]
University of Virginia School of Medicine
Charlottesville, Virginia

William A. Rutala, PhD, MPH [157]
Professor of Medicine
Director, Hospital Epidemiology
Department of Infectious Diseases
University of North Carolina
Chapel Hill, North Carolina

Vikram Sabhaney, BSc, MD, FRCPC [122, 123]
Pediatric Emergency Medicine Fellowship Director, BC Children's
Hospital
Clinical Assistant Professor, Department of Pediatrics
University of British Columbia
Vancouver, British Columbia

Justin W. Sales, MD, MPH [132]
Division of Pediatric Emergency Medicine
Director, Prehospital Coordination
Randall Children's Hospital
Portland, Oregon

Annabella Salvador-Kelly, MD, FACEP [44]
Associate Medical Director
Long Island Jewish Medical Center
New Hyde park, New York
Assistant professor
Hofstra-Northshore LIJ School of Medicine
Hempstead, New York

Tracy G. Sanson, MD, FACEP [281]
Associate Clinical Professor
Division of Emergency Medicine
Department of Internal Medicine
University of South Florida
Tampa, Florida

Sally A. Santen, MD, PhD [233, 238]
Assistant Dean, Educational Research & Quality Improvement
Associate Chair, Education, Department of Emergency Medicine
University of Michigan School of Medicine
Ann Arbor, Michigan

John Sarko, MD (Deceased) [62]
Associated Professor, Department of Emergency Medicine
University of Arizona College of Medicine – Phoenix
Maricopa Integrated Health System
Phoenix, Arizona

Adam B. Schlichting, MD, MPH [223]
Fellow, Critical Care Medicine
Departments of Emergency Medicine and Internal Medicine
Henry Ford Hospital
Detroit, Michigan

Sandra M. Schneider, MD, FACEP [181]
Senior Research Director
North Shore Hospital
Manhasset, New York
Professor
Hofstra North Shore LIJ School of Medicine
Hempstead, New York

Aaron Schneir, MD [211]
Professor of Clinical Medicine
Division of Medical Toxicology
Department of Emergency Medicine
University of California San Diego Health System
La Jolla, California

Abigail Schuh, MD [121]
Assistant Professor
Pediatric Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

Theresa M. Schwab, MD [262]
Assistant Professor
Department of Emergency Medicine
Advocate Christ Medical Center
University of Illinois at Chicago
Oak Lawn, Illinois

Robert W. Shaffer, MD [233]
Assistant Professor
University of Michigan Medical School
Department of Emergency Medicine
University of Michigan Medical Center
Ann Arbor, Michigan

Manish I. Shah, MD [107]
Assistant Professor
Department of Pediatrics, Section of Emergency Medicine
Baylor College of Medicine
Attending Physician
Emergency Center, Texas Children's Hospital
Houston, Texas

Allan Shefrin, MD, FRCPC [124]
Division of Pediatric Emergency Medicine
Department of Pediatrics
Children's Hospital of Eastern Ontario
Assistant Professor, University of Ottawa
Ottawa, Ontario

Suzanne M. Shepherd, MD, DTM&H [103, 296]
Professor
Education Officer
Chair, COAP Committee
Department of Emergency Medicine
Penn Medicine-Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

David C. Sheridan, MD [136]
Pediatric Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Sara Haney Shields, PharmD, BCPS [19, 20]
Pharmacy System Manager, Emergency Department & Perioperative Services
Department of Pharmacy
Wake Forest Baptist Medical Center
Winston-Salem, North Carolina

William H. Shoff, MD [103]
Associate Professor
Director of Travel Medicine
Department of Emergency Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Jonathan E. Siff, MD, MBA, FACEP [303]
Associate Chief Medical Informatics Officer
The MetroHealth System
Associate Professor
Department of Emergency Medicine
Case Western Reserve University School of Medicine
Cleveland, Ohio

Troy Sims, DO [63]
Clinical Assistant Professor
University of Pittsburgh
Pittsburgh, Pennsylvania

Richard Sinert, DO [88,90]
Professor of Emergency Medicine
Vice-Chair In-Charge of Research
State University of New York—Downstate Medical Center and Kings County Hospital Center
Health and Hospitals Corporation
Brooklyn, New York

Adam J. Singer, MD [39, 41, 47]
Professor and Vice Chairman for Research
Department of Emergency Medicine
Stony Brook University
Stony Brook, New York

Aaron Skolnik, MD [193]
Banner-University Medical Center Phoenix
Assistant Medical Director, Banner Poison & Drug Information Center
Assistant Professor, Department of Emergency Medicine
University of Arizona College of Medicine
Phoenix, Arizona

David E. Slattery, MD, FACEP, FAAEM [239]
Assistant Professor and Research Director
Department of Emergency Medicine
University of Nevada School of Medicine
Las Vegas, Nevada

Benjamin Small, PharmD, BCPS [19]
Pharmacist
Emergency Department
Wake Forest Baptist Health
Department of Pharmacy
Winston-Salem, North Carolina

Michael D. Smith, MD, MBA [30]
Associate Professor, Case Western Reserve University
Attending Physician, MetroHealth Medical Center
Cleveland, Ohio

Lane M. Smith, MD, PhD, FACEP [159]
Assistant Professor
Department of Emergency Medicine
Wake Forest School of Medicine
Winston Salem, North Carolina

Brian K. Snyder, MD [214]
Clinical Professor of Emergency Medicine
Attending, Hyperbaric Medicine Division
University of California, San Diego Health System

Mark Sochor, MD [249]
Associate Professor of Emergency Medicine
Research Director, Emergency Medicine Research Office
Department of Emergency Medicine
Charlottesville, Virginia

Mitchell C. Sokolosky, MD [285]
Associate Professor of Emergency Medicine
Wake Forest Health Sciences Center
Winston-Salem, North Carolina

David M. Somand, MD, FACEP [13]
Clinical Lecturer
Department of Emergency Medicine
University of Michigan
Ann Arbor, Michigan

J. Stephan Stapczynski, MD [62, 240]
Professor, Department of Emergency Medicine
University of Arizona College of Medicine - Phoenix
Phoenix, Arizona

Brandy Stauffer, MD [134]
Pediatric Emergency Medicine Fellow
Department of Pediatrics
Department of Emergency Medicine
University of Alberta
Edmonton, Alberta

Mark T. Steele, MD [273, 274]
Department of Emergency Medicine
University of Missouri—Kansas City
Truman Medical Center
Kansas City, Missouri

Christine R. Stehman, MD [79]
Assistant Professor of Clinical Emergency Medicine
Department of Emergency Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Jennifer A. Stephani, MD [10]
Clinical Instructor, Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Richard J. Stevenson, MBChB, BMSc (Hons), FRCEM, MRCP, MFFLM, DFM, DMedTox [301]
Consultant in Emergency Medicine
Glasgow Royal Infirmary
Glasgow, Scotland

C. Keith Stone, MD, FACEP [3]
Professor and Chair
Department of Emergency Medicine
Texas A&M University, Health Science Center
College of Medicine
Scott & White Healthcare
Temple, Texas

Susan C. Stone, MD, MPH [40]
Associate Professor of Emergency Medicine
Los Angeles County Medical Center
Keck School of Medicine of University of South Carolina
Los Angeles, California

Alan B. Storrow, MD [53]
Associate Professor of Emergency Medicine
Vice Chairman for Research and Academic Affairs
Vanderbilt University
Nashville, Tennessee

Charles E. A. Stringer, MD, MSc [122]
Resident, Emergency Medicine
Department of Emergency Medicine
University of British Columbia
Vancouver, British Columbia

Amy M. Stubbs, MD [273]
Assistant Professor
Department of Emergency Medicine
University of Missouri—Kansas City
Truman Medical Center
Kansas City, Missouri

Gerald W. Surrett, MD, FAWM, DiMM [302]
Group Surgeon
10th Special Forces Group
Fort Carson, Colorado

Carolyn Synovitz, MD, MPH [34]
Clinical Associate Professor
Department of Emergency Medicine
Oklahoma School of Community Medicine
Tulsa, Oklahoma
Jackson County Memorial Hospital
Altus, Oklahoma

Sukhjit S. Takhar, MD [153]
Instructor of Medicine (Emergency Medicine)
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Peter Tang, MD, MPH [268]
Director
Hand, Upper Extremity & Microvascular Fellowship
Associate Professor
Drexel University College of Medicine
Allegheny General Hospital
Allegheny Health Network
Pittsburgh, Pennsylvania

Mary E. Tanski, MD [174]
Assistant Professor
Department of Emergency Medicine
Oregon Health & Science University
Portland, Oregon

Wee Siong Teo, MBBS, M Med (Int Med), FRCP (Edin), FACC, FHRS [33]
Senior Consultant
Department of Cardiology
National Heart Centre
Singapore

Stephen R. Thom, MD, PhD [21]
Professor, Emergency medicine
University of Maryland School of Medicine
Baltimore, Maryland

Stephen H. Thomas, MD, MPH [3]
George Kaiser Family Foundation Professor and Chair
Department of Emergency Medicine
University of Oklahoma School of Community Medicine
Tulsa, Oklahoma

Jennifer Thull-Freedman, MD, MSc [128]
Clinical Associate Professor
University of Calgary
Calgary, Alberta

Aleksandr M. Tichter, MD [40]
Assistant Program Director
Emergency Medicine Residency
NewYork-Presbyterian Hospital
Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons
New York City, New York

Joel S. Tieder, MD, MPH [115]
Assistant Professor
Department of Pediatrics
Division of Hospital Medicine
Seattle Children's Hospital
The University of Washington
Seattle, Washington

Adam Z. Tobias, MD, MPH [290]
Assistant Professor of Emergency Medicine
University of Pittsburgh, School of Medicine
Pittsburgh, Pennsylvania

Christian Tomaszewski, MD, MS, MBA, FACEP, FACMT, FIFEM [195]
Professor of Clinical Emergency Medicine
Medical Director, Department of Emergency Medicine
Attending in Medical Toxicology and Hyperbarics
University of California San Diego Health Sciences
San Diego, California

Richard Tovar, MD, FACEP, FACMT [205]
Medical Toxicology
Clinical Forensic Medicine
Wisconsin Poison Center
Milwaukee, Wisconsin

Dennis T. Uehara, MD, MS, FACEP [269]
Chair, Department of Emergency Medicine
Rockford Memorial Hospital
Clinical Professor of Surgery, University of Illinois
College of Medicine, Rockford
Rockford, Illinois

Adam Vella, MD [145]
Associate Professor of Emergency Medicine
Pediatrics and Medical Education
Icahn School of Medicine at Mount Sinai
New York City, New York

Anantharaman Venkataraman, MBBS, FRCP (Edin), FRCS Ed (A&E), FAMS [23, 24, 33]
Professor and Senior Consultant, Department of Emergency Medicine
Singapore General Hospital
Adjunct Professor, Duke-NUS Graduate Medical School, Singapore
Advisor, International Co-operation
SingHealth Corporate Office
Singapore

Raghu Venugopal, MD, MPH, FRCPC [161]
Assistant Professor of Medicine
University of Toronto
Attending Physician
University Health Network Emergency Department
Toronto, Ontario

Robert J. Vissers, MD [29, 111]
CEO and President, Boulder Community Health, Boulder, CO
Clinical Professor of Emergency Medicine, University of Colorado
Instructor, School of Management, Oregon Health Sciences University,
Portland, Oregon

Richard A. Walker, MD [241]
Associate Professor
Department of Emergency Medicine
University of Nebraska Medical Center
Clinical Director
Department of Emergency Medicine
The Nebraska Medical Center
Omaha, Nebraska

Nikki Waller, MD [106]
Assistant Professor
Assistant Residency Program Director
Department of Emergency Medicine
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Vincent J. Wang, MD, MHA [116]
Associate Professor of Pediatrics
Keck School of Medicine of the University of Southern California
Associate Division Head
Division of Emergency Medicine
Children's Hospital Los Angeles
Los Angeles, California

Henry E. Wang, MD, MS [28]
Department of Emergency Medicine
University of Alabama School of Medicine
Birmingham, Alabama

Kevin R. Ward, MD [13]
Professor
Department of Emergency Medicine
University of Michigan
Michigan Center for Integrative Research in Critical Care (MCIRCC)
Ann Arbor, Michigan

Christopher S. Weaver, MD, MBA [37]
Associate Professor of Emergency Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Lindsay Weaver, MD [300]
Assistant Professor of Clinical Emergency Medicine
Indiana University School of Medicine
Indianapolis, Indiana

David J. Weber, MD, MP [157]
Professor of Medicine
Pediatrics and Epidemiology
Medical Director, Hospital Epidemiology
Department of Infectious Diseases
University of North Carolina
Chapel Hill, North Carolina

Ian S. Wedmore, MD, FACEP, FAWM, DiMM [302]
Program Director, Austere and Wilderness Medicine Fellowship
Department of Emergency Medicine
Madigan Army Medical Center
Tacoma, Washington

Scott G. Weiner, MD, MPH [292]
Associate Professor of Emergency Medicine,
Department of Emergency Medicine, Tufts University School of Medicine and Director of Research, Tufts Medical Center
Boston, Massachusetts

Brian Weiss, MD [103]
University of Pennsylvania
Philadelphia, Pennsylvania

Janna M. Welch, MD [75]
Emergency Medicine
University of Texas at Austin
Dell Medical School
Austin, Texas

Howard A. Werman, MD, FACEP [73]
Professor of Clinical Emergency Medicine
The Ohio State University
Columbus, Ohio

Lori J. Whelan, MD [99]
Assistant Professor & Director of Ultrasound
Assistant Program Director
Assistant Medical Student Director
Department of Emergency Medicine
University of Oklahoma School of Community Medicine
Tulsa, Oklahoma

Julian White, MB, BS, MD, FACTM [212]
Professor and Department Head
Toxinology Department
Women's & Children's Hospital
North Adelaide, Australia

Eric Williams, BSc, MBBS, MSc, DM [236]
Associate Lecturer
Department of Surgery, Radiology, Anesthesia and Intensive Care
The Emergency Medicine Division Faculty of Medical Sciences
University of the West Indies
Mona, Jamaica

Joanne Williams, MD, FAAEM [298]
Adjunct Clinical Professor of Emergency Medicine
Keck School of Medicine of USC
Associate Professor of Emergency Medicine
Charles Drew University of Medicine and Science
Los Angeles, California

Jean Williams-Johnson, BSc, MBBS, MSc, DM [236]
Senior Lecturer/ Emergency Medicine Residency Program Director
Department of Surgery
Faculty of Medical Sciences
The University of the West Indies
Medical Director/Consultant Emergency Physician
The Emergency Medicine Division
The University Hospital of the West Indies
Mona, Jamaica

Michael E. Winters, MD, FACEP, FAAEM [57, 58]
Associate Professor of Emergency Medicine and Medicine
Co-Director, Combined Emergency Medicine, Internal Medicine, Critical Care Program
University of Maryland School of Medicine
Baltimore, Maryland

Michael D. Witting, MD, MS [86]
Associate Professor
Department of Emergency Medicine
University of Maryland School of Medicine
Maryland, Baltimore

David A. Wohl, MD [157]
Associate Professor
Division of Infectious Diseases
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

William A. Woods, MD [226]
Program Director Emergency Medicine Residency
Associate Professor, Departments of Emergency Medicine, Pediatrics, and Mechanical and Aerospace Engineering
Director, Pediatric Emergency Department
University of Virginia Hospital
Charlottesville, Virginia

Daniel J. Worman, MD [167]
Associate Professor
Department of Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

David W. Wright, MD, FACEP [257]
Associate Professor, Emergency Medicine
PI, ProTECT III Clinical Trial
Director, Emergency Neurosciences
Department of Emergency Medicine
Emory University School of Medicine
Atlanta, Georgia

Chris Wyatt, MD [31]
Assistant Professor
MetroHealth Medical Center/Case Western Reserve University School of Medicine
Cleveland, Ohio

Santiago Nogue Xarau, MD, PhD [201]
Clinical Toxicology Unit, Emergency Department
Hospital Clinic, Universidad de Barcelona
Barcelona, Spain

Samuel Yang, MD [154, 155]
Associate Professor
Stanford University
Stanford, California

Donald M. Yealy, MD [30, 65]
Chair, Department of Emergency Medicine
University of Pittsburgh / University of Pittsburgh Physicians
Senior Medical Director, Health Services Division, UPMC
Professor of Emergency Medicine, Medicine, and Clinical and Translational Sciences
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

David Hung-Tsang Yen, MD, PhD [92]
Associate Professor
Department of Emergency Medicine
Taipei Veterans General Hospital
Institute of Emergency and Critical Care Medicine
National Yang-Ming University
Taipei, Taiwan

Janet S. Young, MD [100]
Assistant Professor
Department of Emergency Medicine
Virginia Tech- Carilion School of Medicine
Roanoke, Virginia

Esther L. Yue, MD [126]
Pediatric Emergency Medicine Fellow
Department of Emergency Medicine
Division of Pediatric Emergency Medicine
Oregon Health and Science University
Portland, Oregon

Robert J. Zalenski, MD [299]
Brooks F. Bock Professor of Emergency Medicine
Wayne State University
School of Medicine
Director, Center to Advance Palliative-Care Excellence
Detroit, Michigan

Roger Zemek, MD, FRCPC [124]
Associate Professor, Department of Pediatrics,
Children's Hospital of Eastern Ontario, University of Ottawa
Ottawa, Ontario

Christopher M. Ziebell, MD, FACEP [75]
Chairman, Department of Emergency Medicine, University Medical Center Brackenridge
Executive Director, SETON Event Medicine Institute,
Assistant Professor, Dell Medical School
University of Texas
Austin, Texas

Erin Zimny, MD [299]
Clinical Assistant Professor, Wayne State University
Senior Staff Physician, Henry Ford Hospital
Department of Emergency Medicine
Detroit, Michigan

Leslie S. Zun, MD [286]
Professor and Chair
Department of Emergency Medicine
Rosalind Franklin University of Medicine and Science
The Chicago Medical School
North Chicago, Illinois
Chair, Department of Emergency Medicine
Mount Sinai Hospital
Chicago, Illinois

Pharmacy Reviewers

Chapter 17, Fluids and Electrolytes

Christopher B. Adams, PharmD
Emergency Medicine Clinical Pharmacist

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 19, Pharmacology of Antiarrhythmics and Antihypertensives

Andrea Julia Miura, PharmD, BCPS
Critical Care and Emergency Medicine Clinical Pharmacist

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 109, Resuscitation of Children

Kate M. Kokanovich, PharmD
PGY2 Emergency Medicine Pharmacy Resident
University of Rochester Medical Center
Rochester, New York

Nicole Acquisto, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Assistant Professor, Department of Emergency Medicine
Director, PGY2 Emergency Medicine Pharmacy Residency
University of Rochester Medical Center
Rochester, New York

Chapter 194, Beta-Blockers

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 195, Calcium Channel Blockers

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 20, Pharmacology of Vasopressors and Inotropes

Cassie A. Barton, PharmD, BCPS
Critical Care Pharmacist

Chapter 25, Resuscitation in Pregnancy

Ceirra N. Treu, PharmD
PGY2 Emergency Medicine Pharmacy Resident
University of Rochester Medical Center
Rochester, New York

Nicole Acquisto, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Assistant Professor, Department of Emergency Medicine
Director, PGY2 Emergency Medicine Pharmacy Residency
University of Rochester Medical Center
Rochester, New York

Chapter 239, Thrombotics and Antithrombotics

Kristan E. Vollman, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Owensboro Health Regional Hospital
Owensboro, Kentucky

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 289, Mood and Anxiety Disorders

Nadia Awad, PharmD, BCPS
Clinical Assistant Professor, Emergency Medicine
Ernest Mario School of Pharmacy
Rutgers, The State University of New Jersey
Piscataway, New Jersey
Emergency Medicine Pharmacist
Robert Wood Johnson University Hospital Somerset
Somerville, New Jersey

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Chapter 290, Psychoses

Mason H. Bucklin, PharmD
Emergency Medicine Pharmacist
Assistant Professor, Department of Clinical Pharmacy
University of Tennessee Medical Center

Nathan Mah, PharmD
Emergency Medicine Clinical Pharmacy Specialist
Oregon Health and Science University
Portland, Oregon

Preface

This 8th edition marks 37 years of continuous publication of a textbook that began in 1978 as a collection of material used to study for the early board examinations in Emergency Medicine. Each edition has expanded in depth and breadth to represent the complexity and expertise needed to practice emergency medicine in today's environment. For past editions, I have been fortunate to have the editorial collaboration of notable emergency educators—Ron Krome, Ernie Ruiz, Gabe Kelen, and Rita Cydulka. This 8th edition is the result of efforts by Steve Stapczynski, John Ma, Donald M. Yealy, Garth Meckler, and David Cline—and a host of dedicated authors.

How do we identify the scope of practice and knowledge that is today's specialty of emergency medicine? Is it through paper books, blogs, social networking, Google, journals, or clinical practice? While e-information is perfectly suited to the multitasking and frequent-attention shifts of the emergency medicine environment. E-information does not communicate what Emergency Medicine IS. E-information provides information about snippets of care, but not about the comprehensive knowledge set that is our specialty.

Both digital and print materials are available as part of the 8th edition. We have designed the 8th edition, like the past editions, to include the content that comprises the specialty of Emergency Medicine. But this edition is part of a much larger e-work, AccessEmergencyMedicine, the McGraw-Hill compendium of emergency medicine education texts. AccessEmergencyMedicine also includes the digital version of the 8th edition, with online searching of text, videos, tables, and illustrations. Accompanying this print edition is a digital set of procedure videos that were designed for both learner and teacher.

We will continue to combine the best educational tools—print and digital—for contemporary emergency medicine practice as the best way to communicate what Emergency Medicine IS.

Judith E. Tintinalli, MD, MS
Editor-in-chief
Chapel Hill, North Carolina

SECTION 1

Prehospital Care

CHAPTER 1

Emergency Medical Services

C. Crawford Mechem

INTRODUCTION

EMS is the extension of emergency medical care into the prehospital setting. The concept of bringing care to the sick or injured dates back to Roman times. However, today's EMS systems have their roots in legislative and clinical developments of the 1960s and 1970s. The 1966 report "Accidental Death and Disability—The Neglected Disease of Modern Society" highlighted the deficiencies of prehospital care for trauma victims, which were attributable to inadequate equipment and provider training. Up until that time, more than half of ambulance services were run by funeral homes because hearses were among the few vehicles able to transport a stretcher. The National Highway Safety Act of 1966 established the Department of Transportation and made it the lead agency responsible for upgrading EMS systems nationwide.[1]

In 1967, J. F. Pantridge began using a physician-staffed mobile coronary care unit in Belfast, Northern Ireland, to extend cardiac care into the prehospital setting. By doing so, he was able to reduce mortality among myocardial infarction patients.[2] Using physicians to staff ambulances never gained popularity in the United States. However, in the late 1960s and 1970s, nonphysician prehospital personnel in the United States began to learn advanced medical skills, including IV placement, administration of medications, cardiac rhythm interpretation, and defibrillation.[3]

The U.S. EMS Systems Act of 1973 set aside large federal grants to develop regional EMS systems across the country. Approximately 300 EMS regions were established and became eligible for federal funding. To receive funding, the Act required that EMS systems address 15 key elements (**Table 1-1**). These elements form the foundation of many EMS systems today.[4]

The 1970s became something of a Golden Age for EMS in the United States. The U.S. Department of Transportation developed curricula for emergency medical technicians, paramedics, and first responders. EMS communications systems were formalized. In 1972, the Federal Communications Commission recommended that 9-1-1 be implemented as the emergency telephone number nationwide. The concept of designated trauma centers within EMS systems was introduced, the idea being that EMS personnel would transport seriously injured patients preferentially to these facilities.

The Omnibus Budget Reconciliation Act of 1981 eliminated direct federal funding for EMS. Instead, federal funds were given to states in the form of block grants. The result was a decrease in overall funding of EMS as well as decreased coordination of EMS systems. EMS systems took on a decidedly local flavor, with great variation between systems within states and across the country. This trend has had long-term consequences for the field.[1]

In 2011, the American Board of Emergency Medicine recognized EMS as its seventh subspecialty. The certification examination is based on the Core Content of EMS Medicine[5] with four major content areas: Clinical Aspects of EMS Medicine, Medical Oversight of EMS, Quality Management and Research, and Special Operations.

EMS SYSTEM OVERVIEW

A review of the 15 elements of EMS systems identified by the EMS Systems Act of 1973 (Table 1-1) provides insight into the current structure of EMS systems and the challenges they face.

MANPOWER

In most urban areas, paid public safety and ambulance personnel provide prehospital medical care. In contrast, suburban, rural, or wilderness EMS systems commonly use volunteers. Regardless of setting, EMS personnel fall into one of four levels of training, or licensure levels, in accordance with the National EMS Scope of Practice Model, set forth by the National Highway Traffic Safety Administration. These are emergency medical responder, emergency medical technician, advanced emergency medical technician, and paramedic. Each type of provider must master a minimum set of psychomotor skills. Emergency medical responders are usually first on the scene of a medical emergency. They are trained to perform CPR, spine immobilization, hemorrhage control, use of an automated external defibrillator, and other basic interventions while awaiting an ambulance. Emergency medical technicians function as part of an ambulance crew and are trained to take care of immediate life threats. Skills include oxygen administration; CPR; hemorrhage control; and patient extrication, immobilization, and transportation. They are also trained to assist patients in using some of their own medications and can administer to patients certain over-the-counter medications under medical oversight. Advanced emergency medical technician training includes additional assessment skills plus IV insertion, use of esophageal-tracheal multi-lumen airway devices, and administration of certain medications. Paramedics have the highest skill level, with greater training and broader scope of practice than advanced emergency medical technicians. Because of their advanced level of training, paramedics function under a designated physician's medical license.[6]

TRAINING

Training includes initial provider training and continuing education. As EMS call volume increases, providers often care for a disproportionate number of patients with minor medical issues. Maintaining proficiency in skills needed to manage critically ill patients may be difficult. Innovative training methods to ensure skills retention must be sought. Use of computerized human patient simulators is one option, both for reviewing skills and learning new ones.

COMMUNICATIONS

The adoption of 9-1-1 as a nationwide emergency number in the United States has greatly facilitated public access to emergency medical care. In many systems, the local answering center or public safety answering point has enhanced equipment that provides the number and location of a caller (enhanced 9-1-1). Widespread use of cellular telephones has prompted the development of enhanced technology to identify and locate these callers as well, in accordance with Federal Communications Commission regulations. Emergency call takers are trained to collect the necessary information, dispatch appropriate resources, and offer first aid or prearrival instructions, while the ambulance is en route. Ambulance personnel should also be able to communicate with the destination hospital. Most EMS personnel operate under standing

orders and protocols developed by physicians. However, there are times when providers may require online medical control, talking directly with a physician for direction.[7] Historically, communications represent the weakest link in most disaster responses. It is therefore important that EMS communication systems have built-in redundancy to ensure uninterrupted service.

TRANSPORTATION

Ambulances have evolved from simple transport vehicles into mobile patient care vehicles. Ambulance design must enable EMS personnel to provide airway and ventilatory support while transporting the patient safely. Basic life support ambulances carry equipment appropriate for personnel trained at the emergency medical technician level, such as automated external defibrillators, oxygen, bag-mask ventilation devices, immobilization and splinting devices, and wound dressings. They do not carry medications and cannot transport patients requiring IVs or cardiac monitoring. Advanced life support ambulances are equipped for paramedics or advanced emergency medical technicians with supplies appropriate for their scope of practice, including IV fluids and medications, intubation equipment, cardiac monitors, and pulse oximeters. Ground transportation is appropriate for the majority of patients, especially in urban and suburban areas. However, air transport, generally by helicopter, should be considered for critically ill patients when the ground transport time would be dangerously long or if the terrain is difficult to navigate.[4]

FACILITIES AND CRITICAL-CARE UNITS

Patients are often transported to the closest appropriate hospital. In recent years, the number of specialty hospitals has increased. These include pediatric hospitals, trauma and spinal cord injury centers, burn centers, stroke centers, and centers with advanced cardiac or resuscitation capabilities.[8] Tertiary care centers, often affiliated with medical schools, provide many of these services and may also have a large number of critical-care unit beds. The decision to bypass hospitals to go directly to a specialty center or a hospital with a large critical-care capacity, often at greater distances, is not a simple one. Although specialty hospitals often have more resources, transporting an unstable patient past an ED to get to the specialty hospital is not without risks. Furthermore, bypassing hospitals may have negative financial consequences for those facilities that are bypassed.[1] It is wise to solicit input from the local, regional, or statewide medical community before developing destination policies involving such specialty centers.

Due to increasing hospital inpatient censuses and ED overcrowding, at a given time, even the largest hospitals may not have adequate resources to care for EMS patients. This may result in prolonged offload times of ambulance patients, long wait times for patients to be seen, and ED boarding of admitted patients. Furthermore, some EDs may request that EMS divert patients to other hospitals.[9] Because of these issues, regional EMS systems should develop methods to monitor in real-time available resources of their receiving hospitals. A secure, Internet-based Web site of hospital resources, including ED and inpatient bed availability, is one option.

PUBLIC SAFETY AGENCIES

EMS systems should have strong ties with police and fire departments. Many large U.S. EMS systems are run by municipal fire departments. In addition to providing scene security, public safety agencies can provide first responder services because they are often first on the scene. Fire and police automated external defibrillator programs are common.[10,11] In some locations, these have been shown to improve outcomes for cardiac arrest victims. Finally, EMS personnel often provide medical support to police and fire departments in hazardous circumstances.

CONSUMER PARTICIPATION

Public support, both political and financial, is necessary for a good EMS system. It is therefore important that laypersons contribute to the policy-making process. One way to accomplish this is to encourage representation of the general public on the membership of regional EMS councils. In addition, the public can participate by volunteering for local EMS agencies.

ACCESS TO CARE

Successful EMS systems ensure that all individuals have access to emergency care regardless of ability to pay. Often, the EMS system is a patient's primary point of entry into the healthcare system. There should be no barriers or disincentives preventing timely access. A more difficult problem exists when terrain or low population densities result in longer response times for some citizens, as in rural or wilderness areas of the country. Possible solutions include stationing or predeploying ambulances throughout the area with one central dispatching center. Another option is heavier reliance on air medical services.

PATIENT TRANSFER

Patients are often transferred from one medical facility to another for a higher level of care. Safe transfer is an important concept. Many problems can be avoided if the transferring and receiving facilities develop transfer agreements in advance. The Emergency Medical Treatment and Active Labor Act, passed in 1986, sets forth rules that hospitals participating in the Medicare program must adhere to when considering a patient transfer. Under the Emergency Medical Treatment and Active Labor Act, all patients must receive a medical screening exam and be stabilized before transfer is considered. There must also be explicit acceptance of the transfer by the receiving hospital.[12]

COORDINATED PATIENT RECORD KEEPING

Maintaining good medical records is important to any patient encounter. Prehospital medical records need to be legible, intelligible, and readily accessible to hospital providers. Standardization of EMS medical records among different agencies within a region helps to streamline transfer of information between prehospital and hospital providers. The adoption of electronic charting and cloud-based electronic medical record keeping by many EMS systems is a step toward this goal. Electronic charts can be printed out in the receiving ED or downloaded from a secure Internet Web site. Regardless of the charting system used, EMS systems must comply with the stipulations of the U.S. Health Insurance Portability and Accountability Act of 1996, designed to protect the privacy of patient health information.[13]

PUBLIC INFORMATION AND EDUCATION

EMS systems have a responsibility to train the public on how to access EMS and use it appropriately. As EMS call volumes rise and available resources decline, educating the public to use 9-1-1 only for true

emergencies is an appropriate goal. However, given the obstacles that many patients encounter in trying to access office- or hospital-based care, conveying this message is not simple. The public needs to know that EMS will always be there when needed.

Another important message that EMS can convey to the public is the importance of learning CPR, first aid, and basic disaster preparedness. The responses to Hurricanes Katrina, Rita, and Irene and other recent disasters illustrated that, at times, the emergency response infrastructure may be so seriously disrupted that it may take hours, if not days, for help to arrive. A public that is adequately prepared and trained will be in a better position to safely await help.[14]

REVIEW AND EVALUATION

To ensure proper functioning of an EMS system and high-quality patient care, there must be a process for ongoing review and evaluation. This requires input from personnel involved in day-to-day operations and active involvement of a physician medical director. A continuous quality improvement program should be established to assess system performance and formulate improvements.[15] Routine audits of communications, response times, scene times, and patient care records should be performed. Outcome studies of conditions such as cardiac arrest and trauma may be valuable. However, obtaining such outcomes may be problematic. An unforeseen consequence of the Health Insurance Portability and Accountability Act is that hospitals are often resistant to releasing patient information, even to EMS services, for fear of liability. Solutions to this problem are being investigated.

EMS research is invaluable to evaluate prehospital interventions and develop new ones. It is not valid to assume that what works in the hospital will also work in the prehospital setting. Issues such as limited funding, barriers to obtaining patient outcomes, and obtaining informed consent from critically ill patients, or waivers of consent, can make prehospital research daunting. However, these barriers must be overcome if patients are to receive quality care.[16]

DISASTER PLAN

The EMS system is an integral part of disaster preparedness and should be involved in planning along with other agencies and the medical community. The Omnibus Budget Reconciliation Act legislation of 1981 ended direct federal block grants to EMS. Because EMS is often not considered to fall into the category of public safety, emergency preparedness funding for EMS has fallen behind that of police and fire services.[1] Despite this, EMS agencies must maintain a high level of disaster preparedness. This involves having written policies and procedures, stockpiling supplies that may be rapidly depleted in multi-casualty situations, and participating in regional disaster drills with other emergency response agencies and hospitals.[17]

MUTUAL AID

EMS services should develop mutual aid agreements with neighboring jurisdictions so that emergency care is available when local agencies are overwhelmed or unable to respond.[18] Depending on the size and resources of the system, mutual aid may be required frequently or only under dire circumstances. Working out in advance details such as reimbursement, credentialing, liability, and chain of command at incident scenes will streamline the process.

CHALLENGES AND FUTURE TRENDS

The 2006 Institute of Medicine publication *Emergency Medical Services at the Crossroads*[1] detailed many of the challenges facing EMS. These include fragmentation and lack of interoperability between EMS systems, between EMS and other public safety agencies, and between EMS and the rest of the healthcare infrastructure. These limit the efficiency of EMS systems and may have serious consequences in disaster response. In addition, the fallout from the Omnibus Budget Reconciliation Act legislation of 1981 is still being felt. Funding for EMS continues to fall behind other public safety agencies, both for day-to-day operations and for emergency preparedness. Also, restructuring of how Medicare pays for advanced life support and basic life support services jeopardizes reimbursements. Therefore, many EMS agencies must either find other funding sources or cut services. This is occurring at a time when call volumes are rising in many parts of the country, in part due to the aging of the population and limited access to health care.[1]

Although demand for EMS steadily grows, in many parts of the country EMS staffing is not keeping pace. Factors such as low pay, high stress, and limited advancement opportunities cause high turnover rates among providers. As the length of EMS training curricula increases, alternative careers in health care may appear more appealing.[19] Many EMS systems are currently experiencing real or perceived paramedic shortages, prompting them to look at alternative staffing configurations or resource deployment.

As a consequence of funding and staffing constraints amid increasing call volumes, many EMS systems routinely operate at full capacity. As a result, their surge capacity, or ability to accommodate a sudden, large increase in demand for services, is limited. Surge capacity is determined by a system's staffing capabilities, its available resources, and the ability of its organizational structure to react effectively to the increased demand. To enhance surge capacity, EMS systems need funding for additional personnel, vehicles, and stockpiles of supplies that can be readily deployed. They must also participate in frequent training that is realistic and based on those threats they are most likely to encounter.[20-23]

Despite the many challenges EMS faces, the quality of care provided by EMS personnel continues to improve, driven in part by EMS research. Some of the advances involve regionalization of care, resuscitation of cardiac arrest victims, and management of ST-elevation myocardial infarction patients. The quality of cardiac arrest studies has been enhanced by adoption of the **Utstein template** for data reporting. Developed in 1990, the Utstein style presents a systematic and standardized format for reporting cardiac arrest data. This facilitates the comparison of results of studies performed in different EMS systems.[24] The importance of basic life support skills in cardiac arrest and other emergencies is being rediscovered. Basic interventions in some cases can have a greater impact on outcome than advanced life support skills. More widespread use of automated external defibrillators by first responders and the public has the potential to increase rates of resuscitation in cardiac arrest. The emphasis on high-quality, uninterrupted CPR, as set forth by the international 2007 guidelines for CPR and emergency cardiovascular care,[25] is widely reflected in EMS protocols across the United States.[26,27] Automatic chest compression devices and devices that provide instant feedback on the quality of CPR are being introduced in the prehospital setting.[28] Some EMS systems are beginning to induce hypothermia in resuscitated cardiac arrest patients.[29,30] Prehospital use of 12-lead electrocardiograms on patients with chest pain is becoming common.[31-34] Some systems transmit electrocardiograms to receiving EDs. Others activate cardiac catheterization labs directly when an ST-elevation myocardial infarction is identified on electrocardiogram.

EMS is maturing as an important subspecialty of emergency medicine in the United States and abroad. Growing populations and increased urbanization are driving the development of EMS systems worldwide.[35,36] The aftermath of the 2004 Asian tsunami emphasized the need for organized and effective prehospital care in developing countries, as well as for international cooperation among EMS agencies.[37,38] Although EMS systems in some countries are very similar to those in the United States, in other countries, differences in geography, healthcare system design, funding, and political structure present unique challenges and the potential for novel solutions. These developing EMS systems have the advantage of not being encumbered by decades of tradition, so they can take advantage of lessons learned elsewhere. They also present the opportunity for collaboration on international research initiatives that can lead to improved patient outcomes.[39]

CHAPTER 2

Prehospital Equipment

Andy Boggust

INTRODUCTION

To a large extent, early EMS equipment began as hospital equipment that was extrapolated to the field; it was assumed that if something worked in the hospital, then it would work in the field. It soon became apparent that hospital equipment did not always perform under the more rigorous conditions of prehospital care. Over the last 30 years, equipment has evolved specifically for EMS that is better adapted to field use in terms of size, weight, and durability. This equipment is directed at resuscitating and packaging the patient for transport to the hospital and for maintenance of stability during emergency or interfacility transport. As the science of EMS continues to mature, more equipment will be scrutinized for effectiveness.[1] The four basic questions regarding efficacy of EMS equipment are:

1. Does it do the job?
2. Is it safe?
3. Can it be applied to the field environment?
4. Can it be used effectively by prehospital personnel?

The nature of EMS equipment is changing due to the expanded scope of practice by paramedics and the blurring of care levels between basic life support (BLS) and advanced life support (ALS) personnel. Equipment once considered only for ALS care is now being carried on some BLS ambulances (e.g., defibrillators and airway adjuncts). This chapter discusses EMS vehicles; communications; the electronic patient record; personal protective equipment; and specific equipment for stabilization, resuscitation, and treatment.

VEHICLES

The vehicles may be ground ambulances, helicopters, fixed-wing aircraft, or a variety of first-response vehicles (fire engines, police cruisers, or sport utility vehicles). The most common vehicle used is the ground ambulance, categorized into three common varieties:

Type I: A standard truck (e.g., pick-up) chassis with a separate modular box to carry personnel, patient, and equipment

Type II: An enlarged van-type vehicle

Type III: A van chassis with an integrated modular box on the back for medical care and equipment

In types II and III, there is physical access between the driver's and patient care compartments, as opposed to type I, in which these spaces are separate.

Ground vehicles typically have warning devices (lights and siren) as part of their equipment. Unwarranted use of red lights and sirens is dangerous for the EMS crew, the patient onboard (if present), and the general public on the streets.[2] Protocols or guidelines to limit the use of these devices only to times when they are medically indicated are important.

COMMUNICATIONS

The two-way radio is an important piece of equipment carried by prehospital providers. As the arena of wireless communication changes, EMS systems will need to adapt their communications system to best fit their needs. The spectrum of frequencies available for emergency services is limited and shared with other industries that require wireless communications. In the United States, EMS services may use specific frequencies (*channels*) in the very high frequency (around 170 MHz), ultra-high frequency (around 460 MHz), and public safety (around 800 MHz) bands. In an attempt to create more channels for users, the Federal Communications Commission has decreased channel spacing from 25 to 12.5 kHz, and there is a Federal Communications Commission mandate to continue spacing down to 6.25 kHz. Although newer radio equipment can be reprogrammed to allow for the change in channel spacing, older equipment may not function correctly with this spacing.

EMS systems in rural or suburban settings may have no difficulties with local communications; however, as they transport patients into urban settings and attempt to communicate with urban providers, the problems of compatible frequencies and channel congestion may develop. Urban systems may use trunking, in which communications pathways are managed by a central processor between end users, allowing large numbers of users to share a relatively small number of communications frequencies. Trunked systems may be analog, very high frequency/ultra-high frequency digital radio, or 800-MHz digital radio. An 800-MHz digital trunked system is popular because of the advantages of shared equipment between different providers (EMS, police, and fire), enhanced radio coverage, shared or lowered cost, and wide-area communications. The main disadvantage with all trunked systems is the cost necessary to upgrade the current system. In the United States, 800-MHz trunking is slowly being implemented for emergency services providers, largely due to sponsorship by the U.S. Department of Homeland Security, because of improved communications during terrorist incidents and other disasters. Although 800 MHz is a more effective means of communication, the transition to it is slow due to the difficulties with simultaneous upgrading by police, fire, and EMS.

Many urban and suburban EMS providers are choosing cellular/personal communication systems as a means of communication. These systems are abundant in urban settings because they are often inexpensive and easier to use. However, at times, these cellular/personal communication systems are congested, and there are still dead spots, even in urban areas. During many disasters, when landline phones have not worked, cellular systems have also failed to function, so reliance on cell service during major incidents is problematic.[3,4]

ELECTRONIC MEDICAL RECORD

Use of the prehospital electronic medical record has increased substantially over the past 5 years. As usage of these electronic systems increases, research and system quality assurance analysis should become easier because of better data access.[5]

Large systems with enough resources often have their own software specifically written for that system. Smaller EMS systems often use off-the-shelf alternatives. Using one of the latter products may require either modification of a vendor's product or modification of the EMS system workflow to make the software fully functional. Many states are in the process of generating or have already generated a common data set and are collecting statewide data, which are submitted to the state EMS agency. Local and state data systems should be coordinated so they are compatible.

One common difficulty with the prehospital electronic medical record is incompatibility with the hospital electronic medical record. This means that the ambulance record cannot be expeditiously transferred to the hospital database. Long-term solutions need to be devised to ensure that all of these record systems are compatible.

PERSONAL PROTECTIVE EQUIPMENT

Every EMS provider must be protected against exposure to blood and other body fluids from patients. Equipment such as masks, goggles, and gloves for routine use should be carried on every EMS vehicle. On occasion, gowns or sturdy gloves may be needed.[6]

Exposure to hazardous material or biologic or chemical weapons of mass destruction requires more protective equipment. **Minimum personal protective equipment for such exposure should include a high-efficiency particulate air filter mask that filters 99.97% of airborne particles 0.3 μm in diameter (or an acceptable alternative for the purpose, such as an M95 military gas mask), goggles, gloves, and protective clothing.** Protective clothing should be nonabsorbent and puncture resistant (**Figure 2-1**).[7]

Some urban EMS providers wear soft body armor as a standard part of the uniform. Suburban and rural providers can be placed in situations that

FIGURE 2-1. Personal protective equipment: filtered (high-efficiency particulate air, M95, N95, or chemical-specific) mask, goggles, gloves, and protective clothing.[7]

necessitate similar protection. With advances in soft-armor technology, there are now a variety of styles and levels of protection from which to choose. Although each service must consider such variables as comfort, heat, weight, and cost, for EMS providers, a combination of ballistic/stab protection is optimal.

EQUIPMENT FOR STABILIZATION, RESUSCITATION, AND TREATMENT

This section reviews defibrillators, electrocardiograms, airway and ventilation adjuncts, vascular access devices, spinal immobilization, and extremity immobilization.

DEFIBRILLATORS

Defibrillators have been an essential part of prehospital care since Pantridge showed that defibrillation could be done in the field on the streets of Belfast in 1965. **Early defibrillation is the most important factor in surviving a cardiac arrest.** Because of this, defibrillators have become smaller and less costly to expand their use. Paramedic-staffed ALS services typically carry manual monitor/defibrillators, often with additional functions (e.g., 12-lead electrocardiogram, external cardiac pacing, and synchronized cardioversion). An increasing percentage of BLS services carry automated external defibrillators. These devices are shock advisory defibrillators. Automated external defibrillators analyze the patient's rhythm by computer algorithm, determine if the rhythm meets defibrillation criteria, inform the operator that a shock is advised, charge the capacitor, and deliver a defibrillation when the operator pushes the appropriate button. Automated external defibrillators are designed only to shock ventricular fibrillation and very fast ventricular or supraventricular tachycardias (usually >180 beats/min). Automated external defibrillators have become so easy to use and are so effective that many health and medical organizations are promoting these devices for first-responder public safety personnel and for public-access defibrillation by laypersons.[8-10]

Automated external defibrillators are simple and relatively inexpensive. They often do not have monitor screens that display the patient's rhythm. This actually may be better because a rhythm on the screen may only serve to distract a non-ALS operator. The device should have recording capabilities so that the cardiac arrest can later be reviewed for medical oversight and quality assurance reasons. The medical director should be involved in choosing such devices, training in their use, establishing protocols for their use, and reviewing their use afterward for quality assurance.

A defibrillator used by ALS personnel is typically a different, more sophisticated device, usually with additional functions. Defibrillation is facilitated using hands-off combination monitoring/defibrillation adhesive pads rather than with handheld paddles. Pads give better contact with the skin and decrease skin resistance to allow for a higher success rate of rhythm conversion. It is also safer for the operator who does not have direct contact with the patient when the shock is delivered. The ALS defibrillator has a screen for interpreting rhythms and so is also used for ongoing monitoring of patients' rhythms. It may be used for cardioversion of nonlethal rhythms or pacing bradyasystolic rhythms. Additional critical care patient monitoring can be incorporated into an ALS defibrillator, including noninvasive blood pressure, pulse oximetry, end-tidal partial pressure of carbon dioxide in intubated patients, and other physiologic parameters. ALS personnel can use these machines for closely monitoring very ill patients during emergent calls or interfacility transfers.

Modern defibrillators use biphasic waveforms for shock delivery (as opposed to the traditional monophasic waveform). Monophasic waveforms deliver energy in one direction, from the positive to the negative pole. Biphasic waveforms deliver energy in two phases, one toward the positive pole and one toward the negative pole. Biphasic defibrillators defibrillate and cardiovert at lower energy levels and thus decrease myocardial injury.[11]

Prehospital 12-lead electrocardiograms have become increasingly important in the management of ST-elevation myocardial infarctions (STEMI). Both BLS and ALS ambulance services can perform electrocardiograms in the prehospital setting.[12] Analysis of electrocardiograms provided immediately by the electrocardiograph has demonstrated limited sensitivity for detecting ST-elevation myocardial infarction.[13] However, sensitivity can be increased using serial prehospital electrocardiograms, training paramedics to interpret electrocardiograms, and providing computer-assisted interpretation or remote physician overread of the electrocardiogram.[14,15] Irrespective of the method of interpretation, patients with a prehospital 12-lead electrocardiogram showing ST-elevation myocardial infarction arriving at a hospital with a dedicated percutaneous coronary intervention team in place have reduced door-to-balloon time and reduced mortality when compared with similar patients arriving without a prehospital 12-lead electrocardiogram.[16-18]

AIRWAY AND VENTILATION ADJUNCTS

In a patient with acute respiratory failure or arrest, these devices maintain a patent airway that otherwise would have to be maintained by the paramedic. In addition, some airway adjuncts aid in preventing complications of airway management, such as gastric distention or aspiration (**Figure 2-2**). See chapter 28, Noninvasive Airway Management,

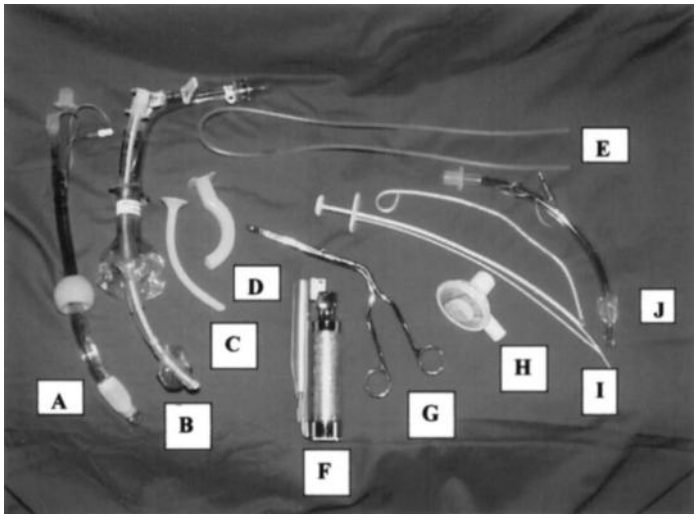

FIGURE 2-2. Airway devices and adjuncts. **A.** Combitube®. **B.** Pharyngeal tracheal lumen airway. **C.** Nasopharyngeal airway. **D.** Oropharyngeal airway. **E.** Tube exchanger. **F.** Laryngoscope. **G.** Magill forceps. **H.** Qualitative expiratory carbon dioxide detector. **I.** Stylets for endotracheal intubation. **J.** Endotracheal tube.

and 29, Intubation and Mechanical Ventilation, for detailed discussions of these topics.

Oral and Nasal Airways The simplest devices for airway management after manual airway maneuvers are the oropharyngeal and nasopharyngeal airways. These basic airway adjuncts usually are paired in the field with a simple bag-valve mask device for ventilation and will work quite well together. Ventilation with the bag-valve mask can be difficult for a single person to both attain a good seal with the mask and compress the bag to produce an adequate tidal volume for the patient. It is probably more effective (especially for first-responder and ambulance personnel who do not perform the skill often) to make this a two-person task (one person to maintain the seal and one person to compress the bag to maintain tidal volume). Along with these adjuncts, effective portable suction devices are available to be carried to the patient's side to help clear the airway.

Supraglottic Airways More advanced airway devices are used if the patient appears to need more prolonged airway management or is at greater risk for aspiration. At the BLS level, these airways include, most commonly, the **pharyngeal tracheal lumen airway (PtL®)**, the **esophagotracheal Combitube** or **King LTS-D airway**, and the **laryngeal mask airway (LMA®)**. Each of these is used in conjunction with a bag-valve mask for ventilation. These devices are great improvements over the esophageal obturator airway and esophageal gastric tube airway, which have unacceptably high complication rates and are no longer recommended for use. Both the PtL® and the Combitube® are for unconscious patients >14 years and >48 inches tall. They improve the airway seal to promote better ventilation than the bag-valve mask with the oral airway and seal the esophagus off with a balloon to prevent aspiration. If either device goes into the trachea, which occurs a small percentage of the time, the device can function equivalently to an endotracheal tube. The Combitube® may be a more reliable device than the PtL® because the large mouth balloon of the PtL® is more easily broken than the more robust Combitube® balloon, and basic emergency medical technicians (EMTs) may find ventilation easier with the Combitube®.[19-22] There are few data on the use of the LMA® for prehospital care. The LMA® provides a seal for ventilation but may not prevent aspiration. One possible advantage of the LMA® is that it may be less expensive than the Combitube® or the PtL®. The PtL® and Combitube® are mostly used by BLS ambulance personnel, but may be used by ALS personnel (or even by hospital personnel) as a fallback rescue device for a patient who has a difficult airway and cannot be intubated with an endotracheal tube (**Table 2-1**).[23-26]

A review of pediatric alternative airway devices in prehospital care discusses the problems encountered in the field with airway management of children.[27] Unlike the PtL® or Combitube®, there are pediatric-sized LMAs® available. It is not clear how useful the LMA® is as a prehospital rescue airway because it is not clear if the LMA® prevents aspiration. Table 2-1 compares the PtL®, Combitube®, LMA®, and King LTS-D® devices.

Endotracheal Intubation Endotracheal intubation is the "gold standard" for airway management in all patients and is especially useful in patients in whom the other airway adjuncts are not satisfactory.[28] The majority of ALS systems use endotracheal intubation as the airway of choice for patients in respiratory failure or with an unprotected airway. Numerous adjuncts to assist with endotracheal intubation can be found in the ED as well as the prehospital setting. However, provider procedural experience is a primary determinant for successful placement. For further discussion, see chapter 29, Intubation and Mechanical Ventilation.

The basic EMT curriculum has an optional module for endotracheal intubation training. Therefore, intubation equipment may be found on some BLS ambulances. Increasing the number of ambulance personnel in need of endotracheal intubation training in an EMS system may cause logistic problems for the medical director. It is sometimes difficult to obtain adequate live intubation opportunities for the personnel in an EMS system to maintain skills. Some studies have shown that basic EMTs do not maintain endotracheal intubation skills and have low rates of successful completion.[29,30] This might suggest that intubation should remain an ALS skill.[31,32]

TABLE 2-1 Comparison of PtL®, Combitube®, LMA®, and King LTS-D®

Device	Use	Comments
PtL®	Adults Adolescents >48 inches tall or age >14 years old	Prevents/minimizes aspiration If inadvertently placed in trachea, will still ventilate Cannot use if gag reflex present Balloon may not be as sturdy as Combitube® balloon
Combitube®	Adults Adolescents >48 inches tall or age >14 years old	Prevents/minimizes aspiration If inadvertently placed in trachea, will still ventilate Cannot use if gag reflex present Sturdy balloon
LMA®	Sizes for adults and children	May not prevent aspiration Can cause respiratory obstruction if incorrectly placed Cannot use if gag reflex present
King LTS-D®	Sizes for adults and children	Prevents/minimizes aspiration If inadvertently placed in trachea, will still ventilate Cannot use if gag reflex present Sturdy balloon Port for gastric decompression tube

Abbreviations: LMA® = laryngeal mask airway; PtL® = pharyngeal tracheal lumen airway.

Rapid-Sequence Intubation Another intubation-related modality that has bearing on the equipment carried on an ambulance is **rapid-sequence intubation**. Critical care transport services have been performing rapid-sequence intubation for more than a decade, and now this same level of care is provided in ALS systems as well. Rapid-sequence intubation raises the level of training, judgment, and psychomotor skills needed by the paramedic but has the advantage of being able to secure more difficult airways. In addition to the usual equipment required for intubation, rapid-sequence intubation requires ALS services to carry the medications needed for sedation and paralysis.[33] The technique increases the need for oversight and vigilance by the medical director. Los Angeles,[34] San Diego,[35] and Orlando[36] have all indicated difficulties with ALS intubation, with or without the assistance of neuromuscular junction blockade/sedation. Intubation, especially rapid-sequence intubation, is a training-intensive modality. Large systems with many paramedics may have difficulties with training type and intensity.[32] Smaller services, such as air medical services, which have a smaller group to train, a smaller span of medical control, and more intubation experience per provider, may be able to attain and maintain the complex skills needed for rapid-sequence intubation.

CONTINUOUS POSITIVE AIRWAY PRESSURE AND BILEVEL POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) maintains a continuous level of positive airway pressure throughout the respiratory cycle. Similarly, bilevel positive airway pressure (BiPAP) delivers CPAP in a preset or measured inspiratory positive airway pressure phase and expiratory positive airway pressure phase. BLS and ALS services become competent in the use of this adjunct with additional training and a broadened understanding of respiratory physiology.[37-39] Use of either modality in the ED and prehospital setting is lifesaving and cost-effective in the treatment of the severely dyspneic patient.[40-42]

VASCULAR ACCESS EQUIPMENT

The equipment used to establish IV access is the same as at the hospital: tourniquets, cleaning agent, IV catheters, IV fluid bags, and IV tubing. ALS ambulances need IV access for fluid resuscitation and for administration

of medications. In general, vascular access for medication administration is completed as soon as possible after the patient is assessed and it is determined that pharmacologic intervention is needed. For fluid resuscitation, usually in trauma patients, vascular access usually is started en route to the hospital after the patient is immobilized, unless there is prolonged scene time due to extrication. This is to avoid prolonged scene times that may be detrimental to a trauma patient who may need intervention in the operating room. In any event, the amount of fluid that can be administered during transport is modest and may not be physiologically significant. Some data show that aggressive fluid resuscitation of hypovolemic trauma patients is detrimental, in that it may increase morbidity and mortality by enhancing exsanguination from vascular or organ injury requiring operative intervention.[43,44] The difference between hospital and EMS usage of IV equipment is that the medical director must provide guidelines for when and how to institute vascular access to allow appropriate interventions at the appropriate time. Use of vascular access should be examined in the quality assurance process in an ongoing manner.

Intraosseous access devices are important adjuncts for difficult vascular access. Studies have not conclusively demonstrated the superiority of one device over another. One small study indicated that the EZ-IO® device (Vidacare Corporation, San Antonio, TX) may be superior to the FAST1® device (Pyng Medical Corporation, Richmond, British Columbia, Canada) because of higher insertion success.[45] Guidance is provided in a position paper from the National Association of EMS Physicians (http://www.naemsp.org).[46,47]

Vascular access is also used by some BLS services for fluid resuscitation. Because BLS services are usually more rural and have longer transport times, fluid resuscitation may be more beneficial in rural hypovolemic trauma patients with blunt rather than penetrating trauma.

PREHOSPITAL ULTRASOUND

US is an important diagnostic tool in the practice of emergency medicine. New diagnostic applications for bedside US in the ED are reported in emergency medicine literature almost monthly. Moving US into the prehospital setting would seem like a logical next step. Multiple investigations demonstrate the feasibility of prehospital US in the United States and Europe.[48-51] Some prospective observational data on prehospital US in European EMS systems is available.[52,53] Remember, however, that these systems are often staffed with physician-level providers. Prospective data from paramedic- and nurse-staffed EMS systems is gradually becoming available.[54,55]

SPINAL IMMOBILIZATION

Preservation of the integrity of the spinal column and spinal cord is of paramount importance in the prehospital setting. The first person to assess the patient should immobilize the cervical spine immediately and, if necessary, simultaneously perform a modified jaw thrust to open the airway. Manual stabilization of the neck is not released until the patient has been transferred and securely strapped to a board. Short or long boards, either alone or in combination, are used to immobilize the spine depending on the initial position in which the patient is found by the EMT or first responder.

Carrying boarded patients takes a physical toll on EMTs and paramedics. Evaluation of the boarded patient is more expensive and time consuming in the ED because of the need to clear the cervical spine. A reasonable approach is for the medical director to develop protocols and guidelines for clearance of the spine in the field. A patient with no neck pain, tenderness, or discomfort (neck pain must be defined liberally and include stiffness or "feels funny"); not in the extremes of age (<10 years or >65 years); no altered sensorium (no drugs or alcohol present, no head injury); and no distracting injuries (long-bone fracture, abdominal or chest injury) may be cleared in the field because there is an extraordinarily low probability of neck injury (**Table 2-2**).[56]

TABLE 2-2 Guidelines for Cervical Spine Clearance in the Field

Absence of neck pain, tenderness, or discomfort
Age between 11 and 65 years
No altered sensorium
No intoxication
No distracting injuries

SPINAL BOARDS AND CERVICAL COLLARS

Long or short spinal boards are made from plastic or wood and provide a rigid surface to minimize movement of the cervical, thoracic, or lumbar spine. Straps secure the patient to the board for transport. Some boards are provided with firm rubber blocks on either side of the head with straps to go across the blocks to keep the head steady. Blanket rolls secured to the board with tape are also effective head blocks. A popular and effective variation of the short board is the **Kendrick Extrication Device®** (**KED®**) (**Figure 2-3**), which consists of slats of rigid material bound together by heavy cloth.

This board immobilizes the cervical spine, wraps partly around the patient, and is then strapped the rest of the way around the thorax and around the thighs for secure immobilization. If necessary, the patient can be lifted by the straps, allowing for easier and safer upward extrication from the vehicle.

Rigid cervical collars are more accurately called cervical extrication devices. Multiple types are used in the field, such as the Philadelphia® collar, the Miami J® collar (**Figure 2-4**), the Stifneck® (Laerdal Medical, Wappingers Falls, NY), and the Nec Loc® (Junkin Safety Appliance Co., Louisville, KY).

The collars come in two asymmetric pieces, which are used and marked for back and front, or as a single piece that is folded into the correct shape. By themselves, collars are not adequate for cervical immobilization but require additional lateral support to avoid movement in that direction. For adequate immobilization, the patient needs to be strapped on the backboard and secured with head blocks and head straps. Once the patient is well secured to the board, the collar does not add a significant amount of stabilization and actually can be removed without compromise of the spine; however, it is often left in place for added protection. Patients with mandible or soft tissue neck injuries probably should not have a collar applied because of the potential for airway compromise, which could be masked by the collar. Newer collars have openings in the front to allow observation of the trachea and jugular veins, but this may not be adequate for observing other neck areas. Soft cervical collars are not adequate or appropriate for prehospital care.

SEQUENCE OF SPINAL IMMOBILIZATION

Prehospital personnel are taught to have a high index of suspicion for spine trauma. **If the patient is sitting in a car after an accident and is stable from respiratory and circulatory standpoints, a short spine board and rigid cervical collar or Kendrick Extrication Device® are first used to get the patient out of the vehicle safely and onto a long spine board.** If the situation at hand is a critical one because of the patient's condition or the threat of hazards, such as chemicals, fire, or water, the patient can be extricated more rapidly using only the cervical collar. After applying the cervical collar, the patient is carefully rotated out and slid onto the waiting long board.

At a noncritical scene, when the patient is still sitting in the vehicle, one EMT secures the neck with his or her hands and applies the necessary airway maneuvers, while the second EMT applies the rigid cervical collar. The short board is then slid in behind the patient, and the patient is strapped to the short spine board. (Short boards are not used if the patient is not seated in a vehicle.) The first EMT maintains manual stabilization of the neck until the patient is secured to the short board. The patient's head and trunk can then be rotated around as one unit and slid directly onto the long board positioned on the car seat or on the ambulance cot. The patient is then strapped to the long board and then to the cot. A properly boarded patient can be turned on the board or even stood on end if necessary to move the patient to the ambulance. If the patient vomits, for instance, the board can be partly log-rolled up to prevent aspiration.

Because of the difference in relative size and positions of head and body, adults and children need slightly different positioning on a backboard. **An adult needs more padding under the head, whereas a child needs more padding under the body to maintain neutral neck position.**

If a patient is walking at the scene when the paramedical personnel arrive but complains of neck pain, the patient can be boarded from a standing position. If the patient is lying on the ground when the EMTs arrive, the patient can be carefully log-rolled by several attendants onto a long backboard.

Immobilization on a rigid board produces midline cervical pain and tenderness, so examination and radiographs should be performed promptly on arrival.[57] Radiographs can be done without difficulty through short and long boards. In general, patients should not be removed from immobilization until the spine has been cleared clinically and radiographically. Transfer from the hard prehospital board to a padded board at the hospital is desirable if the patient may spend prolonged time immobilized.

FOOTBALL HELMET REMOVAL

The National Athletic Trainer's Association (http://www.nata.org) and the Inter-Association Task Force for the Appropriate Care of the Spine-Injured Athlete have developed guidelines for the prehospital care of athletes with potential spine injury. **These guidelines recommend that the face mask of a football helmet be removed at the earliest opportunity, before transportation and regardless of respiratory status.** However, because a properly fitted football helmet with shoulder pads holds the head in a position of neutral spinal alignment, field removal of these devices is not recommended. It is recommended that the helmet and shoulder pads remain on as the athlete is immobilized and transported on a rigid backboard. Simultaneous removal of the helmet and shoulder pads should be done after clinical assessment and radiographs at the hospital, although radiographs may have to be repeated after equipment removal.[58]

Removal of football shoulder pads and helmet requires several individuals to maintain spinal alignment (**Figure 2-5**). One individual stands at the head of the bed to stabilize the patient's head, neck, and helmet, while others stabilize the spine and body. All straps and laces that secure the pads to the torso and arms are cut, not unbuckled or unsnapped. The laces or straps over the sternum are cut, allowing the right and left anterior portions to be spread open, exposing the chest. The posterior portion of the shoulder pads is kept in place to maintain spinal alignment with the helmet. Another individual cuts the chin strap from below while standing beside the patient's chest. Accessible internal padding should be removed from inside the helmet and any air bladders deflated. The individual standing alongside the patient's chest then reaches up into the helmet to stabilize the head by placing a hand with fingers and thumbs spread alongside the jaw, mastoid region, and occiput.

Two additional individuals stand alongside the patient's chest and place their hands directly on the skin in the thoracic region. On command, the patient is lifted slightly, with all four individuals maintaining spinal alignment. The individual standing at the head of the bed can remove the helmet by a slight forward rotation to slide it off the occiput. Slight traction or anteroposterior motion may be necessary, but care should be taken not to move the head and neck unit. Attempting to assist removal by pulling on the ear holes tightens the helmet in the forehead and occipital regions and does not help. The posterior portion of the shoulder pads is removed, and the patient is lowered. A rigid cervical collar can then be placed.

TRACTION SPLINTS

Pelvic fractures and femoral shaft fractures are potentially life and limb threatening. Field or ED stabilization of pelvic fractures is difficult. Devices, such as the T-POD® (Pyng Medical Corporation), for pelvic fracture immobilization have become available, but their place in prehospital care is unclear.

Fractures of the femur can damage vessels and nerves when bony fragments move. Stabilization in the field is important to minimize blood loss and soft tissue damage. The femoral traction splint is the preferred device for femur fractures.

Several leg traction splint variations are available for use. The two most commonly used types are the Hare® splint (Dynamed, Westbury, Tasmania) and the Sager® splint (Minto Research and Development, Inc., Redding, CA). The underlying technique is the application of traction by a hitch on the ankle against resistance when the splint impinges

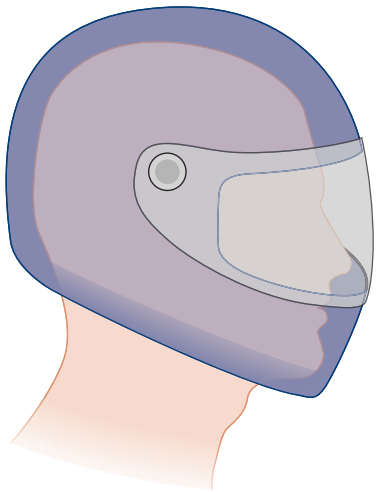

FIGURE 2-5. Helmet removal technique. [Reproduced with permission from American College of Surgeons, Committee on Trauma Brochure, April 1997.]

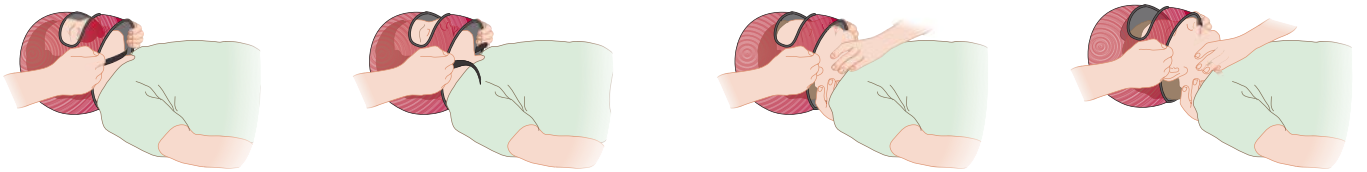
Helmet Removal

The varying sizes, shapes, and configurations of motorcycle and sports helmets necessitate some understanding of their proper removal from victims of motorcycle crashes. The rescuer who removes a helmet improperly may unintentionally aggravate cervical spine injuries.

The Committee on Trauma believes that physicians who treat the injured should be aware of helmet removal techniques. A gradual increase in the use of helmets is anticipated, because many organizations are urging voluntary wearing of helmets, and some states are reinstating their laws requiring the wearing of helmets.

Types of Helmets



Full face coverage—motorcycle, auto racer

Full face coverage—motorcross

Partial face coverage—motorcycle, auto racer

Light head protection—bicycle, kayak

Football

1. One rescuer maintains inline immoblization by placing the hands on each side of the helmet with the fingers on the victim's mandible. This position prevents slippage if the strap is loose.

2. A second rescuer cuts or loosens the strap at the D-rings.

3. The second rescuer places one hand on the mandible at the angle, the thumb on one side, the long and index fingers on the other. With the other hand, pressure is applied from the occipital region. This maneuver transfers the inline immobilization responsibility to the second rescuer.

4. The rescuer at the top moves the helmet. Three factors should be kept in mind:
- The helmet is egg shaped and therefore must be expanded laterally to clear the ears.
- If the helmet provides full facial coverage, glasses must be removed first.
- If the helmet provides full facial coverage, the nose may impede removal. To clear the nose, the helmet must be tilted backward and raised over it.

5. Throughout the removal process, the second rescuer maintains inline immobilization from below to prevent unnecessary neck motion.

6. After the helmet has been removed, the rescuer at the top replaces the hands on either side of the victim's head with the palms over the ears.

7. Inline immobilization is maintained from above until a backboard is in place and a cervical immobilization device (collar) is applied.

Summary

The helmet must be maneuvered over the nose and ears while the head and neck are held rigid.
- Inline immobilization is first applied from above.
- Inline immobilization is applied from below by a second rescuer with pressure on the jaw and occiput.
- The helmet is removed.
- Inline immobilization is reestablished from above.

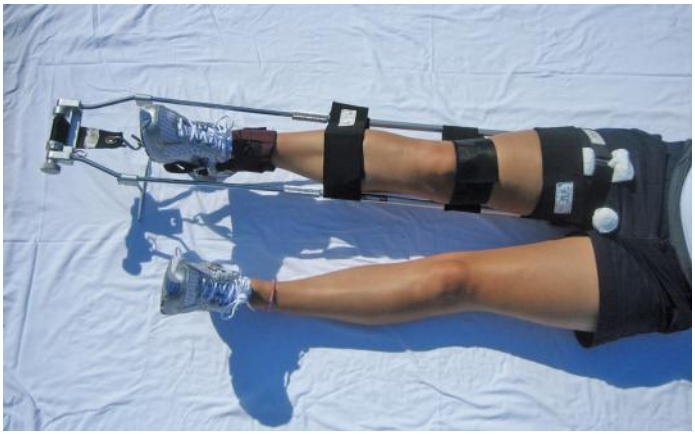


FIGURE 2-6. Hare® traction splint (Dynamed, Westbury, Tasmania). [Courtesy of Jan Smith, RN, MPH, NREMT-P; acknowledgments to Kara Smith and Lucky Bruton, EMT-P.]

proximally on the pelvis. The padded proximal end of the Hare® splint abuts the ischial tuberosity (**Figure 2-6**). The proximal end of the Sager® splint rests against the pubic symphysis (**Figure 2-7**). **These splints cannot be used if a pelvic fracture is suspected because the pressure on the pelvis may further displace a fracture and cause more bleeding. Also, do not apply a traction splint if there is open fracture, hip dislocation, suspicion for neurovascular injury to the extremity, or injury about the knee, as a traction splint may exacerbate neurovascular or knee injury.**

Leg traction splints also may be used for tibial shaft fractures. Traction splints should not be used for fractures near the knee because longitudinal traction may damage neurovascular structures in the popliteal region. Traction splints for the tibia should be reserved for angulated or displaced fractures; otherwise, an air splint or a pillow splint would suffice.

At the scene, clothing should be removed and the extremity assessed for injury and distal neurovascular function. If the Hare® splint is used, the proximal half ring is placed in the crease of the buttocks against the ischial tuberosity. Traction is placed on the ankle with the padded ankle strap by one rescuer while the splint is strapped to the leg. The ankle strap is then attached to a ratcheting mechanism, and traction is tightened. If a Sager® splint is used, the splint is placed on the medial side of the limb up against the groin. The padded ankle hitch is applied, and traction is applied until malalignment is reduced and pain is relieved. Elastic straps are then applied to hold the splint to the leg.

FIGURE 2-7. Sager Emergency Traction Splint; Model S304, Form III Bilateral, Application step 3 "Secure". [Used with permission from: Minto Research & Development, Inc., Redding, CA, USA.]

The Hare® splint can be longer than an ambulance cot when fully extended, and care needs to be taken when closing the rear door of the ambulance. The Sager® splint is shorter than the Hare® splint, and one Sager® splint can be used to splint both legs simultaneously. The Sager® splint is less bulky and therefore takes up less room in an ambulance or a helicopter.

PELVIC STABILIZERS

Unstable pelvic fractures can be immobilized to minimize the risk of bleeding from patient movement and during transport. A sheet wrap, applied around the patient at the level of the trochanter and fastened with a clamp or hemostat, is the simplest stabilization method.[56] Commercial devices, such as the SAM Pelvic Sling®, are also available.

PHARMACEUTICAL SUPPLIES

The basic EMT curriculum has modules that teach EMTs to administer a patient's personal medication in specific circumstances. For example, modules are provided for administering nitroglycerin for chest pain, inhaled β-agonists for bronchospasm, glucagon for hypoglycemia, and epinephrine-preloaded injections for anaphylaxis. Some states have gone beyond this and allow BLS services to stock and provide the medications covered in these modules.

The medications carried by ALS services are more extensive, but prehospital pharmaceutical interventions are limited to the few that make a real difference before or during transport. These include oxygen, glucose, nitroglycerin, inhaled β-agonists, naloxone, parenteral narcotic and nonsteroidal analgesics, benzodiazepines, furosemide, epinephrine, lidocaine, magnesium, amiodarone, adenosine, diltiazem, calcium, and sodium bicarbonate. In the system that provides rapid-sequence intubation, neuromuscular junction–blocking agents (succinylcholine, vecuronium) are also provided.

CHAPTER 3

Air Medical Transport

C. Keith Stone
Stephen H. Thomas

INTRODUCTION

Air medical transport consists of helicopter (or rotor-wing) and airplane (or fixed-wing) transport and is an important component of EMS systems for prehospital care and interfacility transport. These specialized vehicles offer fast speeds, ranging from 100 to 200 miles per hour for helicopters to >500 miles per hour for airplanes. However, planning for appropriate vehicle use involves many other logistic factors in addition to speed. Although many ill and injured patients can be transported safely by ground, air medical transport provides added medical assessment and care capabilities beyond those of the paramedic-staffed ground ambulance. Guidelines for the use of air medical transport exist, but field EMS personnel and physicians involved in transfer decision making should be able to consider situational circumstances to determine the appropriate transportation mode.

With the occasionally important exception of ground transport legs (e.g., from a landing zone to the patient or from an airport to the hospital), air transport modalities are not limited by traffic or road quality. Weather can be an operational limitation, particularly for helicopters. The radius of service differs between helicopters and fixed-wing craft, but, as a general rule, fixed-wing transport is considered when weather conditions are poor or when transport distances exceed 150 to 200 miles.

The complexity of air transport far exceeds the simple act of loading a patient on an airborne vehicle. National organizations such as the Air Medical Physician Association, the Committee on Accreditation of Medical Transport Systems, and the National Association of EMS Physicians have published texts, position statements, and guidelines covering aspects of air medical transport. The Air Medical Physician Association (http://www.ampa.org) *Air Medical Physician Handbook* is a particularly helpful resource for medical issues. The Committee on Accreditation of Medical Transport Systems (http://www.camts.org) accreditation standards address medical, aviation, organizational, and operational issues. The National Association of EMS Physicians (http://www.naemsp.org) has created detailed position statements and guidelines addressing helicopter EMS trauma and nontrauma triage criteria, as well as training of physicians involved as air medical crew or medical directors.

The effectiveness of air medical services is enabled by attention to a myriad of factors that come into play before, during, and after actual patient transport. The transport service should disseminate protocols guiding appropriate triage, and the program's communications personnel (as well as its physician consultants) should be versed and available for rapid decision making as to appropriate vehicle use. Ongoing training of referring agencies should occur to ensure safe and efficient operations during air transport service arrival (e.g., securing of landing zones) and transition of patient care to the flight crew (e.g., loading of patients onto the aircraft). **Rigorous training programs, covering both cognitive and procedural skills, enable flight crews to provide a high level of intratransport care.** In-flight communications capabilities should include the ability of the air medical crew to speak with medical control physicians, as well as arrange for any change of plan (e.g., direct transport to the operating suite) necessitated by patient condition.

HELICOPTER TRANSPORT

AVIATION ISSUES

Individual hospitals, hospital systems, or private for-profit enterprises run most U.S. civilian air transport programs. Because helicopters are expensive (ranging from $750,000 to more than $5 million each) and other aviation needs (e.g., maintenance, pilot training) are also resource intensive, most hospital-based programs lease their helicopters from vendors. The air medical program typically provides and equips communications and medical personnel, whereas the aircraft vendor supplies the helicopters, pilots, and maintenance personnel. Although costs vary depending on geographic region, patient case mix, equipment and aircraft used, and even the methods used for their calculation, annual operating costs for a rotor-wing service typically exceed $2 million.

Safety is an overriding consideration for air transport. Optimization of safety begins well before an actual air transport, with training of the flight crew and of those who interact with them at scenes and hospitals. Training is especially important for scene responses, in which the helicopter may be landing in an unknown area with more nearby obstacles (e.g., wires, trees) than the hospital helipad. Scene setup (depending on the aircraft, an area of up to 100 × 100 ft is required) and demarcation, as well as safety of nearby personnel, must be taught to ground EMS services and others who call for helicopter EMS transport. In addition to providing training for referring agencies, helicopter EMS pilots and medical crew should undergo both initial and recurrent safety training. For added protection, most helicopter EMS programs have followed the lessons of the military experience and adopted injury-prevention maneuvers such as the use of helmets and fire-resistant clothing. As another safety issue, the pilot should be "blinded" to the nature of the call during mission planning; this eliminates the introduction of acuity-related subjectivity as the pilot considers whether the mission should be accepted.

Safety is partially behind the transition of helicopter EMS programs from single-engine helicopters with visual flight rules capability to twin-engine helicopters that can fly under instrument flight rules conditions. The latter aircraft have greater lifting capacity, range, and speed and usually can execute controlled landings in the event of failure of one engine. A visual flight rules aircraft can fly only during good visibility, whereas instrument flight rules aircraft operate safely in poorer conditions; both comply with visibility limitations imposed by the Federal Aviation Administration, but the instrument flight rules helicopter has fewer restrictions. If the pilot unexpectedly encounters bad weather during a flight, an instrument flight rules helicopter (as compared with a visual flight rules aircraft) has a better chance of completing the mission successfully and safely. Due to the complexity of instrument flight rules operations, some programs (especially those with frequent bad weather periods) have elected to use two-pilot instrument flight rules.

Air medical programs operate under rules established by the national aviation authority—in the United States, the Federal Aviation Administration. Additionally, the industry itself has set forth stringent standards under the auspices of the Committee on Accreditation of Medical Transport Systems. On request, the Committee on Accreditation of Medical Transport Systems performs site visits of air medical programs to certify that they comply with strict safety and operational (as well as clinical) standards. As of January 2012, 148 U.S. transport programs were accredited by the Committee on Accreditation of Medical Transport Systems.

AIR MEDICAL CREW

The primary considerations regarding medical members of the flight crew are crew configuration and training. Although there are few absolutes with regard to optimal configuration, initial and recurrent training are at least as important as the credentials of the flight team members.

The air medical team can have multiple compositions: nurse–paramedic, nurse–nurse, nurse–physician, or nurse–respiratory therapist. These differences may be one reason that the literature has failed to answer definitively the seemingly simple question of whether a physician should be on board the helicopter. Studies done outside the United States, where physician staffing is more prevalent, have failed to show outcome improvement associated with physician staffing of helicopter EMS programs.[1,2] Most U.S. programs agree that physicians are not a necessary component of helicopter EMS crews, and individual program staffing configurations generally have remained stable during the ongoing debate on optimal team makeup.

For a number of reasons, it is unlikely that further efforts to define the optimal crew configuration will result in a consensus. The capabilities of most U.S. nonphysician crews represent an *extended scope of practice*. For instance, flight paramedics and/or nurses frequently are credentialed to perform such procedures as neuromuscular blockade–assisted endotracheal intubation and cricothyrotomy. This example of extended practice scope is important, given the importance of prehospital airway considerations and the fact that flight crews represent a highly trained group with particular expertise in this area. Reported success rates for nonphysicians are as high as 94.6% for drug-assisted and 97.7% for rapid sequence intubation–assisted endotracheal intubation and 90.9% for surgical cricothyrotomy.[3] The ability of nonphysicians to perform advanced procedures—and to perform them well—blurs the procedural skills demarcation between physician and nonphysician crew. Physician cognitive contributions are inherently difficult to quantify or associate with patient survival.[1,2]

At this time, the best recommendation with regard to crew configuration is for programs to continue to do what works for them, as the literature does not report the superiority of a particular model. Most U.S. programs perform a variety of scene and interfacility missions for trauma and nontrauma indications, so the nurse–paramedic configuration, combining the complementary skills of prehospital and hospital-based practitioners, is most popular in the United States. Some transport population heterogeneity can be addressed by the accommodation of extra crew members (e.g., neonatal nurses, intra-aortic balloon pump technicians) when logistics allow. Regardless of the background of the air medical crew, initial and recurrent training in both cognitive and procedural skills is necessary to ensure an optimal level of care.

ENVIRONMENTAL FACTORS OF AIR TRANSPORT

Patient care in any transport vehicle differs from that provided while the patient is on a hospital stretcher. Vehicle vibrations, bumpy rides, noise, physiologic stress, ergonomic constraints (**Figure 3-1**), and motion sickness are among the factors that can affect monitoring and interventions.

The impact of most vehicle-related issues in helicopter EMS can be eliminated, or at least reduced. Some solutions are easy (e.g., visual rather

FIGURE 3-1. The patient care compartment in a Dauphin II helicopter.

than aural alarms on ventilators), but flight crews must learn to "work around" other limitations (e.g., perform preflight intubation on patients who appear likely to deteriorate). Some problems will be specific to a service's particular aircraft, mission profile, or crew background. Individual program patient care protocols should take into account the service's equipment and personnel-related capabilities and limitations.

One transport-related issue that cannot be avoided is the question of **altitude and its potential effects on the patient and the crew**. In fact, altitude considerations vary with location—a Denver-based program has concerns that are different from those of a Miami service. Environmental conditions also have an impact on altitude considerations, because aircraft operating under instrument flight rules frequently fly at higher altitudes than those operating under visual flight rules. Of course, fixed-wing transports have more pronounced altitude considerations.

Helicopter (or fixed-wing) altitude and environment have potential effects on patient pathology as well as the crew's ability to monitor and care for the patient. Helicopters generally transport patients at about 1000 to 3500 ft above ground level (not necessarily sea level), although sometimes these altitudes are increased for instrument flight rules flights or for clearing of obstacles or terrain. Therefore, altitude-related problems such as hypoxemia, dehydration, and low temperature tend to be mild or relatively easily to overcome. However, geographic differences are important. Some western U.S. programs fly with supplemental oxygen for the medical crews.

Pressure-related problems related to Boyle's law (the volume of a gas increases when the pressure decreases at a constant temperature) may represent the most important consideration for helicopter-transported patients. For example, even the relatively low transport altitude range for helicopter EMS may affect patients with certain diagnoses (e.g., decompression sickness, cerebral arterial gas embolism) or instrumentation (e.g., tamponading devices for esophageal variceal hemorrhage). Endotracheal intracuff pressures increase an average of 33.9 cm of water at a mean altitude of 2260 ft.[4] This could raise the cuff pressure above the perfusion pressure of the tracheal mucosa, leading to injury. Hand-held commercially available devices can be used to keep cuff pressure within the target range of 20 to 30 cm of water. The devices are held in one hand and connected to the cuff inflation port. An inflation bulb can be used to further inflate the cuff or an air-release button can be used to remove air while the cuff pressure is simultaneously measured by the device.

In some cases, an understanding of altitude issues is important in preventing complications. To minimize aspiration risk, gastric intubation should be performed for unconscious patients transported by air. Alternatively, understanding of the relevant science can be used to prevent overreaction to potential barometric risks. For example, not all patients with small pneumothoraces who do not otherwise require tube thoracostomy require pretransport chest decompression simply because they are to be transported by air.

CLINICAL USE OF HELICOPTERS

While trauma still constitutes the majority of helicopter transports for most programs, as more time-critical treatments develop, **more transports will be arranged for noninjured patients**. There are many schemes (age group, scene/interfacility mission type) for categorization of helicopter EMS transports, but the simplest categorization is into trauma and nontrauma. Logistical issues are important to both categories. Therefore, these are considered first.

LOGISTICS AND HELICOPTER EMS USE

Some logistic prompts for helicopter consideration include **(1) lengthy transport time for ground ambulances to reach the tertiary center, (2) ground vehicle transport time to the local hospital exceeds the time required for helicopter transport to the tertiary center, and (3) for entrapped trauma patients, extrication time is expected to exceed 20 minutes**. In some cases, helicopter EMS is used because local ground EMS personnel lack the expertise to provide the indicated level of intratransport care. Another important consideration is whether a region's ground EMS system can provide transport to the receiving tertiary center while maintaining the ability to cover its base area with appropriate advanced life support care. Questions that can assist healthcare providers in determining the appropriate transport modality for an individual patient are listed in **Table 3-1**.

The ideal helicopter trauma response guideline is appropriate patient selection without overtriage. Various anatomic, physiologic, and mechanism criteria have been tested, without agreement on any detailed protocol. Retrospective utilization review and ongoing education are critical to system evaluation.

HELICOPTER EMS FOR TRAUMA PATIENTS

There is one group of trauma patients—those in **traumatic cardiac arrest**—for whom air medical scene response has shown a very low rate of resuscitation and essentially zero survival.[5] Most helicopter EMS programs have their crews accompany traumatic arrest patients by ground to the nearest facility.

After the initial triage response decision, **the larger issue is whether helicopter EMS actually improves outcome for *any* injured patients**. There is disagreement over this question, but multiple studies have shown improved outcomes.[6-9]

The largest study to demonstrate improved outcomes after traumatic injury related to helicopter transport analyzed 258,827 patients from the National Trauma Data Bank transported by helicopter (16%) or ground EMS (84%). Helicopter transport patients had a 22% decrease in mortality compared to ground transport, regardless of patient age or mechanism of injury.[6] In addition, the study showed that the injury severity scores of patients decreased as the distance of the injury site from the trauma center increased, which demonstrated that the selection criteria used nationwide to use helicopter transport seemed appropriate. Another study of 10,268 trauma patients demonstrated that the 2-week mortality in patients transported by helicopter decreased by 33% compared to ground transport. The subanalysis showed that the reduction

TABLE 3-1 Questions to Aid in Determining Need for Helicopter Transport

Is minimization of time spent out of hospital important?
Is time-sensitive evaluation and treatment involved, and is it available at the referring facility?
Is the patient inaccessible to ground transport?
What are the transport route weather conditions?
Does the weight of the patient preclude air medical transport?
Are aircraft landing facilities available at or near the referring hospital?
Is critical-care life support required that is not available with ground transport?
Would ground transport leave the local area without adequate EMS coverage?
If local ground transport is not an option, are regional ground critical-care transport services available?

was most evident in patients with a Revised Trauma Score (based on the vital signs at the scene) of 3 to 7.[7]

The outcomes of rural trauma patients are thought to be worse than those of urban trauma victims. After controlling for age, gender, and Injury Severity Score, a Utah study[10] of helicopter scene transports from rural and urban trauma scenes found no difference in mortality. This study demonstrated that the helicopter scene transport of rural trauma victims appears to be a mortality equalizer.

A shortcoming of the literature is that studies generally address only the hard endpoint of mortality, with little emphasis on either mechanisms for survival improvement or nonmortality endpoints. Regardless of these shortcomings, the primary issue for trauma helicopter EMS is not whether some patients benefit, but rather how well those patients most likely to benefit from helicopter use can be identified by improved triage criteria. Although definitive criteria are lacking, the National Association of EMS Physicians has published guidelines for clinical situations that are appropriate for air transport (**Table 3-2**).

TABLE 3-2 Air Transport Indications for Scene Trauma

General and mechanism of injury
Trauma score <12
Unstable vital signs
Significant trauma in ages <12 or >55 years and pregnant patients
Multisystem injuries
Ejection from vehicle
Pedestrian or cyclist struck
Death in same passenger compartment
Penetrating trauma of the head, neck, chest, abdomen, or pelvis
Crush injury of the head, chest, or abdomen
Fall from height
Near drowning
Neurologic injuries
Glasgow Coma Scale score <10
Mental status deterioration
Obvious skull fracture
Spinal cord injury
Thoracic injury
Major chest wall injury (e.g., flail chest)
Pneumothorax
Hemothorax
Suspected cardiac injury
Abdominal/pelvic injuries
Significant abdominal pain postinjury
Seatbelt sign or abdominal contusion
Rib fractures below the nipple line
Unstable pelvis
Open pelvic fracture
Pelvic fracture with hypotension
Orthopedic injuries
Amputation of limb (partial or complete)
Finger or thumb amputation when replantation is available
Fracture/dislocation with associated vascular compromise
Limb ischemia
Open long-bone fractures
Two or more long-bone fractures
Thermal injury
Burns of >20% body surface area
Burns of face, head, hands, feet, or genitalia
Inhalation injury
Chemical or electrical burns
Burns associated with other traumatic injuries

HELICOPTER EMS FOR NONTRAUMA PATIENTS

The reason that helicopter EMS trauma literature is (relatively) abundant is that there are ready means for controlling for the differing acuities of air- and ground-transported patients. Unfortunately, there is no such easy methodology for patients with nontrauma diagnoses, and acuity scales for nontrauma patients generally have not been accepted for use in assessing the association between transport mode and outcome.

Some general guidelines are available (**Table 3-3**), and the logistic considerations noted previously in the section "Logistics and Helicopter EMS Use" apply to nontrauma flights. **In most helicopter EMS programs, the largest single nontrauma diagnostic category is cardiac.** Patients in cardiac arrest should be transported to the nearest hospital rather than loaded on an aircraft. Transport for primary or rescue coronary intervention for ST-elevation myocardial infarction is a frequent indication for helicopter use and can be done rapidly and safely.[11,12] Cardiac patients with pacemakers or those who have received thrombolytic therapy can be transported safely and effectively by helicopter EMS.

Another growing indication is the provision of lytic therapy or vascular intervention for ischemic stroke.[13] The American Stroke Association (http://www.strokeassociation.org) Task Force on Development of Stroke

TABLE 3-3 Air Transport Indications for Nontrauma Conditions

Cardiac
Acute coronary syndromes
Cardiogenic shock
Cardiac tamponade
Mechanical cardiac disease (cardiac rupture)
Critically ill medical or surgical patients
Pretransport cardiac arrest
Pretransport respiratory arrest
Mechanical ventricular assist
Continuous vasoactive medications
Risk of airway deterioration
Severe poisoning
Need for hyperbaric oxygen treatment
Emergent dialysis
Unstable GI bleeding
Surgical emergencies (e.g., aortic dissection)
Obstetric
Delivery will require obstetric or neonatal care beyond the capabilities of the referring facility
Active premature labor <34 wk or estimated fetal weight <2000 grams
Acute abdominal emergencies <34 wk or estimated fetal weight <2000 grams
Preeclampsia or eclampsia
Third-trimester hemorrhage
Fetal hydrops
Complicated maternal medical conditions
Predicted severe fetal heart disease
Neurologic
CNS hemorrhage
Spinal cord compression
Status epilepticus
Neonatal
Gestational age <30 wk or fetal weight <2000 grams
Supplemental oxygen exceeding 60%, continuous positive airway pressure, or mechanical ventilation
Extrapulmonary air leak, interstitial emphysema, or pneumothorax
Medical emergencies (e.g., congestive heart failure, disseminated intravascular coagulation)
Surgical emergencies (e.g., diaphragmatic hernia, necrotizing enterocolitis)

Systems[14] identified helicopter EMS as an important part of stroke systems. However, a study of 122 patients transported to a stroke center after receiving recombinant tissue plasminogen activator at the referring hospital demonstrated no benefit in patient outcomes in air-transported patients.[15]

Obstetric transports are a special consideration for air transport because many high-risk patients are best delivered at tertiary care centers. The question for this population is primarily one of safety during transport. In-flight deliveries are a major resuscitation problem for both mother and infant. Experience has provided some reassurance that the use of helicopter EMS to transport high-risk obstetric patients did not result in deliveries in the back of the helicopter, and **neonatal outcomes are not adversely impacted by transport**. Helicopter EMS transport of obstetric patients in an urban area is one solution to the problem of traffic congestion.

FIXED-WING AIR MEDICAL TRANSPORT

Fixed-wing aircraft can serve a wide variety of missions, from urgent to routine, over great distances. Because airplanes land only at airports, they cannot respond to the scene, and fixed-wing transports need ground ambulance connections at both ends of the flight to transport the patient between the hospital and airport. Because of these factors, fixed-wing flights generally take longer to arrange and are uncommonly used for truly emergent patients.

Helicopters are virtually always dedicated as air medical transport vehicles when used by U.S. EMS services, but fixed-wing airplanes used for medical transport may have other roles. When fixed-wing aircraft are used for air medical transport, cabins must be reconfigured. Vendors have developed removable medical equipment modules that can be placed relatively quickly in the aircraft cabin.

On a per-mile basis, fixed-wing transports are less expensive than helicopter EMS transports. However, the optimal transport radius for fixed-wing triage varies with regional and patient-specific considerations. The appropriate aircraft to use for any one mission depends on many factors: distance, the nature of the airport at the patient's pickup point, the condition of the patient, the amount of equipment, and the crew required in transport. A larger plane that can be pressurized can fly above 3000 m (10,000 ft), which means that the aircraft can travel faster, farther, and more comfortably. At these higher altitudes, flight crews must have a deeper understanding of altitude physiology issues. Cabin pressure (i.e., indicated altitude above sea level) should be recorded on medical records because of the importance of pressure issues to physiology, and crew safety training should include measures to take in case of inadvertent cabin depressurization.

All fixed-wing services must comply with civil aviation authority rules for airplanes. The Commission on Accreditation of Medical Transport Systems has developed standards for air medical fixed-wing transport. These standards, which are also a useful primer for more detailed information about fixed-wing air medical transport, deal with aircraft configuration, medical equipment requirements, medical crew configuration and training, and medical director qualifications.

MEDICAL DIRECTION OF AIR MEDICAL SERVICES

Medical direction may be even more important with rotor- and fixed-wing services than with ground services; it is certainly more complicated because it involves most aspects of ground EMS in addition to vehicle-specific and altitude- and acuity-related issues. The medical director should be familiar with the physiology and stress of flight on patients and should oversee the teaching of these and other applicable principles to the air medical crew. Overall, **a flight crew requires more initial and ongoing training than do most ground EMS personnel due to the higher patient acuity and extended practice scope**. Because flight crews are often far from their base of operations and may be out of voice contact, they must be sufficiently trained so that they can act independently when necessary. For nonphysician crew, standing orders or protocols (especially for advanced procedures such as cricothyrotomy) are needed. Periodic review and updating of these protocols, as well as close inspection of every transport record, are among the many responsibilities of the medical director. The Air Medical Physician Association and the National Association of EMS Physicians have published information on the responsibilities and function of the air medical program physician director.

CHAPTER 4

Mass Gatherings

Michael G. Millin

INTRODUCTION

Mass gathering medical care refers to the provision of medical services to organized events or venues with relatively large numbers of people in a defined geographic area. Typically, mass gatherings are considered to be events that have at least 1000 people; however, this does not have to be the case.[1,2] Although the principles of mass gathering medical care traditionally apply to congregations of large numbers of people, these principles also apply to smaller venues with a relatively high concentration of people in a limited space and those where it may not be easy to access the general system of EMS. Therefore, the principles of mass gathering medical care also apply to athletic events with fewer than 1000 people, as well as airplanes, cruise ships, and wilderness environments.

Table 4-1 lists some of the major factors affecting planning for a mass gathering event. Physical barriers may inhibit easy entry and exit from the site. These barriers can make it difficult to get medical resources into, and to get patients out of, the event location. **Reliable communication between medical personnel, event organizers, and outside medical resources is key to a successful medical response.** Environmental factors will also affect the response, especially at extremes of cold, wet weather that can precipitate hypothermia or hot weather that can precipitate dehydration and heat stroke. Finally, event planners should consider possible public health threats of widespread communicable disease and the potential for a terrorist attack with explosive or other devices.

EPIDEMIOLOGY

The need for mass gathering medical care was first described after two spectators collapsed and died during a University of Nebraska football game in 1965.[3] The event organizers were not prepared to manage medical emergencies in the midst of the event, and consequently, when these two patients needed medical care, the organizers were not able to meet the need. Medical directors have become experienced in mass gathering medicine, and case reports are described for sporting events, concerts, expositions, and other large congregations of people.[2]

One of the largest global gatherings, the Islamic Hajj pilgrimage to Mecca, Saudi Arabia (reaching 2.5 million in 2009), has required officials to manage threats to public safety from outbreaks of infectious disease to major traumatic injuries from stampedes. Other notable global mass gatherings include the 2010 World Expo in Shanghai, China,

TABLE 4-1 Factors Affecting Planning for a Mass Gathering Event

Venue entry and exit
Communication
Environment
Potential public health threats

which attracted approximately 70 million visitors, and the FIFA 2010 World Cup in South Africa, during which more than 1 million foreign visitors entered the country.[4] As large-scale global mass gatherings become more common, it is evident that there is a need for a global effort to develop the science of mass gathering medicine. This is exemplified by the mass gathering conference held in collaboration with the Kingdom of Saudi Arabia Ministry of Health in Jeddah, Saudi Arabia, in 2010[4] and the formation of an online registry for mass gathering data collection as developed by the University of British Columbia.[5]

Interestingly, despite the fact that mass gatherings are generally attended by individuals in good health, these events tend to have a higher incidence of illness and injury than that which would be found in the general population.[6] The incidence of usage of medical care at mass gatherings has been reported to range from 4 to 440 patients per 10,000.[2] The wide variance in medical usage rate is a function of the type of event and environmental factors.

COMPONENTS OF A MEDICAL ACTION PLAN

In preparing for a mass gathering event, medical directors should develop an organized approach through the development of a medical action plan.[7]

PHYSICIAN MEDICAL OVERSIGHT

All mass gathering events should have an identified physician medical director who is responsible for developing the medical action plan. The medical director is also responsible for providing medical oversight before and during the event. This person should be board certified in emergency medicine and have a current medical license from the state(s) where the event will be located. The medical director should also have experience in the medical direction of EMS and the provision of medical care at mass gathering events. In the future, it will be desirable for the event medical director to be board certified in EMS. Experience and training in EMS provide an event medical director with skills in field medicine, including creative thinking, the ability to make diagnostic and treatment decisions purely on clinical grounds, and an awareness of operational environments that are very different from a typical ED.

The medical director is responsible for developing plans for indirect medical oversight and ensuring a coordinated system of direct medical oversight. Indirect oversight describes a system of written protocols that provide the medical personnel with a standardized set of directions for the care of a variety of traumatic and medical conditions that may be encountered during the event. **These protocols should always be consistent with local EMS protocols unless the medical director has prior approval from the local jurisdictional EMS medical director to deviate from them.** Direct medical oversight describes a method of direct communication with medical providers during the event to answer questions and provide medical direction in real time during the event. Although direct oversight can be delegated to a team of physicians for an event of long duration, ideally, the medical director should plan to be on site during the event as much as possible.

COMMAND AND CONTROL

In addition to an event medical director, mass gathering plans should have an organized system of command and control. Although many systems exist for the command and control of resources at emergency incidents or mass gatherings, one of the most well-tested and efficient methods is the Incident Command System. It was initially developed as a consequence of poor management of a series of wild-land fires in Southern California in 1970.[8] The system can be used for any type or size of emergency, disaster, or mass gathering, with the purpose of allowing either a single agency or multiple agencies to communicate using common terminology and operating procedures. Further, the ease in putting the system into action allows it to be functional from the time an incident occurs until the requirement for operations no longer exists. In fact, since its original development, the Incident Command System has been adopted by the National Fire Academy and currently provides the structure for the Federal National Incident Management System.[8]

The purpose of establishing a command and control system like the Incident Command System is to define clear lines of reporting and

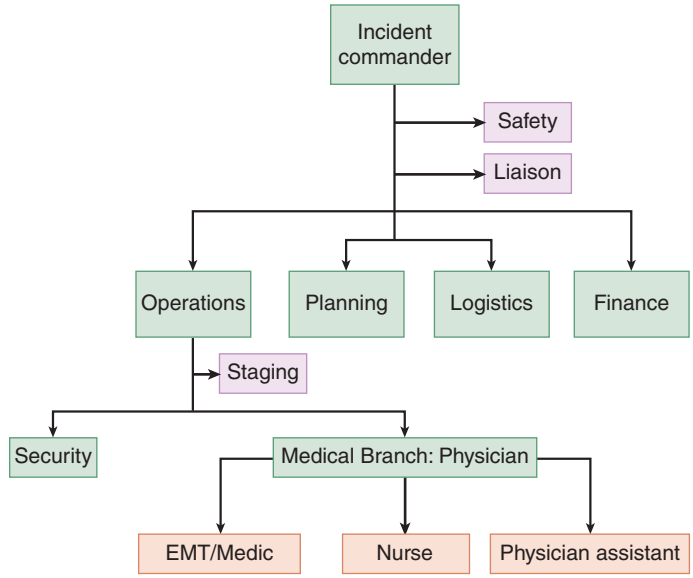

FIGURE 4-1. Incident Command System organizational chart.

communication among all major functioning components that may coexist during an incident. The organizational structure develops in a modular fashion from the top down and may incorporate five functional divisions.[8] While the Command function is always established, the other divisions, which include Operations, Logistics, Planning, and Finance, form as needed (**Figure 4-1**). The incident commander for a mass gathering event ideally should be someone with experience functioning within an Incident Command System structure. A lead fire official would be well suited as the incident commander, because officers in the fire service typically have extensive experience working within the Incident Command System. However, if the local fire department is not involved with the event, as may be the case in smaller events, command should be managed by someone with EMS experience and ideally should not be a physician. As will be discussed later, the physician's role within the Incident Command System structure should be focused on direct oversight of patient care and not involve the global issues that are the concern of the incident commander. In short, the incident commander must be involved in directing available resources, communicating effectively within the organization, continuously assessing the incident priorities, coordinating activities of outside agencies, and always retaining ultimate responsibility for the incident.

Within a typical Incident Command System, the provision of medical care to the public occurs within the Operations Section. Often referred to as the "doers," it is the function of the Operations Section to complete the primary tasks of the mission. The medical branch in Operations should establish a similar modular command framework for organizing the various medical teams, each having at a minimum their own team lead. Members of the medical teams include, but are not limited to, EMTs, paramedics, nurses, physician assistants, and physicians. It is not required that the physician take the lead role of each medical team. In fact, it may be more beneficial to have the individual with EMS or fire service experience in the role of team lead, which ideally may be an EMS physician. Depending on the number of agencies involved, there may be more than one EMS medical director on scene. An agency's medical director should be available for direct medical oversight as needed and should ideally be on site as much as possible. The medical director(s) should function as a commander within the Operations Section and report back to the section head of Operations who ultimately reports to the incident commander. Key to the success of the Incident Command System is that every individual abides by the established hierarchical ranks of command.

Perhaps the most important functional component for ensuring a successful mass gathering event within the Incident Command System structure is the Logistics Section. Logistics personnel are responsible for ensuring that all equipment and supplies are available and in working order when needed. Whereas the Operations personnel are the "doers," the Logistics

personnel are the "getters." They "get" the supplies needed by Operations. Because the ability to effectively care for the public at a mass gathering event is highly dependent on having a certain amount of supplies, it cannot be stressed enough that a well-functioning Logistics unit is critical to the success of the event. The event medical director should not have to be responsible for acquiring necessary supplies if Logistics is functioning well.

The Incident Command System also provides a framework for accountability of personnel, which is paramount to maintaining safety during a potentially long and unpredictable event. Within each branch under Operations, there should be a designated safety officer. The sole responsibility of this individual is not to provide care, but instead to maintain a system by which all personnel are accounted for at all times. This may include simply keeping a visual account of personnel, which would only be feasible at a very small event, or implementing a method that uses an identification tag that is kept by the safety officer during the time each individual is operational on scene. Each functional unit safety officer should ultimately report to the command staff safety officer for the event, who reports to the incident commander.

Closely related to the concept of accountability is the notion of force protection. This is a term used by the U.S. military to describe preventive measures taken to mitigate hostile actions against individuals. The number one priority in all events is scene safety. It is well known that if a medical provider becomes sick or injured, the provider will use resources intended for the public and distract other providers from the ability to perform their duties. As such, a sick or injured medical provider has the potential to dramatically disrupt the overall medical mission for the event. While medical personnel are always responsible for assessing and assuring their own safety and those with whom they work, it is imperative to have a well-designed plan for the overall medical care and protection of the medical providers at the event. One of the duties of the event medical director is to be prepared to provide care to the other medical providers should the need arise. In addition, communication with law enforcement personnel will help to ensure the overall protection of the medical providers. Their support should be readily available and have the means to immediately respond to any location should the situation become unsafe. Depending on the type of event, threats could range from those that are readily seen (i.e., crowds at a concert) to those that are hidden (i.e., explosives and other weapons carried by an individual with the goal of using mass gathering events to kill and injure).

RECONNAISSANCE

In the beginning stages of preparation, the medical director and assistants need to assess the site to identify the geographic variants that will affect their ability to provide medical care to the public. Within the Incident Command System structure, this establishes a role for the event medical director in the Planning Section. Most important, the planners will need to determine routes of ingress and egress for the event. Backup plans should also be developed. Planners should determine ideal locations for setting up a base of operations, fixed medical care sites, and staging areas for mobile units. Decisions should take into account the effects of predicted traffic flow, predicted sites of high-volume medical need, natural geographic barriers, and location of receiving medical facilities.

NEGOTIATIONS

The process of developing a medical plan for a mass gathering event requires a cohesive teamwork approach with multiple interest groups. First and foremost, the medical planners should develop a plan that meets the needs of the public and the event planners. This first step may require some negotiations with event planners in determining locations for fixed and mobile medical units, level of care to be provided, and resources provided to the medical units. Negotiations will determine if the medical units will be paid under contractual terms by the event planners or if they will volunteer their services to the event. This negotiation stage should also resolve who will finance the purchase of needed supplies and pay for other needed resources, such as costs of transportation and liability coverage.

Regardless of who pays for supplies, it is important that the medical teams coordinate with the Logistics Section to ensure that equipment and supplies are readily available when needed. Similarly, regardless of who is responsible for acquiring supplies, there is value to the event medical director having ultimate control over the acquisition and maintenance of critical medical supplies, as this will ensure that the medical needs of the public are assured.

Medical planners should also establish communication and agreements with other outside agencies that have a potential need to interact with the medical response team for the event. Medical teams that are formed outside the local jurisdictional EMS system should have an agreement with local EMS that addresses transportation of patients out of the event to local resource hospitals. Transfer and acceptance agreements should be developed with the hospitals. Local law enforcement should be contacted for assistance with traffic flow and security. Events that have the potential to be affected by security issues on a national scale may also require agreements with the U.S. Department of Homeland Security for disaster and security response.

HUMAN RESOURCES, LEVEL OF CARE, AND TRAINING

The event medical director should determine the desired level of care for the event based on the predicted medical need and available resources. Depending on the needs of the event, the desired level of care may range from emergency medical responders to physicians. Once the desired level of care and the predicted patient volume are determined, the medical director will be able to develop a plan for human resource needs. These resources may be acquired through the local EMS system, area hospitals, medical training programs, or other sources such as ski patrols and medical reserve corps.

Medical personnel should be licensed to practice at their level of training in the local jurisdiction. Although the medical personnel should be trained for their established level of care, the medical director may want to have additional training sessions to address specific injuries and medical conditions that are predicted to be encountered by the medical personnel during the event. Regardless, it is important that the providers work within a defined scope of practice as determined by level of training and any operational-specific protocols that may be authorized by local authorities for mass gathering events.

EQUIPMENT

When considering equipment for a mass gathering event, planners and medical directors should take into account the type of event, the weather, and the skill level of the medical staff. Medical units comprised of personnel at the EMT level or lower will need to carry significantly less equipment than units staffed by personnel at the paramedic level or higher. Units with physicians may elect to have on hand supplies to do simple suturing and advanced resuscitation. However, thought should be given to the available time needed to suture a wound in balance to the patient volume and the availability of the fixed standing acute care centers. If available, it may be more advantageous to refer patients needing procedures to acute care hospitals. The appropriate way to manage the need for procedures is dependent on the available resources and the overall mission of the medical care at the event.

Often, a large proportion of time spent planning out supplies is focused on generating a broad list and subsequently obtaining supplies that would be necessary to provide medical care for a critical patient. As discussed earlier, it is important to consider that rapid transport of this patient away from the incident to the controlled environment of an acute care hospital may be more beneficial for the patient and free up the provider to care for other patients who would likely not receive evaluation given the time-consuming nature of the critical patient. In addition, proportionally fewer critical patients are seen at a given event compared with the vast majority who seek aid for minor complaints such as scrapes, blisters, headaches, and sprains. Therefore, more effort should be placed on obtaining supplies in highest demand. As suggested by the number and type of complaints seen, those supplies in highest demand typically include bandages, foam padding for blisters, ice for sprains, fluids for oral rehydration, acetaminophen, and ibuprofen.

In general, the incidence of cardiopulmonary arrest and the need for major resuscitation at mass gathering events is low. However, **medical units should, at the very least, have access to an automated**

external defibrillator. Event-specific protocols should address the use of advanced airway equipment, including the possible use of medications for rapid sequence intubation. Plans for other resuscitation needs should also be addressed prior to the event so that all providers manage these small numbers of cases in a standard format (e.g., fluids for sepsis, postresuscitation care, management of cardiac arrhythmia, status asthmaticus). Although it is rare that there is a need for major resuscitation, there may be value to having supraglottic airways (e.g., KING LT Airway®) and adult intraosseous needles (e.g., EZ-IO®).

In addition to the level of training of the medical staff, equipment needs will be determined by the mobility of the unit. Some events may need mobile medical units that are able to reach patients in difficult locations or easily move through large crowds. Units on foot and other nonmotorized means of travel will be able to carry fewer supplies than those using motorized vehicles such as golf carts. For events using nonmotorized mobile units, it will be important to design a means to bring heavier supplies to a patient should the need arise, such as equipment needed to manage a patient with a high suspicion of spinal cord injury. Units in fixed locations will be able to stock a greater quantity of materials, possibly including cots, shelter, and additional medical supplies.

Although the equipment needs are unique for each event, there are some things that are universal. **Tables 4-2** and **4-3** show suggested items for both mobile and fixed units as well as suggested equipment based on the skill level of medical personnel.

TABLE 4-2 Equipment List for Mobile Units

	Item
Basic (BLS-level EMS provider and above)	Automatic external defibrillator (*May alternatively place in a strategic location in the site venue*)
	Cervical collar (*May strategically place in the site venue a method for transport of a patient requiring in-line spinal immobilization*)
	Airway adjuncts
	Oxygen delivery devices (nasal cannula, nonrebreather mask, bag-valve mask)
	Oxygen and suction (*May be strategically placed in site venue*)
	Bandages (4×4, roller gauze)
	Triangular cravats
	Adhesive bandages
	Nonlatex gloves
	Splints
	Stethoscope
	Sphygmomanometer
	Tape
	Shears
	Flashlight
	Documentation forms
	Hazardous waste bags
	Compact foil space blankets
	Petroleum jelly (used to prevent chaffing by marathon runners)
	Oral fluids for hydration (water, sports drinks)
Advanced (ALS-level EMS provider and above)	Advanced airway equipment including laryngoscope with assorted blades, endotracheal tubes, and cricothyrotomy kit (*May alternatively use a supraglottic airway device*)
	IV access devices and tubing (*May choose to carry an adult intraosseous set*)
	Normal saline in 1-L bags
	Glucometer
	Dextrose for IV administration
	Advanced cardiovascular life support medications: epinephrine, atropine, amiodarone, adenosine
	Aspirin
	Nitroglycerin
	IV diphenhydramine
	Parenteral benzodiazepine
	Multidose inhaler albuterol
	Epinephrine in 1:1000 concentration
	Morphine
	Airway medications: induction agent, paralytic

Abbreviations: ALS = advanced life support; BLS = basic life support.

TABLE 4-3 Equipment List for Fixed Units

	Item
Physician-level care (some of these skills and/or medications may be available for use by EMS providers with authorized operational-specific scope of practice for mass gathering events)	Suture kits with absorbable and nonabsorbable sutures
	Needles and syringes
	Forceps
	Scalpel
	Normal saline for irrigation
	Local anesthetics
	Otoscope
	Analgesics: acetaminophen, ibuprofen, morphine
	Antacids
	Antiemetics
	Prednisone
	Antibiotics: ointment, oral
	Activated charcoal
	Airway management: induction agent, paralytic
Nonmedical equipment	Cots
	Shelter
	Blankets
	Chairs
	Hazardous waste receptacle
	Sharps box

TREATMENT FACILITIES

Medical directors will need to determine if the scope of the event will require fixed treatment facilities or if mobile units will be sufficient. Factors that contribute to this decision are the predicted number of patients expected to seek medical care, length of the event, distance to off-site medical care, and environmental factors. Fixed treatment facilities can be set up in mobile tents or within a permanent structure. Regardless, fixed treatment facilities should be set up in such a way as to be able to withstand the predictable weather conditions that may be encountered during the duration of the event. From a patient care perspective, it is important to have a facility that has environmental control to manage heat-related illness in warm weather and cold-related illness in cold/wet weather. Off-site treatment facilities should be arranged with local hospitals.

TRANSPORTATION

Nonmedical and medical transportation is necessary, taking into account the number, capacity, and staging location for transport units. Nonmedical transportation units move personnel and resources throughout the site. Medical transportation moves patients within the event location and out to area hospitals.

Planners may also need to address nontraditional modes of transportation, such as golf carts, boats, bicycles, horses, snowmobiles, and toboggans. Protocols should also be developed that address the appropriate use of air medical transportation, including location and setup of a safe landing zone.

TABLE 4-4 Public Health Concerns to Be Considered for a Mass Gathering Event

Access to potable water
Proper waste management for human waste
Waste management for nonhuman waste
Proper management of food service to prevent spread of foodborne illness
Proper road/traffic management to prevent traffic-related injuries
Other considerations for injury prevention
Large-scale natural or man-made disaster

PUBLIC HEALTH

Public health concerns during a mass gathering event may be addressed by the event managers or delegated to the local public health authority or the medical director and EMS system. Even if these concerns are not delegated to the medical response team, public health concerns can affect patient care, and therefore the medical director should be aware of these issues. **Table 4-4** lists some potential public health concerns.

ACCESS TO CARE

The event managers and medical director should develop plans to ensure that the public will be able to access emergency care, if needed. These plans should ensure that the locations of fixed treatment facilities are well marked with signs and other visual aids and that there are limited barriers to access these facilities. Fixed treatment facilities should be accessible to all members of the public and comply with guidelines that are in accordance with the Americans with Disabilities Act. Mobile medical personnel should also wear vests or other high-visibility clothing easily identified by the public. Pamphlets or signage can alert the public about methods for accessing emergency care.

COMMUNICATIONS

Successful management of any mass gathering event is contingent upon an effective communication system. To maintain coordination and control, the system must be tailored to the unique needs of the scenario. The design is dictated by a variety of factors, including geography and size of venue, number of participants, budget, and the systems of those with whom providers will be interfacing. Consideration should also be given to environmental factors including temperature extremes, water, and noise. Venues at music concerts and motor sports may require special communication devices to allow for providers to communicate with each other while in the presence of loud background noise.

Modalities can range from simple flag signals to sophisticated radio networks and may include consumer Family Radio Service devices (walkie-talkies), cellular systems, and landline phones. Each has their strengths and weaknesses. Walkie-talkies have a multitude of channel options but are typically limited to a 1- to 2-mile range. Cellular and other phone systems may provide an inexpensive option but are easily overwhelmed by large numbers of users during a crisis. Two-way radios with more power and range than Family Radio Service systems may be analog or digital, using very high frequency, ultra-high frequency, or 800-MHz frequencies. Systems using a repeater antenna allow for communication over greater distances and across rugged terrain. Large-scale, trunked radio systems provide central control of end-user access to selected channels, allowing a greater number of people to function within a limited spectrum. These systems also allow for discrete groups of responders to communicate among themselves without disturbing other groups.

If the communications network is not linked to surrounding resources, a protocol must be in place for making contact and for relaying information as needed. In an urban environment, this may be in the form of an on-site representative from the local EMS system or an identified phone number or frequency designated for the activation of additional resources. In a remote area, one or more people may be tasked with relaying messages via radio or traveling to the nearest telephone or area of cellular service to contact local authorities, or a specific "communications tent" may be organized.

TABLE 4-5 Documentation

Purposes of medical documentation for a mass gathering event
Assist in transfer of care from the event site to off-site medical facilities
Record medical interactions for the purposes of liability control
Establish a means of data capture for continuous quality oversight and research
Essential components of medical documentation for a mass gathering event
Patient's name, contact information, sex, and age
Vital signs
Chief complaint
Focused physical examination
Suspected diagnosis
Medical care rendered
Disposition

DOCUMENTATION

The medical director should develop a system for documentation of patient encounters during the event. This system need not be as extensive as that which would be found in the typical ED setting and, instead, should be focused on the event to address specific components of the patient encounter as outlined in **Table 4-5**. Medical documentation should be easy to complete and not exhaustive, such that it can be quickly completed if large numbers of patients seek medical care at the same time. Medical directors may want to consider a method of electronic documentation. Paper documentation should ideally be on a single sheet that can be used by all providers involved in the patient's care (**Figure 4-2**).

LIABILITY

All members of the medical response team for a mass gathering event should have medical liability coverage. Depending on the restrictions of the carrier, liability coverage may be provided by the policy of one's primary employment or may need to be purchased as additional coverage. The medical director may want to arrange coverage for all members of the medical response team as a group. This should be factored into the cost of providing medical care for the event and should be discussed with planners during the negotiation stage before the event. It is important to note that, if the medical personnel will be reimbursed for services in the form of legal tender or payment in kind (even in the form of a free meal at the event), they may not be protected from liability through Good Samaritan laws, depending on the state. In addition, if the medical providers are advertising their medical services to the public at an event even by setting up an established medical tent, the providers have established a duty to act and are liable to the public to provide care at an established standard. In order to mitigate untoward risk, the medical director should review the laws that pertain to the local area before the event.

CONTINUOUS QUALITY IMPROVEMENT

Unless an event is anticipated to be a one-time occurrence of a short duration, the medical director should establish a method of continuous quality improvement. The continuous quality improvement program should begin with a review of the documentation for patient encounters to identify elements of the system that are performing well and elements that need improvement. The results of continuous quality improvement review should then be used to improve upon the system of delivery of care. The medical director may also consider having regular case reviews with the medical personnel at the event to improve the care being delivered.

COMMERCIAL AIRLINE FLIGHTS

Commercial airline flights represent a special scenario in mass gathering medicine. The steadily rising number of travelers, the increasing

mobility of people with chronic illness, and the aging population all contribute to make in-flight medical emergencies more and more common. Yet, the exact incidence is not known because a formal system to report in-flight medical emergencies is not required by the Federal Aviation Administration.[9] However, it is known that cardiac, neurologic, and respiratory emergencies comprise the more serious complaints as defined by a need to divert the aircraft or use ground-based EMS resources.[10-12] GI complaints, such as abdominal pain, nausea, and vomiting, are common yet rarely represent medical emergencies and require little intervention. The combined data suggest that medical emergencies occur at a rate of 20 to 100 per million passengers, with a death rate of 0.1 to 1 per million passengers.[10,13,14]

Factors unique to the airline environment that affect medical care include the lower partial pressure of oxygen, potential exposure to chemical irritants, dry air, virulent airborne particles, and venous stasis. The aircraft cabin is typically pressurized to the equivalent of 5000 to 8000 feet above sea level. For individuals with cardiopulmonary disease, this relative decrease in arterial blood oxygen saturation may compromise cardiovascular reserves, thus precipitating an emergency. For chronic obstructive pulmonary disease and asthma patients, a combination of dry cabin air, respiratory irritants, reduced partial pressure of oxygen, and lack of access to their bronchodilators may trigger respiratory problems. In addition, this setting may aggravate normal health behaviors through alcohol ingestion, dehydration, and the inaccessibility of prescribed medications.

The management and disposition of medical emergencies on commercial airline flights are dependent on available personnel and equipment. Airline crew members receive education in basic first aid and CPR as mandated by the Federal Aviation Administration.[15] In addition, most large commercial flights include passengers with some medical training who are called upon to assist a passenger or crew member in distress. Assuming that care rendered is provided on a volunteer basis, Good Samaritan laws should provide protection from medical malpractice liability.

Onboard medical supplies are limited. The Federal Aviation Administration requires passenger-carrying aircraft weighing more than 7500 pounds maximum capacity with at least one flight attendant to carry an enhanced emergency medical kit in addition to a basic first aid kit, as outlined in **Table 4-6**.[16] Some airlines may choose to supplement these supplies with additional types of medications or equipment. Oxygen supplies are plentiful in the case of cabin depressurization, but there is typically limited availability of supplemental oxygen for sick passengers. In some cases, the pilot may be able to lower the cruising altitude to

Mass Gatherings: Hajj

Mohammed A. Alsultan

The Kingdom of Saudi Arabia is host to the annual event of Hajj (pilgrimage), the largest mass gathering in the world, in the city of Mecca, Saudi Arabia. All Hajj worship activities have to be accomplished in 4 to 5 days; an estimated 4 million pilgrims participated in 2011, 6 million are projected for 2015, and 10 million are projected for 2025. A complex infrastructure is required to handle transportation, accommodation, water, food, sanitation, safety and security, health, and hospitality for the millions of pilgrims who participate in Hajj.

Cultural, socioeconomic, and geographic factors contribute to the complexity of Hajj and require detailed planning. Communication must be provided in multiple languages for pilgrims from 140 countries with vastly different educational backgrounds, cultures, and health literacy, and communication must also accommodate illiterate pilgrims. The city of Mecca sits in a valley just above sea level and lies in a corridor between mountains, so space for population movement is very limited. Hajj is held in the twelfth lunar month and is not synchronized with seasons, so over the years, the weather varies between the extremes of heat in summer and flooding in winter. Most pilgrims are elderly, with considerable variation in health-related behavior, underlying health status, and medical needs. Challenges include visa management, illegal immigrants, illegal pilgrims, and security against terror attacks and for high-profile pilgrims.

Because free health care is provided to all pilgrims, the majority of Saudi Arabia's healthcare resources are redirected to Mecca during Hajj. There are 20 hospitals in Mecca, of which seven are seasonal. One hospital, with 3350 beds, has cardiac catheterization capabilities. During Hajj, there are more than 100 walk-in clinics and emergency centers, which are operated by 20,000 emergency care givers. All of these centers are run mainly by the Ministry of Health, but other governmental institutions (mainly military) participate in healthcare provision, so that coordination between the various centers is challenging.[1] Prehospital care is provided by the Saudi Red Crescent Association with more than 300 ground ambulances, hundreds of homemade wagons, five air ambulances, and many Red Crescent stations. Also, there are hundreds of mini-clinics that come with every international pilgrim group, and while they usually liaise between the hospitals and health centers, they have never been part of strategic health planning.

In 2010, the total number of outpatient visits to hospitals and health centers was 1 million, with an increase of 8.9% from the previous year. The admission rate was 1.1%, with 666 deaths (23.9 deaths/100,000 pilgrims).[2] All healthcare documentation is in English, and treatment records are given to every pilgrim who visits any medical facility. Planning is under way to develop an electronic medical record system that will be integrated with other medical records in or outside of Saudi Arabia.

The Ministry of Health prepares all year for the Hajj. The Ministry conducts several workshops for medical and nonmedical staff on disaster preparedness, triage, and emergency care. During Hajj, public health issues are precisely and completely reported because of the international and intercontinental repercussions in terms of the spread of infectious disease.[3] Regular reports are generated concerning stampedes, motor vehicle crashes, burns, and heatstroke. The Ministry submits a weekly epidemiologic report to the World Health Organization, indicating pilgrim vaccination status before traveling to Mecca (meningococcal meningitis and poliomyelitis if traveling from a polio-endemic country, or yellow fever if traveling from a country at risk of yellow fever) and other recommended health measures (seasonal flu vaccine and health education programs in the pilgrim's country of origin).[3] Different countries have varying vaccination policies and different endemic diseases. Historically, there were many documented outbreaks of plague and cholera during Hajj, involving large numbers of pilgrims, when quarantine was the principal means of control. Today, the speed of air travel means that pilgrims incubating infectious diseases at their time of departure may not manifest illness until after arrival in Mecca, thereby facilitating the spread of disease and even full-blown epidemics.[4] In 2010, the Ministry of Health established 25 health centers at entry points to the Holy Land (Jeddah airport, seaport, and land ports) and provided preventive services to 1.8 million pilgrims at these sites. For example, 435,000 pilgrims were given infectious disease chemoprophylaxis, and 463,000 pilgrims were vaccinated against poliomyelitis.

The Minister of the Interior is the general commander for Hajj. He is the overall leader of the Hajj Higher Committee, which includes the Governor of Mecca province, the Minister of Islamic Affairs, the Minister of Health, the Minister of Municipality, the Minister of Finance, the President of the Saudi Red Crescent Authority, the Minister of Transportation, and other high-ranking government members. This committee acts as the highest command center. Each one of the above members chairs a command center in his field and reports back to the Hajj Higher Committee. For example, the Minister of the Interior heads the military command center, which includes civil defense, traffic police, passport officers, and security police departments, besides chairing the Hajj Higher Committee.

In a disaster situation, the disaster commander is the head of Civil Defense, and the Ministry of Health and Red Crescent teams fall under that command. The Ministry of Health team leader at the scene is responsible for dispatching patients from the scene, and the commander from the Ministry of Health controls patient distribution to all the hospitals. There is a central operational room that serves as headquarters for one representative from each service (e.g., civil defense, traffic, police, Ministry of Health, Red Crescent, municipal affairs). This also serves as the communication center and is fully equipped with radios and telephone landlines.

The Saudi Arabian government is responsible for safety and fire prevention and fire fighting, with more than 40 centers set up during the Hajj period. These centers monitor security, prevent and manage any terrorist acts (e.g., bombing near the holy mosque in 1989), assist in disaster management (76 people were killed when a hotel in Mecca collapsed in a narrow street in 2006), and provide and control travel access to and from the Holy Land borders. The Hajj mass gathering demands an enormous amount of preparation by, and cooperation between, politicians, military staff, media, laboratory scientists, public health officials, emergency physicians, and other Saudi Arabian authorities. Some of the future challenges during the Hajj are the training of pilgrims prior to arrival as part of the visa-issuing process; mega food storing; prohibiting the use of fires inside pilgrim tents; providing special mobile shelters; minimizing air and water pollution; and providing climate control. However, the greatest future challenge is crowd management inside the Holy Mosque during Tawaf, the ritual of circumambulating the Kaaba seven times (Figure 1). The Custodian of the Two Holy Mosques Institute of Hajj Research was established in 1975 to provide support for researchers and scientists in the medical, civil engineering, sociology, cultural, and public health fields to continue to improve all services in the vicinity of the Holy Shrine of Hajj.

increase the cabin pressure and subsequently increase the level of oxygen. In 2004, the Federal Aviation Administration mandated that all domestic flights carry an automated external defibrillator.[15] Finally, passengers on board may provide their own medicines for use by others during an emergency, providing an inconsistent but possibly valuable resource.

The decision to divert an aircraft for a medical emergency is a balance between medical need, cost, and logistic constraints. Although the final decision to divert is made by the pilot, there are a number of resources available for guidance. Most airlines contract with some form of ground-based online medical support. Usually directed by an emergency physician, these services provide information on resources available at airports in the vicinity and along the route of flight. From a medical perspective, it is necessary to decide if the patient is stable enough to continue to the planned destination or if there is a need for immediate definitive care. The cost of diverting an aircraft, including rebooking of flights and the cost of dumping fuel to meet maximum landing weight, can be quite high, running from $30,000 to $750,000. Logistically, diversion requires finding a landing site that can accommodate the aircraft and has appropriate medical resources nearby. The decision to divert an international flight may be complicated by legal issues, such as landing rights and passenger screening requirements.

The advent of long-haul travel brings to the forefront the issue of global spread of infectious disease. Passengers may travel across the globe between continents while in the prodromal phase of a disease, or they may knowingly travel while ill, making efforts to mask signs and symptoms with medications. It has been reported that risk of infection is greatest on flights longer than 8 hours and among passengers seated within two rows of the infected individual, particularly referring to the transmission of tuberculosis.[17] This is a testament to the well-contained local circulation of cabin air. However, there is the misconception by some that when an infected passenger sneezes, the majority of the passengers of the aircraft will become infected. In reality, cabin air is a mixture of outside air that enters the aircraft engine continuously and recirculated air passing through high-efficiency particulate air filters that remove particles as small as 0.003 μm.[17]

Both the outbreak of severe acute respiratory syndrome in November 2002 and the H1N1 influenza pandemic outbreak of April 2009 demonstrated the urgent need for a rapid, appropriate, and coordinated international response to deal with the spread of pandemics. Consequently, the concept of quarantine is often considered as an option for preventing the spread of disease. Drawing on the most recent experience and analysis of the response efforts to the 2009 H1N1 pandemic, it is evident that airport quarantine inspection is not effective in preventing the spread of influenza virus.[17,18] It has been determined that between the large number of people in the incubation period (thus not showing any symptoms), the low accuracy of the inspection kits used, and the poor cost-effectiveness, quarantine inspection in itself is not effective in preventing the spread of respiratory viruses. However, follow-up information obtained from passengers, follow-up surveys distributed to passengers, and information disseminated on symptoms to be aware of are believed to be important in mitigating the secondary spread of viruses.

CRUISE SHIP MEDICINE

Nearly 10 million people travel on cruise lines each year, the majority of whom are from North America. With an average customer age of 55 years on many ships, the number of people with chronic medical conditions can be quite high.[19] Large vessels carry >2000 passengers and 1000 crew, resulting in a uniquely isolated environment with a high probability of encountering sick patients.[20]

The most common complaints seen in the ship's infirmary are shortness of breath and injuries. Other complaints are outlined in **Table 4-7**. On a typical week-long cruise with 1100 passengers, it is estimated that there will be an average of four potentially life-threatening conditions, with one patient terminating the cruise early as a result.[19] The decision to continue onboard treatment, to transport to a shore-based facility, or to arrange aeromedical evacuation must be made in light of weather forecasts, predicted flight time, and the quality of local resources. This choice is often made in conjunction with online medical support services provided by the cruise line.

WILDERNESS MEDICINE

Mass gathering events that are located within a wilderness environment can present unique challenges to the provision of medical care. Ideally, medical directors for wilderness mass gathering events should be experienced in both wilderness medicine and EMS. The 16-hour National Association of EMS Physicians/Wilderness Medical Society's Wilderness EMS Medical Directors Course provides concrete skills that are beneficial to a medical director for a wilderness mass gathering event. These events can occur in environments with extremes of temperature that medical personnel should be prepared to manage, both for themselves and for the care of patients. Most significantly, mass gatherings in wilderness environments can present challenges in the extrication of patients and may necessitate the use of alternative means of transport such as horses, snowmobiles, and aircraft.

ULTRA-DISTANCE ATHLETIC EVENTS

One of the clinical situations often encountered during exercise, particularly in individuals involved in endurance events such as marathons, triathlons, and ultra-distance athletic races, is the management of fluid and electrolyte repletion, specifically severe and potentially life-threatening hyponatremia. Exercise-associated hyponatremia, first described in the early 1980s, is defined as serum sodium below the normal reference range of the laboratory occurring during or up to 24 hours after prolonged physical activity.[21,22] Both fluid intake in excess of fluid loss and impaired urinary water excretion due to persistent secretion of antidiuretic hormone are important pathologic mechanisms contributing to this rapid, predominately dilutional decrease in serum sodium. Risk factors for developing exercise-associated hyponatremia include a high rate of fluid consumption during and after exercise (often associated with weight gain compared with

prerace weight), exercise time longer than 4 hours, female sex, and a low body mass index.[23]

Athletes presenting to first aid tents during ultra-distance events should be evaluated for electrolyte abnormalities.[24] Although a serum sodium level should ideally be checked before administering IV fluids, this may not always be feasible in the mass gathering environment. Therefore, it is critical to be able to identify individuals with signs and symptoms consistent with hyponatremia and to differentiate those with life-threatening presentations. The majority of hyponatremic athletes are asymptomatic or mildly symptomatic, with manifestations such as nausea and vomiting, malaise, lightheadedness, dizziness, headache, and fatigue. Severe, life-threatening manifestations include confusion, seizures, and coma, which may indicate the development of cerebral edema and impending death.

Hyponatremia during athletic events is best managed by preventative means. Oral rehydration using fluids that contain both carbohydrates and sodium, as found in commercial "sports drinks," results in less of a dilutional effect; however, they are still relatively hypotonic compared to plasma. It has also been previously suggested that maintaining a fluid balance during the event by limiting drinking to <500 mL/h will help to prevent hyponatremia. However, given the wide variation in sweat production and renal water excretion between individual athletes, and in the same individual depending on conditions during the race, it is not feasible to develop specific universal guidelines. Overall, recommendations for endurance athletes support the concept of drink according to thirst.[22]

Athletes presenting with the clinical manifestation of mild to moderate hyponatremia should have fluid restriction and observation until the onset of spontaneous diuresis rather than administration of hypertonic saline, since similar symptoms may occur in hypernatremia.[22,25] However, among those with severe symptoms, when it is not feasible to measure serum sodium due to the constraints of the mass gathering event, treatment should be initiated empirically. Recommendations suggest an initial 100 mL bolus of 3% hypertonic saline, which should raise the serum sodium by 2 to 3 mEq/L. The bolus can be followed by an infusion rate of 3% hypertonic saline at 2 to 3 mL/kg/h to establish an increase in the serum sodium concentration of 4 to 5 mmol/L over the first 1 to 2 hours in order to reverse the osmotic gradient.[26] An alternative approach is to administer an additional two boluses of 100 mL of 3% hypertonic saline every 10 minutes until life-threatening symptoms have resolved.[27] Once clinical improvement occurs, the rate of infusion is decreased to follow the guidelines recommend for the safe correction of chronic hyponatremia (maximum increase of 12 mmol/L over 24 hours).[26]

CARDIAC ARRESTS

Although cardiac arrests comprise a small percentage of medical occurrences at mass gathering events, results can be detrimental if planners are not well prepared for this potential need. At the very least, planners should prepare to have an adequate number of automated external defibrillators and make calculated decisions as to where these devices should be placed to minimize response time for all locations within the event. Planners should also consider the placement of ambulances within the event for easy egress and the provision of advance life support care.

MASS CASUALTY

In planning for a mass gathering, the event medical director should be cognizant of and prepared for the potential of a mass casualty incident. Plans should include methods of triage, coordination of the mass casualty with local EMS, and distribution of large numbers of patients as needed to area acute care facilities. Ultimately, the medical teams should function seamlessly in the Incident Command System structure such that patient flow is managed in the same manner regardless of the numbers of patients seen at any point in time and the potential influx of large numbers of patients in the event of a mass casualty situation.

SECTION 2

Disaster Management

CHAPTER 5

Disaster Preparedness

Robert G. Hendrickson
B. Zane Horowitz

INTRODUCTION

Disasters have claimed millions of lives and cost billions of dollars worldwide in the past few decades. Examples of large-scale disasters include the terrorist attacks of September 11, 2001; the 2004 Pacific Ocean tsunami; the 2010 earthquake in Haiti; the 2011 earthquake and tsunami in Japan; and Superstorm Sandy of 2012. Emergency physicians frequently have extensive responsibilities for community and hospital-level disaster preparedness and response. This chapter discusses the definition of a disaster, disaster preparedness and planning, the hospital emergency operations plan, field disaster response, and the ED disaster response.

DISASTER DEFINITION

The World Health Organization defines a disaster as a sudden ecologic phenomenon of sufficient magnitude to require external assistance. A disaster is an event that overwhelms the resources of the region or location in which it occurs. Furthermore, a hospital disaster may similarly be defined as an event that overwhelms the resources of the receiving hospital. A hospital disaster may be of any size and is not limited to mass casualty incidents. A single patient who ingested an organic phosphorous pesticide may overwhelm the resources of a hospital if that hospital is not prepared to decontaminate external to the ED. A single patient with suspected smallpox or a single influential patient (e.g., world leader or a celebrity) may use so many ED resources that it affects the care of other patients.

Whether an event is a disaster further depends on the time of day, nature of the injuries, type of event, and the amount of preparation time before the arrival of patients. The ED "surge capacity" (ability of the ED to care for more patients than is typical) may be severely limited by hospital overcrowding.

When it appears that the normal procedures of an ED may be interrupted by an event, there must be policies and procedures in place to activate a disaster response, direct the mobilization of personnel and equipment, and permit the rapid triage, assessment, stabilization, and definitive care of victims.

TYPES OF DISASTERS

Disasters are subdivided into several categories (**Table 5-1**). **External disasters occur at locations that are physically separate from the hospital (e.g., transportation accident, industrial accident). An internal disaster is an event that occurs within the confines of the hospital (e.g., bomb scare, laboratory accident involving radiologic agents, power failure).** Disasters can be both internal and external (e.g., earthquake with mass casualties as well as damage to the internal hospital). Further discussions of disasters are provided in the following chapters: chapter 6, Natural Disasters; chapter 8, Chemical Disasters; and chapter 9, Bioterrorism.

DISASTER CHARACTERISTICS

Regardless of the cause, most disasters have common characteristics that are important for disaster preparedness and planning. In an acute disaster, or a disaster with an identifiable time of onset that produces casualties (e.g., explosion, chemical release, fire, earthquake), the event is followed by a large number of minimally injured patients presenting to the nearest hospitals, usually without prehospital triage or evaluation.[1,2] This is typically followed by prehospital transport of the most affected patients to the same hospitals.[3] Initial patients can be expected within minutes, and peak volumes can be expected at 2 to 3 hours after the event.[2,3] The vast majority (~80%) of patients are not transported by prehospital agencies, but instead self-transport by car, van, police vehicle, cabs, foot, or any means available to the nearest ED.[2-4] Even in acute events, ED volumes tend to remain elevated for days to weeks after events.[3] In nonacute events, such as a pandemic of an infectious disease, ED volumes have a slower onset of surge, but ED and hospital volumes remain elevated for extended periods.

Based on previous events, common factors that may hinder ED response are listed in **Table 5-2**. A large amount of federal funding has been supplied to address these issues, but they likely remain as the major common limitations to effective ED disaster response.

DISASTER PREPAREDNESS AND PLANNING

Planning for any type of disaster consists of common elements. A hospital disaster planning group is responsible for generating the hospital's emergency operations plan. Include a diverse membership of hospital employees and decision makers. **Table 5-3** lists some potential members and their roles. The group should meet on a regular basis to assess hazards, develop and update short- and long-term disaster plans, plan exercises and training, and redesign the disaster plan based on evaluations of exercises and real events.

The general components of the disaster plan include hazard vulnerability analysis, compliance with agency requirements, hospital–community coordination, integration with national response assets, and training and disaster drills. Develop specific plans (for radiation, explosions, mass casualties, decontamination) based on an assessment of the potential disasters in the area as well as study of the events that would cause the most disruption to the ED and hospital.

HAZARD VULNERABILITY ANALYSIS

The hospital planning group should address those disasters that are most likely to occur in their community and geographic area. For example, planners on the West Coast of the United States may make earthquake planning a priority and those on the Gulf and Atlantic coasts may prioritize hurricane planning. Give consideration to the proximity of population centers to chemical release threats (military chemical weapons depots, large industrial sites, or transportation hubs).[5] Industrial sites that store large volumes of potentially harmful chemicals are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning committees. Industries are required to report spills of potentially harmful chemicals, and the approximate location of these sites may be found at http://toxmap.nlm.nih.gov. Terrorist-related disasters may be prioritized in hospitals that are in proximity to sites that may be significant terrorist targets. Include factors such as proximity to transportation facilities (e.g., ports, airports) as well as locations where large numbers of people collect (e.g., festivals, stadiums, arenas) with the risk assessment.

The hazard vulnerability analysis can prioritize planning efforts because different disasters are characterized by different morbidity and mortality patterns and different challenges to the ED and hospital.

TABLE 5-1 Types of Disasters

Disaster Type	Definition	Examples
Natural disaster	Disaster caused by a naturally occurring event	Earthquakes, tsunamis, tornadoes, hurricanes/typhoons, volcanic eruption, pandemic influenza
Man-made disaster	Nonnatural events that are not purposefully produced	Vehicle crashes (e.g., car, plane, bus), mass casualty events, explosions, fires, industrial accident/chemical release
Terrorist-related disaster	Events that are purposefully produced in an effort to cause terror	Events of September 11, 2001, as well as intentional chemical, biological, radiologic, or toxin releases
Internal disaster	An event that occurs within the hospital	Hazardous materials spill in hospital laboratory, fire or explosion within hospital, power failure
External disaster	An event that occurs external to the hospital	Transportation accident, industrial accident
Acute disaster	Disaster that occurs in a narrow and well-defined time frame	Explosion, industrial release, earthquake
Nonacute disaster	Disaster with no well-defined start point or continuous production of casualties over a broad time frame	Pandemic infectious disease, incremental release of a biological or toxin (e.g., anthrax sent through mail)

TABLE 5-3 Hospital Planning Group

Hospital Planner	Role in Disaster Planning and Response
Public safety	Crowd control, hospital lockdown, and hospital access control
Facilities/engineering	Evaluate structural damage and advise on stability of facilities
Logistics/equipment supply	Provide supplies/equipment; arrange for rapid ordering of additional supplies
Pharmacy	Provide pharmaceuticals, antidotes, and antibiotics; arrange for rapid ordering of additional pharmaceuticals
Transportation	Assist with patient transport
Clinical fields	A wide array of clinical fields should be represented, including representatives from the ED, primary specialties (internal medicine, family medicine, pediatrics), and surgical specialties
Media/public relations	Act as single point of contact for media; liaise between media and clinical areas, emergency operations center, and other hospital resources
Communications officer	Coordinate communication to employees during a disaster through e-mail, Web site, paging groups, phone, or social media
Nonclinical patient care	Housekeeping and food services
Safety officer	Determine and ensure safe practices for employees (e.g., appropriate personal protective equipment for decontamination)
Radiation safety officer	Prepare plan for and respond to radiologic emergencies
Infection control officer	Prepare for and respond to infectious disease emergencies

For example, earthquakes may cause severe traumatic injuries requiring a concentration on surge capacity of the critically ill patient. Rescue operations may last several days. Unique needs, such as dialysis for renal failure for multiple crush injury victims, may need to be considered. Natural disasters often cause large numbers of homeless or displaced persons whose everyday medical needs are exacerbated by limited access to usual health care, as occurred after Hurricane Katrina. Chemical releases may require mass decontamination as well as large numbers of ventilators, oxygen, and specific antidotes that are not typically available in large quantities.

THE JOINT COMMISSION REQUIREMENTS

The Joint Commission requires that member hospitals have a written plan for the timely care of casualties arising from both external and internal disasters, and the hospital must document the training and exercise of these plans.

HOSPITAL–COMMUNITY COORDINATION

Every hospital should integrate its emergency operations plan with those of community disaster management agencies. This is especially important regarding disaster notification and communications, transportation of casualties, and provisions for dispatch of hospital medical teams to a disaster site. Strong relationships with community agencies (e.g., fire department, regional EMS system, local emergency management, or public health agency) are important to ensure a coordinated disaster response. There are a large number of community agencies that have some responsibility for disaster planning and response (**Table 5-4**).

Other organizations that a hospital may interact with during the disaster planning process include the military, local chapters of the American Red Cross, local emergency planning committees, Citizen Corps Councils, and other volunteer agencies, along with state and

TABLE 5-2 Factors That May Hinder ED Response to Disasters

Poor communication between ED and disaster scene
Poor communication within the hospital (e.g., ED to emergency operations center, emergency operations center to patient care areas)
Inability to control volunteer healthcare personnel who are unfamiliar with the ED function and their roles in disaster response
Inability to engage and control convergence of media to the ED
Inability to engage, control, and direct visitors who are searching for loved ones
Inability to control large numbers of patients (i.e., crowd control)
Difficulty maintaining high staffing needs for extended periods

TABLE 5-4 Community Agencies Involved in Disaster Planning

Community Agency	Responsibilities
Federal Bureau of Investigation	Incident command if a federal crime may be involved
FEMA	Incident command in public health disaster
State governor	Authority to declare health emergency; requests federal assistance (e.g., FEMA); responsible for public safety
State health department	Authorized by governor to coordinate disaster response
State emergency management association	State-level equivalent of FEMA
City/county health department	May have jurisdiction for local disasters (variable); may be initial incident command for local health disasters
EMS	Patient triage in field; decontamination in field (if necessary); stabilization and transfer to definitive care facility
Fire service	Overall scene command in an acute disaster; victim rescue and hazard control
Police service	Traffic management and scene security in an acute disaster
Public works	Support equipment and personnel; structural safety expertise
Hazardous materials (HAZMAT) teams	Initial incident command at scene of hazardous materials spill/exposure

Abbreviation: FEMA = Federal Emergency Management Agency.

federal agencies (e.g., National Disaster Medical System, Metropolitan Medical Response System, Centers for Disease Control and Prevention). Medical planning in a community is usually the responsibility of local and state health departments and EMS councils.

INTEGRATION WITH NATIONAL RESPONSE ASSETS

Some of the important federal response resources are listed in **Table 5-5**. During a response, these agencies may play pivotal roles and may interface and coordinate with hospitals and emergency physicians.

TRAINING AND DISASTER DRILLS

Regular training and drills familiarize staff with their disaster roles and responsibilities and identify weaknesses or omissions in the plans that require additions or revisions. Drills can range from full-scale, community-wide simulations, with moulage (use of makeup or theater techniques to represent injuries) victims, to tabletop triage scenarios, mini-drills that test only certain components of the disaster plan (such as call-up of personnel), and tests of communications. The Joint Commission requires two annual drills. The scenarios should reflect incidents that are likely to occur in the community as determined by the hazard vulnerability analysis.

HOSPITAL EMERGENCY OPERATIONS PLAN

The hospital emergency operations plan provides for an organized response of the hospital from the time of notification of a disaster until the situation normalizes (**Table 5-6**).

Functions include activation of the emergency operations plan, establishment of an emergency operations center, assessment of hospital capacity, surge capacity planning, communications, supply and resupply, triage and treatment of casualties, establishment of support areas, and termination of the disaster state to allow for recovery and the return to normal activities.

ACTIVATE THE EMERGENCY OPERATIONS PLAN

Clearly delineate the roles and responsibilities of all employees in the ED and any employees who may respond to the ED in the planning process; those roles must be clearly listed and easily accessed in the event of a disaster. Clarify the reasons for activation of the emergency operations plan. Activation of the emergency operations plan should provide for the immediate mobilization of supplies, equipment, and personnel.

ESTABLISH EMERGENCY OPERATIONS CENTER

The Incident Command System is a standard emergency management system used throughout the United States to provide a flexible command and control structure upon which to organize a response.[6] The Incident Command System is generally used when there is an identifiable single scene for a disaster event, such as the site of a plane crash. By standardizing an organizational structure and using common terminology, the Incident Command System provides a management system that is adaptable to incidents involving a multiagency or multijurisdictional response. At the most basic level, there are five main components to the organizational structure: (1) incident command, (2) operations, (3) planning, (4) logistics, and (5) finance. With this type of organizational infrastructure and the flexibility to expand and collapse as needed, an orderly and efficient response to any incident can theoretically be implemented.

The Hospital Emergency Incident Command System is modeled after the Incident Command System. Upon declaration of a disaster, an emergency operations center within the hospital should be established in a predesignated area. This center should be able to communicate with the ED and triage area and with external authorities (regional EMS, police, fire, public health agencies). Provisions for multiple redundant modes of communication should be made. Other responsibilities of the emergency operations center include opening up additional hospital wards or

TABLE 5-5 Federal Response Resources

Agency	Role
U.S. Public Health Service/Office of Emergency Response; http://www.phe.gov/preparedness/pages/default.aspx	Office within DHHS. Management and coordination of federal health and medical activities related to preparation, response, and recovery from major emergencies or presidentially declared disasters.
Metropolitan Medical Response System For more information: http://www.bt.cdc.gov/planning/CoopAgreementAward/presentations/mmrs-oep10minbriefing-jim11.pdf	Enhance local emergency preparedness systems by promoting coordination between local responders (e.g., police, fire, hazardous materials agencies, EMS, hospitals).
National Disaster Medical System; http://ndms.fhpr.osd.mil/	Asset sharing program between DHHS, Federal Emergency Management Agency, U.S. Department of Defense, U.S. Department of Veterans Affairs, and public/private organizations—developed to provide surge capacity for natural disasters, wartime military casualties, and large-scale bioterrorism events.
DMAT; http://www.phe.gov/Preparedness/responders/ndms/teams/Pages/dmat.aspx	Multidisciplinary teams that deploy in response to federally declared disasters and emergencies to support a local jurisdiction's response. Teams include physicians, nurses, medics, pharmacists, and logisticians.
National Disaster Medical System Response Teams; http://www.phe.gov/Preparedness/responders/ndms/teams/Pages/default.aspx	Specialty teams, based on the DMAT concept, developed to respond to chemical, biological, and radiologic events.
Disaster Mortuary Operational Response Teams; http://www.phe.gov/Preparedness/responders/ndms/teams/Pages/dmort.aspx	Teams that respond to federally declared disasters and emergencies to support a local jurisdiction's ability to process large volumes of deceased patients.
Centers for Disease Control and Prevention http://www.bt.cdc.gov	Centers within DHHS. Lead federal agency in developing and applying disease prevention and control. Advisory agency in bioterrorism response.
CDC Outbreak Response Teams	Teams of CDC epidemiologists to assist with local efforts in investigating potential outbreaks, confirmation of cases and exposures, and environmental clean-up.
Laboratory Response Network; http://www.bt.cdc.gov/lrn/factsheet.asp	Network that links local and state public health laboratories to advanced-capacity laboratories, including military, chemical, veterinarian, agricultural, water, and food testing labs.
National Electronic Disease Surveillance System; http://wwwn.cdc.gov/nndss/script/nedss.aspx	National public health surveillance system.
Health Alert Network; http://emergency.cdc.gov/han/	System that allows for rapid early warning broadcast alerts to health departments for potential emerging infectious diseases or outbreaks.
Strategic National Stockpile; http://www.cdc.gov/phpr/stockpile/stockpile.htm	Two-part system designed to provide local jurisdictions with medications, vaccines, and equipment during a disaster. Prepackaged cache—delivered within 12 h in the U.S. Situation-specific cache—delivered within 36 h in the U.S.
Federal Bureau of Investigation	Lead federal agency for crisis management. Has authority to conduct law enforcement investigations into acts of terrorism.

Abbreviations: CDC = Centers for Disease Control and Prevention; DHHS = Department of Health and Human Services; DMAT = Disaster Medical Assistance Teams.

TABLE 5-6 Components of the Hospital Emergency Operations Plan

Component	Function
Activate emergency operations plan	Notify and mobilize personnel and equipment
Set up emergency operations center	Nerve center for hospital response and communication with outside agencies
Assess hospital capacity	Determine safety of hospital itself; determine capabilities of hospital in all units
Create surge capacity	Determine ways to handle the maximum number of patients
Establish communication systems	Develop multiple and redundant systems, including cellular phones, satellite phones, two-way radios, runners
Provide supplies and equipment	Deliver available supplies to proper areas and plan for resupplying or obtaining other needed materials
Establish support areas	Volunteer, media, and family information centers
Establish decontamination, triage, and treatment areas	Decontamination, triage, resuscitation, acute care, and minor care areas; surgical triage and holding; psychiatric area; morgue
Terminate disaster response and provide for remediation	Return personnel and supplies to normal activity; provide emotional support for caregivers; improve emergency operations plan for future incidents

clinics, obtaining outside assistance, evacuating endangered patients, assigning staff to treatment areas, and terminating the disaster mode of operation.

ASSESS HOSPITAL CAPACITY

Before the hospital can receive casualties, it must be determined if the hospital itself has sustained any structural damage or loss of use as a result of a disaster. These include blocked passageways or inoperable elevators; potential for fire, explosion, or building collapse; failure of utilities; loss of equipment or supplies; contamination of water; and outside access problems. This damage assessment is usually the responsibility of the hospital safety officer or engineer. If the hospital's structural integrity has been compromised, it may be necessary to initiate the evacuation plan to evacuate staff and patients.

Once it is determined that the hospital itself is safe, the hospital should determine how many casualties from the disaster site it can safely manage. This may be limited by available personnel, beds, operating room and intensive care unit capacity, and supplies, as well as by the type of disaster and the availability of other community resources. At the time of disaster notification, it is necessary to know the status of many of the hospital's capabilities: how many beds are available, how much critical supplies and medications are available, how many personnel are on duty, what damage has been done, how many operating rooms are in use, which clinicians are present in the hospital, and so forth.

CREATE SURGE CAPACITY

Surge capacity is the ability to increase hospital bed capacity over normal limits. Intrahospital surge may include doubling patients in rooms, converting an acute care ward to an intensive care level unit, opening previously closed wards, or caring for patients in typically nonclinical locations, such as the cafeteria. Interhospital or regional surge may include discharging hospitalized patients to an external low acuity unit, either mobile or fixed, and altering standards of care (typically a role of the state governor and legislature and only during governor-declared disasters).[7,8] The standards of care should be altered only in the most extreme circumstances, as patient surge has been linked to somewhat worse outcomes for individual patients.[9]

ESTABLISH COMMUNICATIONS SYSTEMS

Establishment of good communications is critical in any disaster or mass casualty situation. Even the best disaster plans fail without well-established communications systems. Unfortunately, experience shows that this essential function is difficult to achieve for a variety of reasons. Many communication modes become inoperative during a disaster. Cellular telephones, in particular, are often overwhelmed in disasters. Disaster planning must include a multi-tiered plan for intrahospital (blackboard, two-way radios, messengers/couriers) and interhospital (citizen band groups, cellular telephones, satellite telephones, two-way radios) communication.

SUPPLIES

During a disaster, necessary supplies and equipment must be ready for immediate distribution to appropriate locations in the hospital. Each hospital will need to estimate the amount of supplies that will be needed in stock over and above their regular hospital supply. Unfortunately, due to "just in time" stocking, most U.S. hospitals do not have a surge of supplies that may be used in a disaster. The Centers for Disease Control and Prevention has arranged a series of medication push-packs throughout the United States that can be delivered to any area of disaster within 12 hours (http://www.bt.cdc.gov/stockpile/index.asp). Once delivered, additional time is necessary to unpack the supplies and deliver the supplies to individual hospitals. The regional/local disaster plan must include a mechanism to unpack the push-packs, determine the hospitals in greatest need of individual items, divide the push-pack contents, and deliver the supplies to the hospital. This logistical issue makes it necessary for most hospitals to rely on their own supplies for a period of at least 96 hours.

ESTABLISH SUPPORT AREAS

Family Information Center During a disaster, families and friends will arrive at the hospital seeking information about victims. This convergence can seriously interfere with efforts of the hospital to respond effectively to the situation. For this reason, predesignate a separate area for family members seeking information. This area may also be used to discharge in-hospital patients and treated disaster victims.

Volunteer Coordination Center In major disasters, anticipate the potential for large numbers of volunteers, including those wishing to donate blood. Although some of these people may have appropriate clinical skills, they are unlikely to be familiar with the hospital functions and could be more hindrance than help. A separate place should be identified to handle these volunteers and, if appropriate, credential and decide how they may best be used. This area should include all equipment and personnel that are required to perform emergency credentialing (if appropriate and necessary).

Media Center Direct members of the media to a room or office of the hospital away from the ED and closely supervised by a hospital administrator or public information officer. Identify a single hospital spokesperson to relay information to the media.

DECONTAMINATION, TRIAGE, AND TREATMENT

Certain areas of the hospital must be designated for specific functions, including decontamination, triage, care of major and minor casualties, presurgical holding and surgical triage, psychiatric care, and morgue facilities. The plan should be quite specific as to the function of these areas, staffing requirements, and basic supplies to be used.

DECONTAMINATION

Perform decontamination in an area that is outside of the clinical care area of the ED.[4] Typically, this area is located external to the ED but may be in internal locations. Use the decontamination facility to remove clothing and cleanse the skin and hair of patients exposed to a chemical or radioisotope (**Table 5-7**).[10] Provide patient coverage and protection from the environment. Make sufficient

TABLE 5-7 Decontamination Guidelines

Decontaminate patients exposed to solids, liquids, vapors, or mists.
Patients exposed only to a fully dispersed gas need to be assessed for pulmonary symptoms and systemic toxicity and do not require decontamination. When uncertain if a substance is a gas or actually a vapor or mist, decontamination should occur.
Hospital personnel should have the **initial ability to decontaminate one patient at a time with a shower or hose system** while setting up a larger tent or a multiple-person decontamination system.
Perform decontamination outside of the ED in a way that prevents patients from entering the ED before decontamination.
Hospital personnel require level C personal protective equipment while performing decontamination. Higher levels of protection are not necessary and should only be used by hospitals that follow stringent training protocols and criteria, and use only personnel who have been specifically trained to use the equipment. **Sufficient equipment for multiple personnel and rotations of personnel in and out of the decontamination zone every 30 min is suggested.**
The first and a very effective method for decontamination is to disrobe, brush off solid dusts or powders, and wash and dry the face. Patient clothing and belongings should be individually bagged and labeled. Watches, earrings, body piercings, jewelry, and contact lenses should be removed. Hearing aids should be wiped with a moistened cloth and may be returned to patients after the decontamination procedure because the need to hear instructions outweighs any risk of wearing the hearing aid.
Warm water is the universal decontamination fluid. Hosing a patient from head to toe (or showering) for 5 min will decontaminate most ambulatory patients.
Patients with adherent materials will need additional scrubbing of hair and affected body parts with soap to remove these; medical assistance will be necessary in some circumstances. An additional check to ensure the removal of all earrings and body piercings should be done.
Young children need assistance and reassurance and should be decontaminated with the aid of a parent or guardian who can hold and reassure the child while medical personnel perform the decontamination.
After the decontamination procedure, provide hospital clothing (cloth or paper gowns) and triage patients to an area to await further assessment. Retriage patients with eye pain after whole-body decontamination for individual irrigation of their eyes with sterile normal saline. Patients with contaminated wounds will likely need additional irrigation of debris in wounds.
Contain runoff water from the decontamination to prevent environmental contamination.
Critical medical devices (infusion pumps, hearing aids, ostomy bags, etc.) may remain with the patient unless a high-risk chemical has been identified. Wash canes and walkers with soap and water or diluted household bleach and return to patients to ensure their mobility.
At least one radiation survey meter (e.g., Geiger-Muller counter) and staff that are trained in its use are necessary for events that potentially involve radioisotopes. Patients may need a radiation survey sweep before and after decontamination, and further decontamination may be needed until levels reach background radiation levels.
Staff involved in the decontamination process and systems need annual training and practice drills. Share an assessment of strengths and weakness learned from each drill with hospital personnel to improve preparedness and performance.

personal protective equipment available for hospital staff assisting with decontamination.

TRIAGE

Restrict patient entry to only one location—the triage area. The primary functions of a disaster triage area are rapid assessment of all incoming casualties or ill patients, patient registration and identification, the assignment of priorities for management, and distribution of patients to appropriate treatment areas in the ED and hospital.

TREATMENT

Patient care in disasters requires alteration of scale and sometimes location of clinical care, but staff should perform the clinical roles that are familiar to them. Several exceptions to this rule may exist (decontamination); however, in general, staff are more efficient at performing typical tasks quickly than learning new tasks in real time.

Organize patient care stations so that clinicians who are familiar with the assessment and treatment of the clinical problems may staff them. One suggested method of organizing patient care stations includes "resuscitation" and "minor treatment" areas.

RESUSCITATION

From the triage location, most, if not all, of the **seriously injured patients will be sent to the resuscitation area** (trauma and cardiac resuscitation, treatment of hypovolemic or septic shock, severe respiratory distress). This is usually physically located in the ED and staffed by emergency physicians.

MINOR TREATMENT AREA

In most disaster situations, the majority of patients are not very seriously injured. **These low-acuity patients can be sent to an "urgent care" area for definitive care**, including splinting of fractures, primary closure of lacerations, tetanus prophylaxis, and observation for delayed symptoms. This minor treatment area can be established in the hospital's outpatient clinics and staffed by the clinic physicians.

PRESURGICAL HOLDING AREA AND SURGICAL TRIAGE

Send trauma patients who are initially stabilized in the ED to the presurgical holding area for preoperative preparation and observation. **The number of operating rooms that can be staffed is the main limiting factor in the provision of definitive care for a large number of severely injured casualties.** The most experienced surgeon available should take the responsibility to prioritize cases and to rapidly assign surgeons to individual cases.

MENTAL HEALTH

In the event of a disaster involving mass casualties, and even property damage with loss of possessions, it is common for patients to present with episodes of anxiety and depression, or exacerbations of their psychiatric disorders.[11] Agitated patients, visitors, or staff can be extremely disruptive to hospital disaster operations. Consider a separate isolated area to receive individuals in need of psychological intervention. Include consideration for assessing patients and hospital staff who are psychologically affected by the disaster. Consider providing a critical stress response team, including social workers and psychiatrists, to provide support and critical stress debriefing.

MORGUE FACILITIES

Disasters can result in a large number of fatalities. Morgue capacities may need to be expanded to other areas of the hospital (medical school anatomy area, auditorium), enhanced by mobilization of local freezer trucks (this must be prearranged during the planning stage), or enhanced by federal assets (Disaster Mortuary Operational Response Teams). Viewing of deceased patients should take place here, not in treatment areas.

TERMINATING DISASTER RESPONSE (RECOVERY)

As soon as appropriate, direct efforts toward returning the hospital to normal operations. Besides restocking and cleaning, give consideration to the emotional stress experienced by both the EMS and hospital staff. In an attempt to reduce the psychological impact of these events on medical responders, a technique known as *critical incident stress debriefing* was introduced in 1993. The critical incident stress debriefing offers immediate emotional support to healthcare workers. Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction, resulting in improved patient care.[12] Provide all members who participated in the disaster, not just

medical personnel, the opportunity to participate in critical incident stress debriefing.

Carefully record and review deficiencies in a hospital's disaster plan that are revealed during a disaster, and write an after-action report. Take immediate steps to correct these flaws in the plan.

FIELD DISASTER RESPONSE

Elements of field disaster response are field triage and medical care, communications, distribution of casualties, and management of on-site disaster medical teams.

FIELD TRIAGE AND MEDICAL CARE

In the field, rescue personnel often use a simple triage and rapid treatment technique that depends on a rapid assessment of respiratory status, perfusion, hemorrhage control, and mental status. Patients are then triaged to immediate care, delayed care, or dead/dying.[13,14] Subsequently, determining how much and what type of care to administer at the disaster site depends on several factors. If the number of patients is small and there are sufficient prehospital personnel and transportation resources available, on-site medical care can proceed in a fairly normal manner, with rapid stabilization and transportation to nearby hospitals. When extrication will be prolonged, interventions such as fluid resuscitation and pain control should be instituted in the field. On the other hand, early, rapid transportation with a minimum of treatment should be practiced when there is danger to rescuers and casualties from fire, explosion, falling buildings, hazardous materials, and extreme weather conditions.

When patients are likely to have significantly delayed transport from a scene (e.g., number of casualties exceeds transportation capacity or damage to hospital infrastructure), the "Secondary Assessment of Victim Endpoint" triage system may be helpful to identify patients who are most likely to benefit from the care available under austere field conditions.[15] The Secondary Assessment of Victim Endpoint triage system is intended to triage patients into categories that reflect a balance between resource use and probability of survival. Category 1 includes patients who will die regardless of how much care they receive. Category 2 includes patients who will survive whether or not they receive care. Category 3 includes patients who will benefit significantly from austere field interventions.[15]

COMMUNICATION—DISASTER SITE TO HOSPITALS

The local emergency communications or emergency operations center should alert hospitals in the affected area of possible mass/multiple casualty situations or disasters. This report should include the total number of injured, the number of seriously injured (who may need intensive care unit capability), and the number for whom ambulatory treatment is sufficient. Hospitals should report to the local emergency communications center the following information: bed availability, number of casualties received thus far, number of additional casualties that the hospital is prepared to accept, and specific items in short supply.

DISTRIBUTION OF CASUALTIES TO RECEIVING HOSPITALS

Maintain good communication between hospitals and on-site EMS command in order to minimize unequal distribution of victims. **Alert the on-scene incident commander immediately of a potentially overloaded hospital.** In this situation, the less injured and more stable can be sent a further distance to outlying hospitals.

Casualties with special problems, such as major burns, carbon monoxide poisoning, spinal cord injuries, or victims of chemical or biological terrorism, may need to be transferred directly to specialized units, although it may not be possible for these units to accept a large number of ill or injured. For that reason, develop regional plans to allow for the care of specialty patients in nonspecialty hospitals.

MANAGEMENT OF ON-SITE DISASTER MEDICAL TEAMS FROM HOSPITALS

On-site disaster medical teams dispatched from local hospitals may be of value in situations in which victims require prolonged extrication; transportation routes are blocked, preventing easy evacuation to hospitals; or the number of casualties is of such magnitude that they exceed transportation capacities. Dispatch such a team with great caution. Physicians and nurses function optimally in an in-hospital setting. Few, however, are prepared to work under austere field conditions. Such hospital-based teams should probably not come from the ED staff until back-up staff has arrived to care for patients arriving from the disaster site or who are already present. Explicitly describe how such personnel are placed in action in the hospital emergency operations plan and coordinate with state and local agencies through memoranda of understanding.

Carefully map out the resources for such field response teams on a regional basis. At least one institution from each region should maintain an on-site triage team of physicians and nurses. The designated hospital should store disaster triage kits containing essential resuscitation and stabilization equipment for field use.

ED DISASTER RESPONSE

INITIAL RESPONSE

When a call is made to the hospital indicating the occurrence of a disaster or potential mass casualty–producing event, the incident must be verified by the appropriate predesignated official, who then puts the emergency operations plan into effect. In some events, the first sign of a disaster may be patients arriving at the hospital. In this case, contact the regional emergency communications center to notify the regional hospitals of the impending disaster and initiate the emergency operations plan.

This sets a series of activities into motion. The information obtained from the call is given to the charge nurse; the nursing and medical personnel in the ED are notified of the impending arrival of casualties; and the ED's plan for calling additional staff is activated. If hospital telephone communications have been completely disrupted, ED personnel may have to be reached by radio, cellular phone, e-mail, or television announcement. In many disasters, cellular phone and text messaging systems are quickly overwhelmed. Alternatively, a calling station remote from the hospital, such as at the residence of an administrator, physician, or nurse, may be able to handle this extensive calling job without taxing the hospital's phone system.

An initial needs assessment is conducted by the nurse and/or physician in charge, given the information available. They should evaluate the current status of the patients in the ED and make the appropriate disposition decisions. The ED physician or charge nurse becomes the on-site incident commander until the plan-designated incident commander arrives. **Among the decisions to be made are those related to the admission, discharge, or transfer of patients, and decisions about the priority of patient care.** Discharge all nonemergency patients from the ED with responsible individuals.

Based on the initial assessment, the number of patients that the department can receive is determined and communicated to the prehospital disaster communications center. The nurse and the physician in charge then assign staff to those areas in the department to be used during the disaster.

Take all available litters and wheelchairs to the ambulance entrance immediately on announcement of the disaster status. Patients from the disaster site are met at the receiving area by hospital escorts who assist the EMTs in transferring patients to wheelchairs or stretchers.

Place essential equipment, such as endotracheal tubes, IV fluids, cervical collars, splints, and bandages, near the ambulance entrance to permit convenient restocking of the ambulance (when plans call for ambulance restocking from hospitals) and rapid return to the disaster site.

SECURITY

Hospital security diverts nonessential vehicles and ensures a smooth, one-way flow of traffic to the ambulance entrance. Once patients, family, and media arrive, security is also responsible for protecting the treatment areas and inhibiting unplanned entry into the hospital.[4]

TRIAGE

Triage establishes priorities for care and determines the clinical area of treatment. Many seeking help will arrive independent of the EMS system.[3,4] **Triage will need to be performed at the ED entrance even if it was done at the scene.**

Triage category is identified by use of a colored band or trauma/disaster tag that is placed on the patient to document that triage has been done.

The approach to patient evaluation and treatment is quite different when dealing with disaster situations that result in high casualties.[16] To accomplish the most good for the most number of patients, the triage team should evaluate all patients arriving at the ED and classify their condition with regard to severity of injury and need for treatment. Some principles of medical care must be altered to achieve the best overall result. Patient care at triage should be limited to manually opening airways and controlling external hemorrhage.

The most common triage classification in the United States still involves assigning patients to one of four color-coded categories (red, yellow, green, or black), depending on injury severity and prognosis (Table 5-8). In addition to the nature and urgency of the patient's systemic condition, triage decisions should be sensitive to factors affecting prognosis, such as age, general health, and prior physical condition of the patient, as well as the qualifications of the responders and the availability of key supplies and equipment.

Catastrophically injured patients who have a minimal chance for survival despite optimal medical care should be classified as "expectant" ("black": to include patients with burns involving 95% body surface area, and patients in full cardiac arrest or septic shock). Devoting time and resources to patients who are not likely to live jeopardizes other patients who are truly salvageable. The goal with these "expectant" patients should be adequate pain control and the opportunity to be with friends and family.

TRIAGE TEAM

A team consisting of an emergency physician, an ED nurse, and medical records or admitting clerks should receive every patient. In extraordinary situations, several triage teams may be required to handle the casualty load. Acknowledge the physician performing hospital triage as being in command of the triage area (clearly identified by a specially colored vest or other garment) and understanding all triage options.

Assign one member of the triage team (admitting or medical records clerk) the job of recording the victim's name on the disaster tag along with the triage destination within the hospital. If identification of the patient is not available, ethnicity, gender, and approximate age should be noted on the tag. An initial diagnostic impression should also be registered on the tag. This information is entered into a department log or into the electronic medical record, if possible. In some patient tracking systems, a scan of the bar code on the disaster tag may allow for immediate registration by disaster tag number and open an electronic medical record. Additional care can be recorded in the electronic medical record or in a paper disaster chart and kept with the patient at all times and later scanned into the electronic medical record.

TABLE 5-8 Triage Categories

Red
First priority
Most urgent
Life-threatening shock or hypoxia is present or imminent, but the patient can likely be stabilized and, if given immediate care, will probably survive.
Yellow
Second priority
Urgent
The injuries have systemic implications or effects, but patients are not yet in life-threatening shock or hypoxia; although systemic decline may ensue, given appropriate care, can likely withstand a 45- to 60-min wait without immediate risk.
Green
Third priority
Nonurgent
Injuries are localized without immediate systemic implications; with a minimum of care, these patients generally are unlikely to deteriorate for several hours, if at all.
Black
Dead
No distinction can be made between clinical and biological death in a mass casualty incident, and any unresponsive patient who has no spontaneous ventilation or circulation is classified as dead. Some place catastrophically injured patients who have a slim chance for survival regardless of care in this triage category.

ED DISASTER PATIENT CARE

Disaster care concepts often vary from the typical ED routine. Care that is not immediately time sensitive can be provided the next day. For example, wounds may benefit from delayed closure after copious irrigation due to delayed presentations or gross contamination. In the event of prolonged extrication from rubble, assess for delayed signs and symptoms, including cardiac dysrhythmias, hyperkalemia from crush injury, renal failure, and pulmonary blast injury.

Terrorist-related or industrial explosive events may lead to medical conditions or exposure to chemicals that are not familiar to clinicians.[4] Patients may require prolonged observation (e.g., exposure to phosgene or ricin) or unique testing. For infectious exposures, the Centers for Disease Control and Prevention and local/state public health agencies can guide testing, observation time, and treatment. Immediately contact the local public health agency if a biological terrorist agent or a rare and potentially fatal infectious disease is seen or suspected in the ED. In the event of a chemical agent, the Carolinas Poison Center (1-800-222-1222) can provide information and guidance on whether decontamination is necessary, as well as testing, observation time, and antidotal or supportive treatment. Fact sheets on biological, chemical, and radiologic agents are available at http://www.bt.cdc.gov.[4,17]

Use radiographic and laboratory studies sparingly, if at all, in a mass casualty situation, and only if the results of such tests will change treatment. For example, possible closed, nonangulated fractures can be splinted, and radiographs can be safely delayed for 24 to 48 hours. A chest radiograph may be appropriate in those patients complaining of chest pain, dyspnea, or abnormal chest wall motion, or who were potentially exposed to blast waves secondary to bombs. CT imaging may be quicker than plain radiographs in some injuries, and prioritization to CT may be required. Ultrasonography to detect free intraperitoneal fluid, pericardial fluid, and pneumothorax is time- and cost-effective, and has been used in earthquakes to triage operative care.[18]

With the exception of identification of biological and chemical agents, there are few indications for laboratory testing in disaster medicine. If testing will change management, use point-of-care testing to expedite care. For example, obtain a baseline hematocrit and type and crossmatching for blood in cases of hemorrhagic shock. Pulse oximetry monitors may need to be used as spot assessments, rather than continuous bedside monitoring of a single patient. Consider laboratory studies to be accessory and ordered only in specific circumstances (carboxyhemoglobin in cases of smoke inhalation).

In a disaster situation involving many casualties, the blood bank should have up to 50 units of blood available and should have access to volunteer donors who can be rapidly mobilized. Potential donors include friends and family members of patients, as well as mildly injured patients.

CHAPTER 6

Natural Disasters

Lisa D. Mills
Trevor J. Mills

INTRODUCTION AND EPIDEMIOLOGY

Natural disasters continue to be an unpredictable source of worldwide morbidity and mortality and present unique challenges for practitioners of emergency care. The 2002 to 2011 annual average worldwide mortality rate was 107,000 deaths/year from natural disasters, with an average of 268 million worldwide victims per year during the same time period and an economic cost of $143 billion in 2012.[1] With the increase in rapidly mobilized recovery teams, emergency physicians are at the forefront of patient care following a natural disaster. It is here that we can have the greatest impact in treating survivors and minimizing secondary morbidity and mortality, often in the setting of a significantly impaired healthcare system. Research suggests that the burden of natural disasters is likely to rise in the coming years, due to increasing population density in high-risk areas and risks associated with expanding technology (e.g., fires or earthquakes in larger and taller buildings or critical infrastructure).[2]

Although the mechanics, warning period, and impact vary widely between types of natural disasters, there is a predictable pattern of events that occur and may be used to maximize the subsequent response. Natural disasters result in a combined loss of resources—infrastructure, economic, social, and health. While this may be tempered by pre-event preparedness and infrastructure strength, this combination of resource loss has a synergistic impact on the health of and the delivery of health care to the affected population. Another commonality is the predictable pattern of pathology, seen in the progression from the impact of the event itself, through the acute aftermath, to the immediate postdisaster phase, into the recovery phase (**Table 6-1**). Perhaps most salient for emergency practitioners, relief efforts can be implemented based on data from previous disaster experience, while simultaneously being tailored to the type of disaster (e.g., hurricane, earthquake, tornado, flood, tsunami, or snow) and region affected. Finally, disaster responders should be prepared to face the duty of management of dead bodies, on a scale otherwise only seen in the setting of combat.

LOSS OF RESOURCES

Most natural disasters—whether by water, wind, fire, or snow—cause some disruption of power, communication, and transportation systems. In developed and developing nations, entire cities can be destroyed instantly, overwhelming nearby healthcare facilities and personnel. In such cases, the traditional triage system may not be effective.[3] A Centers for Disease Control and Prevention posthurricane assessment in 2012 determined that most of the resulting public health emergencies were directly due to loss of public health infrastructure and related to clean up and repair activities.[4] Because standard amenities, such as power, running water, and sanitation methods, may be unavailable for extended periods of time, all medical disaster planning must include practical, simple alternatives to technologies that are likely to fail during a disaster.

Lack of communication is a common feature of both the impact and delayed phases of a disaster. Even the most sophisticated equipment may fail due to regionwide outages or loss of electricity for charging devices. In our experience during the active phase of Hurricane Katrina, the only working means of communication within Charity Hospital was a single landline telephone. Difficulty in communication has led to recent innovation with proposals for disaster-specific electronic medical records.[5]

Evidence suggests that the predisaster level of preparedness and resources in a community has a significant impact on its response to a catastrophic event. Analysis of four earthquakes in different regions (developed and developing countries) found that regions with the least preparedness and weakest preexisting medical infrastructure had the highest number of deaths per patients injured.[6] Investment in targeted disaster preparedness efforts before an event occurs, particularly for the most vulnerable populations, is crucial in mitigating the effects of an inevitable disruption in resources during a disaster.[7]

DISEASE BURDEN

Understanding of the likely health emergencies to be encountered in the acute and postdisaster phases is crucial to any emergency response. Although it is widely thought that outbreaks of rare and/or severe disease inevitably follow many types of natural catastrophe, evidence does not support this belief.[8,9] Common medical problems after natural disasters include traumatic injury, infectious disease, exacerbations of chronic medical conditions, and a surge in mental health issues (**Table 6-2**). In addition to the common medical problems previously listed, the handling of bodies has an additional unique impact on the health of the affected population.

TRAUMA

Traumatic injuries frequently occur in the acute phase of a natural disaster, commonly from direct trauma from collapsing structures or flying debris. A second spike in trauma is seen during the recovery/clean-up phase, mainly due to unsafe infrastructure. However, this secondary spike in trauma may also include violent injuries, depending on the level of civil unrest.[10] Although most trauma is minor, management of severe injuries by healthcare professionals can prove especially challenging when resources are lacking, as they often require coordinated surgical care. **This necessitates adequate resources of anesthesia, blood products, surgical equipment and the ability to sterilize it, intensive care capacity, and operating theaters.** When these resources are unavailable, limb amputation, nonunion, and missed injury rates are high, and lack of safe blood products hampers surgical capability.[11,12] Recommendations for adequate surgical capability include mobile blood banks with adequate supply and well-trained staff, at least two units of blood available per operation, adequate supplies of appropriate anesthesia, strict adherence to national or international quality and safety standards, and functioning critical care units.[3,12,13]

INFECTIOUS DISEASE

Infectious diseases are commonly feared and should be anticipated after natural disasters. Although popular media often focuses on the possibility of rare disease epidemics, most postdisaster infections are directly related to the usual pathogens of that region.[9,14] One exception to this was the outbreak of cholera after the 2010 earthquake in Haiti, which is believed to have been brought in by United Nations relief workers.[15] Evidence indicates that the combination of communicable disease and population malnutrition is the major cause of morbidity and mortality in most disasters. Infectious disease predominantly occurs in the extended postevent phase.[16] Infectious disease risks are heightened by certain characteristics common to natural disasters: mass population

TABLE 6-1 Timing of Disease Presentation

Timing of Onset	Presentation						
Acute phase	Trauma	Stress reactions	Drowning	Inhalational injury	Burns		
Immediate postevent phase	Infectious complications of trauma	Exacerbation of chronic disease	Acute stress disorder	Burns	Inhalational injury		
Recovery phase	Trauma	Communicable disease	Infectious complications of trauma	Soft tissue infections	Exacerbation of chronic disease	Vectorborne disease	Posttraumatic stress disorder

TABLE 6-2 Common Disease Patterns

Trauma	Communicable Disease	Chronic Medical Conditions	Infectious Disease	Mental Health
Strains and sprains	Respiratory infections	Hypertension	Soft tissue infections	Stress reactions
Falls	GI infections	Diabetes	Open fractures	Depression
Lacerations		Renal failure	Vectorborne disease	Exacerbation of chronic condition
Burns		Chronic obstructive pulmonary disease	Local diseases	
Fractures				

movement and resettlement; overcrowding; poverty; sanitation and waste issues, including water contamination; absence of shelter, food, and healthcare access; and disruption of public health programs. Respiratory, GI, skin/soft tissue, and vectorborne infectious diseases are most commonly analyzed in disasters.

Respiratory illnesses range from direct aspiration of contaminated water (floods and tsunamis) to airborne droplet transmission to inhalation injuries caused by excess dust or debris. Although most infections are mild, respiratory illness may account for 20% of all natural disaster deaths in children <5 years old.[13] In the acute phase of a flood or tsunami, inhalation of water with polymicrobial contamination may cause aspiration pneumonia.[17] Most respiratory outbreaks, however, emerge several weeks after disaster as disease spreads through shelters and settlement camps. **Both disaster victims and rescue workers are at risk for respiratory illness due to crowded conditions and compromised sanitation.**[18,19] Some respiratory illnesses (pertussis and measles) are preventable with adequate vaccination; thus, knowledge of the predisaster vaccination status of a population and sufficient vaccine stores may prevent severe outbreaks. Tuberculosis presents a special challenge for public health officials. To prevent outbreaks, adequate stores of antimicrobials must be on hand, and strict adherence to surveillance of known infectious cases is essential.[9]

GI illness—primarily diarrheal—is another common feature of postdisaster health care. Approximately 40% of deaths in the acute postevent phase (with 80% of these being children) can be attributed to diarrhea. These diseases are mainly due to issues of water quality and availability, sanitation, and cleaning materials; in one study, the mere presence of soap decreased diarrhea by 27% in a refugee camp.[16] As with respiratory illness, the incidence of GI disease often peaks several weeks after the disaster, and the infections are generally mild. With good health surveillance and attention to typical endemic disease patterns, severe GI illness outbreaks requiring extraordinary public health resources are rare.

Skin and soft tissue infections are seen in a variety of natural disasters. Falling debris from wind, fire, or earthquake can cause traumatic abrasions or lacerations. With a disrupted healthcare system or contaminated water exposure to the wound, the incidence of infection is likely to increase. Although wounds are frequently seen in the acute phase of a disaster, they are also often encountered during the clean-up phase several weeks to months after an event.[20,21] Severe infections are not prevalent; however, organisms such as *Vibrio vulnificus* in water-based disasters and gram-negative bacteria due to soil contamination of wounds in tornadoes and earthquakes have the potential for severe threats to life and limb.[9,22]

Vectorborne illnesses, such as yellow fever, malaria, and dengue fever, generally have a higher incidence during water-based disasters but can occur after any event in a vulnerable population. Although rare, the outbreak can occur up to 8 weeks after disaster.[13] Regions without predisaster populations of vectors or disease are not likely to suddenly acquire such infections; thus, although there was intense media speculation of the perceived risk of malaria, yellow fever, and other vectorborne illnesses after Hurricane Katrina, these illnesses were not seen in the Gulf Coast.[9] In regions where these illnesses are endemic, vector control is key, and initial postdisaster public health efforts should direct resources toward appropriate programs.

TABLE 6-3 Commonly Neglected Disaster Response Medications and Supplies

Antihypertensives
Tetanus prophylaxis
Soap
Analgesics—oral and parenteral
Insulin
Oral hypoglycemics and sulfonylureas
Antibiotics, especially for soft tissue infections
Albuterol and ipratropium inhalers

CHRONIC MEDICAL CONDITIONS

Management of the chronic health conditions of a displaced population is a significant contributor to postdisaster morbidity. Separation from medications or health technology products, removal from the usual sources of care, and disruption of the healthcare infrastructure after a catastrophic event can all contribute to exacerbations of patients' chronic disease. In an analysis of patients presenting to one of the few healthcare facilities available in the 2 months after Hurricane Katrina, 51% of all native patients had at least one preexisting medical condition, and half took at least one regular medication.[20] Other studies have shown that >25% of patients presenting after a variety of natural disasters have chronic medical conditions, and "medication refill" or "chronic medical problem" is frequently among the top five diagnoses made in disaster relief health clinics.[21,23]

Inability to properly control chronic diseases, such as hypertension, diabetes, asthma, or coronary artery disease, may well be the biggest unanticipated health threat to a postdisaster population (Table 6-3).[7] Understanding of the common chronic diseases of a region is essential for health relief efforts. In our experience, well-meaning donations of medications for conditions not normally experienced by our population (e.g., outdated psychiatric medications, older generation antiarrhythmics) went unused. Conversely, we were unable to keep enough antihypertensives or diabetic medications to supply the vast demand.

MENTAL HEALTH

An often-overlooked consequence of natural disasters is the psychological burden inflicted on survivors. Destruction of communities and property, witnessing terrifying and often fatal events, and disruption of normal life for days to years after the disaster can cause severe mental health consequences in survivors. In one study of post–Hurricane Katrina survivors, rates of posttraumatic stress disorder were 10 times the expected population incidence and on par with rates in returning Vietnam War veterans.[24] Psychological disorders may be exacerbated by lack of housing and illness or death of a close family member due to the disaster.[25] Disaster-related physical injury or illness may also contribute to mental health comorbidity. The number of emergency amputations due to the 2004 tsunami in an Indonesian surgical clinic quickly overwhelmed the ability of the healthcare system to provide the necessary psychological counseling for patients.[26] Conversely, mental health conditions, such as major depression, may exacerbate acute or chronic physical ailments due to weakened immune systems, disconnection with the larger community and healthcare systems, or attempts to cope by using drugs or alcohol. Suicide rates may also be elevated years after a significant disaster. Any appropriate healthcare response to disasters must include sufficient resources to deal with the degree and severity of psychological disorders suffered by survivors, including children, first responders, and those who have endured severe trauma or loss.

HANDLING OF BODIES

Any natural disaster with a significant number of casualties requires efficient and sanitary removal and proper burial of dead bodies. Although the fear of disease outbreak from survivor or rescue worker exposure to corpses is prevalent, such exposures are rare. Most initial victims of natural disasters die of traumatic injuries; few are likely to

have acute, communicable diseases, although the standard transmission risks of chronic infectious diseases, such as human immunodeficiency virus, tuberculosis, or hepatitis, to body-handling rescue workers are present.[27] Universal precautions for protective coverings, hand washing, disposal bags, and vaccinations should be followed by anyone working with dead bodies; this includes having sufficient refrigerated trucks on standby should morgue capabilities be overwhelmed.

HURRICANES

Hurricanes are among the most destructive natural disasters, particularly in coastal areas. Morbidity in the acute phase may be due to wind forces (collapsing buildings or flying debris) or water (storm surge or rapid flooding). Hurricanes tend to cause more structural damage than floods and therefore can disrupt infrastructure and population resettlement more severely.[28] Hospitals themselves are frequently damaged, but even if structurally intact, they may be affected by loss of power.[29] With catastrophic destruction of a densely populated region, such as in Hurricanes Katrina and Sandy, temporary medical facilities may be needed months after a disaster. **Indeed, hurricanes may be the only natural disaster where more injury and death occur during the recovery period than in the acute phase.**[30]

Most posthurricane illness and injury falls into predictable categories. Studies from eight different hurricanes over the last 15 years all list a handful of patient diagnoses that comprise the vast majority (up to 75%) of visits to healthcare centers: infections (specifically respiratory, GI, and skin); treatment of chronic medical conditions; wounds and lacerations; musculoskeletal injury and trauma; and rashes.[19,20,28-34] In functioning healthcare facilities, ED visits peak several days to weeks after the hurricane as citizens are allowed reentry into the area; there may be an acute, brief influx of several times the normal patient volume or a steady rise in visits over time.[5,20,31]

Initial traumatic injury directly due to hurricanes is relatively uncommon, and simple supplies for minor sprain, strain, and fracture care are recommended. Although surgical units and personnel are an important adjunct, basic supplies and some radiographic capability may provide the best investment of limited resources.[28,30] Unintentional injuries predominate; a post–Hurricane Katrina evaluation of injuries found that only 2% were due to intentional trauma.[18] Causes of traumatic death in the acute period include falling objects, motor vehicle crashes, and electrocution. In the recovery period (weeks to months after the hurricane), clean-up–associated trauma predominates. One study after Hurricane Hugo found that one third of all wounds evaluated in an ED were caused by chainsaw accidents.[32]

As with other disasters, infections are generally mild, reflective of the typical local disease burden, and occur several weeks to months after the hurricane. Scattered outbreaks of mild respiratory and GI illness have been described, with overcrowding in shelters and sanitation issues the main predictors of disease. Unless hurricanes are associated with concomitant prolonged flooding in endemic areas, the risks of waterborne disease are minor. Post–Hurricane Katrina incidence of *V. vulnificus* skin infection was consistent with typical nondisaster rates.[9]

Individuals without transportation or with tenuous connection to community resources are potentially more likely to be negatively impacted by the effects of a severe hurricane. These individuals may not be able to evacuate in advance of a storm and thus suffer greater risks of direct trauma and water- or wind-related morbidity during the initial impact. Effects may persist beyond the acute phase. A study of Hurricane Mitch survivors noted that GI illness and emotional distress were more likely months after the storm in those without access to housing, food, or medical care.[25] Other population concerns often seen in hurricanes include the healthcare burden of relief workers (civilian and military). Recovery efforts often require massive numbers of workers whose living conditions are often on par with storm victims. In one study, relief workers were nearly six times more likely than natives to use nonhospital healthcare facilities, and a spike in respiratory illness was attributed to transmission through a military battalion.[18] Our experience found that although younger than the native population, nearly half of relief workers seeking care had significant comorbidities that further burdened the struggling medical system after Hurricane Katrina.[20] Disaster planning should account for the needs of disenfranchised citizens as well as the expected influx of relief workers, many of whom may have chronic medical conditions.

EARTHQUAKES

Earthquakes are a unique disaster phenomenon in that there is no technology to detect a pending earthquake and thus no opportunity to provide a warning. Due to the lack of warning, supplies and a response plan must be continuously available. As was evidenced by the Haiti experience in January 2010, earthquakes can destroy water, electric, communication, gas, and sewage lines and cause structural instability. With no opportunity to evacuate before an earthquake, there is increased potential for casualties. People are at increased risk for being trapped in rubble or stranded. The first 1 to 14 days of response to an earthquake are dedicated to recovery of the injured. After an earthquake, the majority of fatalities occur within the first 3 hours.[35]

Injuries after earthquakes are the result of falling structures and debris. The most common injuries are fractures and crush injuries.[36,37] One hospital that registered 2892 patients after an earthquake reported that 37% of patients had musculoskeletal injuries. This hospital also reported the frequent occurrence of scalp injuries with large tissue defects.[36] Another hospital that registered 1500 patients in the first 72 hours after an earthquake reported that 78.4% of patients had extremity injuries; 50.4% of injuries were fractures, primarily closed. This same study reported that 37% of injuries required extensive debridement.[12] After the Mansehra earthquake in Pakistan in 2005, the medical equipment that the response teams found most useful was "external fixators that are easily applied."[36]

As with all disaster areas, the most common "illnesses" are the "regular medical needs of the people living in the earthquake zone."[36] In undeveloped regions recovering from large earthquakes, "preventable diseases, such as measles, are on the rise."[37] With proper sanitary and sewage techniques and adequate supplies of potable water, GI disease remains uncommon.

People with compromised mobility, including some geriatric patients, people with paralysis, amputees, people on ventilators, and people in wheelchairs and walkers, will be less likely to evacuate before the disaster and will have increased difficulty extracting themselves from the ruins. These people are more likely to be stranded in debris and to sustain crush injuries (also see chapter 7, "Bomb, Blast, and Crush Injuries") by collapsing buildings. These populations are especially at risk after earthquakes, because there will be no opportunity to evacuate before the disaster. Rescue and health services coordinators should make provisions for larger numbers of patients with increased needs after earthquakes. One study analyzed a metropolitan area in the United States and found that 31.6% of people >65 years old had a disability and 16.6% of people >65 years required assistance to evacuate. Planning for and responding to earthquakes requires an estimate of the number of citizens with special needs.[38]

TORNADOES

The continent of North America sustains more tornadoes than any other location in the world.[39] Nationally, 800 tornadoes are sighted annually. The annual human toll is estimated to be 80 deaths and 1500 injuries.[40] Tornadoes cause focal damage to buildings and lines above ground. It is unusual for entire regions to lose power and communications capacity. It is unusual for multiple hospitals to be disabled by a single tornado.[41,42] As a result, medical infrastructure in developed countries remains functional. Surge capacity may be tested in the immediate aftermath, but the provision of adequate chronic medical care is usually unhampered.

Most commonly, injuries from tornadoes result from being struck by flying debris or being thrown by the force of the tornado. Patients who were thrown or airborne as a result of the tornado sustain more severe injuries than patients who are struck by debris.[43,44] Additional risk factors for hospitalization or death include being struck by broken glass or falling objects, having one's home lifted off of its foundation, collapsed ceiling or floor, or loss of walls of the shelter structure.[44,45] Injuries are

commonly multisystem. Fractures and soft tissue trauma are the most common injuries reported.[39,46-48] In one study, most patients (91%) sustained injuries to the extremities. Head, chest, and abdominal injuries were also common, occurring in 45%, 45%, and 27% of patients, respectively.[43] Head injuries are the more common cause of death.[39,47,48] Death from the impact after being thrown by the tornado is thought to most often occur at the scene, rather than en route to or at the hospital.[49-51]

Wound contamination is common among patients who are thrown by the tornado. Polymicrobial contamination is common.[39,46] Gram-negative organisms commonly infect the wounds of those injured by tornadoes.[43] Studies that report low infection rates attribute this to meticulous attention to open wounds.[52]

Where functioning tornado warning systems exist, injury and loss of life are dramatically reduced.[40,53] People in mobile homes or outdoors without cover are more likely to sustain severe and fatal injuries during a tornado.[45,53,54] Deaths are more common in patients who are in mobile homes or in rooms above ground with windows, who are "older," or who have less warning regarding the approaching tornado.[43,44,48,49,55] Use of a tornado shelter is associated with a significant reduction in tornado-associated injuries.[54]

FLOODS AND TSUNAMIS

Water-based natural disasters, such as floods and tsunamis, can be extremely destructive. Although floods can occur from a storm or flowing body of water, tsunamis are formed when a massive force (for example, an underwater earthquake, volcanic eruption, meteorite impact, or landslide) displaces a large amount of water in a rapid period of time. A spring flood of the Yangtze River in China in 1931 caused >3 million deaths, and more recently, deaths from the Indian Ocean tsunami in 2004 approached 300,000. Factors that contribute to the catastrophic nature of these events include the short (if any) warning period to vulnerable populations and their association with other natural events, such as an oceanic earthquake resulting in a tsunami. Key challenges faced by healthcare providers include severe and prolonged incapacitation of physical buildings due to structural damage or persistent standing water; handling and identification of large numbers of dead bodies; and the chronic needs of a large, displaced population in temporary shelter.[26,56,57]

Acute injuries may be caused by sheer force of water, drowning, and trauma from falling objects. A review of flood deaths from 1989 to 2003 found that morbidity and mortality after flood were related not only to direct physical impact but also the socioeconomic conditions of the affected area. Two thirds of fatalities were from drowning, mostly associated with motor vehicles in the acute phase (e.g., when floodwaters are still high); low crossings and bridges were most dangerous. Only 12% of deaths were from trauma, and the vast majority of cases occurred in the initial impact phase of the disaster.[58]

Illnesses from water-based disasters generally occur after the acute phase and are dominated by infectious disease. True epidemics are rare, and respiratory illnesses predominate. These are generally minor and self-limited, although uncommonly severe pulmonary infections or pneumonitis directly related to aspiration of floodwaters (e.g., "tsunami lung") may occur. As long as clean, safe, adequate supplies of potable water are available, acute gastroenteritis and diarrheal illnesses are relatively rare; a Sri Lankan refugee camp after the 2004 tsunami diagnosed GI complaints in <1% of patients.[23] Minor skin trauma is common and has the potential to progress to infected wounds if prolonged exposure to floodwaters and delayed access to care are present.

Certain population groups have been shown to have higher risks of morbidity and mortality after floods and tsunamis. Women had three times the risk of death compared with men after the 2004 tsunami due to heavier clothes impeding escape, risking lives to save their children, lack of swimming ability, and increased dangers in settlement camps.[26] In a comprehensive study of flood deaths, however, men had more than twice the mortality rate of women, which the authors surmised was due to increased risk-taking behavior during the storm (attempting to drive through flooded passages, traveling to unsafe areas in an attempt to retrieve belongings).[58] Public awareness of the rapidity and danger of water, simple swimming instruction, and clear warnings of the dangers of driving during floods may prevent at-risk populations in flood-prone areas from loss of life in future disasters.

BLIZZARDS AND SNOW DISASTERS

A blizzard is a winter storm with wind speeds of 35 miles per hour or higher accompanied by significant falling or blowing snow. The Mid-Atlantic, New England, Midwest, Plains, Rocky Mountain states, and Alaska are affected by blizzards and snow disasters. Above-ground power and communication lines are the primary resources lost during winter storms. Traditionally, these are restored relatively quickly as compared with the duration without resources after other natural disasters.[59]

Generally, ED volumes do not significantly increase after blizzards and snow disasters. However, there is a shift in the presenting complaints.[59-61] Injuries after winter weather disasters most commonly result from slipping on the ice, falling from trees while clearing branches, and injuries from clearing snow. The most common injuries are back injuries and fractures.[62,63] In one study, the incidence of fractures increased until the sixth day after the storm.[64]

Carbon monoxide poisoning increases dramatically during and following winter weather disasters.[60,62,65-68] Most people presenting with carbon monoxide poisoning report using a portable generator.[69] A smaller group reported burning charcoal in the house to generate heat.[65] In one study after a blizzard, the local hyperbarics services were overwhelmed and unable to respond to the sudden surge in carbon monoxide poisonings.[62]

One study documented an increase in the number of myocardial infarctions and angina after a blizzard. This was primarily in association with shoveling snow. The majority of these cases were in people who did not have previously diagnosed coronary artery disease. One fourth of these patients were women.[70]

RELIEF EFFORTS

Of particular importance to the emergency medical practitioner is the experience and effect of postdisaster volunteer relief efforts. Although well meaning, the literature is filled with examples of emergency personnel who ended up burdening rather than assisting a fractured community. Any emergency practitioner who truly wishes to provide meaningful health care to a displaced and disenfranchised patient population should be mindful of the lessons learned from a variety of natural disasters.

Medical relief volunteers are often the first outside help to arrive in the aftermath of a disaster, and although some are well coordinated, many are not. Volunteers are often exuberant, expecting dramatic rescues and emergency interventions. They may be unwilling to provide much-needed routine medical care, unfamiliar with the region or local disease patterns, and unable to fully comprehend the loss of resources.[71] Furthermore, the needs of rescue personnel often strain a fragile infrastructure, with demands on housing, food, health care, and essential resources; one analysis of relief efforts after the 2004 tsunami concluded that "personnel who do not bring essential skills are often a burden—much more should also be done to ensure that the right type of people are sent on relief missions."[26]

Embedding locals familiar with the language, culture, and healthcare patterns of the affected region can significantly enhance the effectiveness of relief efforts and promote cooperation between disparate volunteer groups. Furthermore, appropriate anticipation by relief groups of the true population needs can be crucial: reproductive hygiene kits were distributed to women in a postflood refugee camp after an initial spike in sexual assaults and were widely credited with improving patient morale and health.[26]

The National Disaster Medical System, a government agency responsible for sending highly organized and often experienced teams to disaster areas, recommends the following for disaster response: teams with well-trained and organized support staff; the ability to be self-sufficient for at least 72 hours; clear communication with area hospitals and medical resources; individuals dedicated to transportation issues; a

designated coordinator of walk-in volunteers; and professional methods of record keeping, forms, and copy-making capability.[30] Our experience during Hurricane Katrina also suggests that strong, coordinated partnerships between local emergency personnel and formal military medical units have great promise for sophisticated, expanded acute and delayed postdisaster medical relief as well as continuance of medical education and resident training programs in a devastated community.[20]

CHAPTER 7

Bomb, Blast, and Crush Injuries

Michael J. Bono
Pinchas Halpern

BOMB AND BLAST INJURIES

EPIDEMIOLOGY

Blast injuries using conventional weapons have emerged as the terrorist weapon of choice. Terrorist attacks have increased dramatically over the last decade. The National Counterterrorism Center reported more than 14,000 terrorist attacks in 2007, with 44,000 injuries and 22,000 deaths, which was a 20% to 30% increase over 2006.[1] Explosive devices in military conflicts have killed or injured more than 25,000 U.S. and Coalition forces and more than 100,000 Iraqis.[1] Blast injuries are increasing in the civilian setting, particularly suicide bombings, and emergency personnel must be familiar with the management and treatment of blast injuries, ad potential mass casualty incidents.[2-9] The United States is not immune from intentional bombings, with about 36,000 bombing incidents reported from 1983 to 2002 - including explosive, incendiary, premature, and attempted bombings.[6] There were 281 injured in the 2013 Boston Marathon bombing, with most injuries involving the lower extremities and soft tissue.[8] Death, survival, and hospitalization rates vary greatly, depending on the type of explosive, distance from the explosion, and whether the explosion occurred in an open or closed space. Although some victims die immediately at the scene, the majority of injuries suffered by the immediate survivors of bombings are potentially survivable. Blast injuries commonly occur not as isolated incidents, but as part of multiple-casualty incidents of varying sizes. This pattern, combined with the fact that most emergency physicians have never encountered a blast injury victim or a true mass casualty incident, makes the care of often eminently salvageable victims contingent upon appropriate training and skill retention by the individual emergency physician, along with appropriate institutional leadership, planning, and preparation.

Terrorist bombings result in high injury scores for victims as well as higher hospital resource use by victims than by victims of other trauma. Blast victims have increased immediate scene mortality, greater hospital mortality, more frequent need for surgical intervention, longer hospital stays, and greater use of critical care.

PATHOPHYSIOLOGY

An explosion is the instantaneous transformation of a solid or liquid into a gas, releasing tremendous kinetic and heat energy. Detonation of a conventional high explosive generates a blast wave that spreads out from the detonation point and displaces air, water, or anything in its path. The blast wave consists of two parts: a shock wave of high pressure followed closely by a blast wind, which is air mass in motion. The blast wave loses its energy over distance and time.

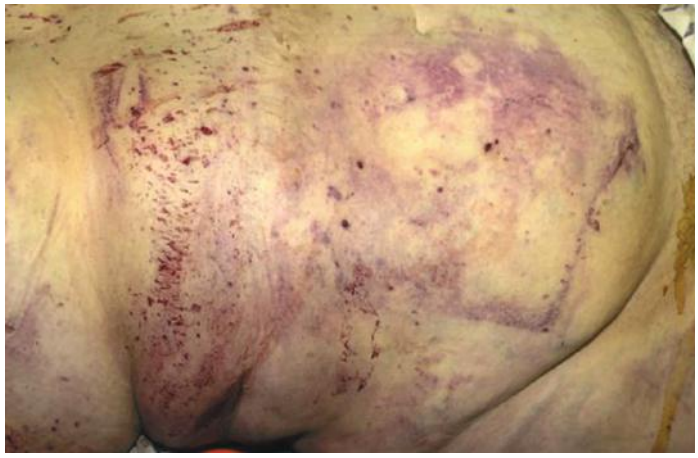

FIGURE 7-1. Secondary blast injury to the chest and abdomen due to flying debris. It is difficult to assess the degree of underlying internal organ injury without imaging and careful clinical follow-up, especially if the patient is unconscious. [Image used with permission of Tel Aviv Medical Center.]

BLAST INJURIES

There are four main types of blast effects. A primary injury is caused by a direct effect of blast wave overpressure on tissue. Primary blast injury mostly (but not exclusively) affects air-filled structures such as the lungs, ears, and GI tract, by the following mechanisms: spalling, shearing, and implosion. Spalling is displacement and fragmentation of a dense medium into a less dense medium.[10] An example is a blast wave causing the lung parenchyma to explode into the alveolar space like a geyser. Shearing, sometimes called inertia, is a stress caused by the blast wave traveling through different tissue densities at different velocities. An example of shearing is the blast wave traveling through the pulmonary vessels and air spaces, resulting in ruptured vascular and bronchial pedicles. Implosion is the opposite of spalling, where the less dense material is displaced into denser material. An example of implosion is the blast wave causing the flexible air spaces to rebound to greater than original size, sometimes causing air embolism from the alveoli into the pulmonary vessels.[10] A secondary blast injury is due to collateral damage from flying objects and shrapnel (**Figures 7-1 and 7-2**). Tertiary blast

FIGURE 7-2. This young patient came in fully conscious and hemodynamically stable. Multiple externally visible shrapnel wounds required imaging. This x-ray image shows severe lung injury due to shrapnel. She also suffered multiple abdominal injuries, including major liver lacerations and bowel perforations, and required extensive surgery. [Image used with permission of Tel Aviv Medical Center.]

injury results from the victim being propelled through the air and striking stationary objects. A quaternary blast injury is a result of burns, smoke inhalation, or chemical agent release.

FACTORS AFFECTING BLAST INJURY

The effects of a bomb blast are difficult to predict in the individual victim, as well as in the group. However, a number of important principles are known:

Distance of victim from explosion: The intensity of an explosion pressure wave declines with the cubed root of the distance from the explosion. A person 3 m (10 ft) from an explosion experiences eight times more overpressure than a person 6 m (20 ft) away. Proximity of the victim to the explosion is an important factor in a primary blast injury.

Enclosed versus open space: The effects of an explosion in a closed space, like a room, bus, or train, are much greater than in an open space. Injuries are more severe, and mortality is greater.

Surrounding environment: Blast waves are reflected by solid surfaces; thus, a person standing next to a wall may suffer increased primary blast injury.

Quantity of explosive: A greater quantity of explosive produces greater potential for damage at any distance.

Type of explosive: Explosives are commonly classified as either low-order or high-order. Low-order explosives burn rapidly and produce a blast wave of less than 1000 m/s.[11] Black powder is an example of a low-order explosive. High-order explosives detonate when a shock wave passes through them, causing an almost instantaneous transformation of the original explosive material into gases occupying the same volume of space under extremely high pressure. These high-pressure gases expand rapidly, compress the surrounding medium, and produce a supersonic, overpressure blast wave, moving at greater than 4500 m/s, followed closely by a negative pressure wave.

Embedded shrapnel: Many terrorists purposefully embed multiple pieces of metal and plastic in the explosive, maximizing the number and severity of secondary injuries.

CLINICAL FEATURES

The nature of the injury may produce a multiplicity of external signs (**Figure 7-3**), making detection of important internal injuries challenging. Insufficient or suboptimal resources need to be prioritized in a mass casualty incident. High-grade clinical expertise is even more in demand to allow optimal use of resources.[2-9]

FIGURE 7-3. The severe external injuries often seen with explosive blast may or may not indicate associated severe internal injury. Clinical examination is difficult and requires a high degree of experience and suspicion as well as early use of imaging. [Image used with permission of Tel Aviv Medical Center.]

CARDIOPULMONARY SYSTEM

The lung is very susceptible to primary blast injury. **Pulmonary barotrauma is the most common fatal primary blast injury** and the most common critical injury in people close to the blast center. Pressure differentials across the alveolar–capillary interface can cause disruption, hemorrhage, pulmonary contusion, pneumothorax, hemothorax, pneumomediastinum, and subcutaneous emphysema. Air embolism is another well-recognized consequence of blast lung injury and is probably one of the major factors leading to cardiac dysfunction and immediate death after blast wave exposure, although it is usually difficult to diagnose specifically. The resulting neurologic symptoms caused by air embolism must be differentiated from the direct effects of CNS trauma. Pulmonary fat embolism is a finding of clinical importance in survivors of blast trauma because it can lead to the development of acute respiratory distress syndrome and significantly affects clinical outcomes.

In general, managing blast lung injury is similar to caring for pulmonary contusion and acute respiratory distress syndrome, except that early recognition of the syndrome may be complicated by initially benign symptoms, especially in the context of hectic mass casualty incident situations. Hypoxia is an almost universal finding.[12] Monitoring of respiratory rate and room-air pulse oximetry, as well as serial chest radiographs, may be needed. Fluid administration should ensure tissue perfusion without volume overload. The decision to institute mechanical ventilation must be made carefully because it entails the assignment of what may be scarce critical care unit beds and ventilators and also exposes the patient to the potential complications of pulmonary barotrauma, commonly seen with the friable lungs associated with blast lung syndrome. **Keep tidal volume to 6 to 7 mL/kg ideal body weight to limit the peak inspiratory pressure and to minimize ventilator-induced lung barotrauma.** Often, neuromuscular paralysis and early institution of pressure-limited ventilation (plateau pressures <30 cm H_2O),[13] with the lowest pressures compatible with adequate ventilation, may be the best strategy. Inverse inspiratory-to-expiratory ratio ventilation may be useful. Permissive hypercapnia is acceptable depending on cerebral perfusion pressure or increased intracranial pressure.[13] Aggressive methods of oxygenation, such as extracorporeal membrane oxygenation or intravascular oxygenation, may become necessary within hours of the injury.

There are no definitive guidelines for observation, admission, or discharge of patients with possible blast lung injury. Admit patients requiring complex management to an intensive care unit. In general, asymptomatic patients with normal chest radiographs and normal room-air pulse oximetry may be considered for discharge after 4 to 6 hours of observation as long as there is no clinical deterioration. Survivors of this type of injury typically have no long-term pulmonary complaints, and most have normal physical examinations, chest radiographs, and normal lung function tests.

EARS

The tympanic membrane ruptures at 1 to 8 psi of dynamic overpressure. Dislodgement of ossicles may also occur. Patients with an isolated tympanic membrane perforation and no other immediately identified injuries should have a chest radiograph ordered but do not automatically require an extended period of observation. Conversely, intact tympanic membranes do not imply the absence of serious injury, and the use of the perforation of tympanic membrane as an indicator of primary blast injury missed up to 50% of those suffering a primary blast injury to the lung.[14] Clinical judgment is necessary, and limited observation is reasonable for patients with intact tympanic membranes.

ABDOMEN

Abdominal injuries from explosions may be occult. Reported injury rates are low, but missed injuries may carry significant morbidity due to delayed intestinal perforation and necrosis. A review of the literature on abdominal trauma from primary blast injury reveals an incidence of 1.3% to 33%, and the terminal ileum and cecum were the most commonly injured areas.[15] Serial clinical examinations, serial imaging as needed, and 24- to 48-hour observation are indicated whenever the suspicion arises. **Air is a poor conductor of blast-wave energy; thus,**

patients who were subjected to enough energy to damage abdominal organs probably were situated near the explosive device.

BRAIN INJURY

The conflicts of the Global War on Terror in Iraq and Afghanistan have resulted in over a quarter of a million diagnosed cases of traumatic brain injury.[16] Mild traumatic brain injury has been labeled the "signature injury of the war in Iraq."[1,17-22] The clinical examination may be misleading for penetrating injuries. Shrapnel are low-velocity missiles, often producing small entry wounds in survivors. Small entry wounds may be missed under the hair, and evidence for traumatic brain injury may initially be benign or masked by anesthesia as the patient undergoes treatment for other life-threatening injuries. Neuroimaging is an important early diagnostic tool (**Figure 7-4**).

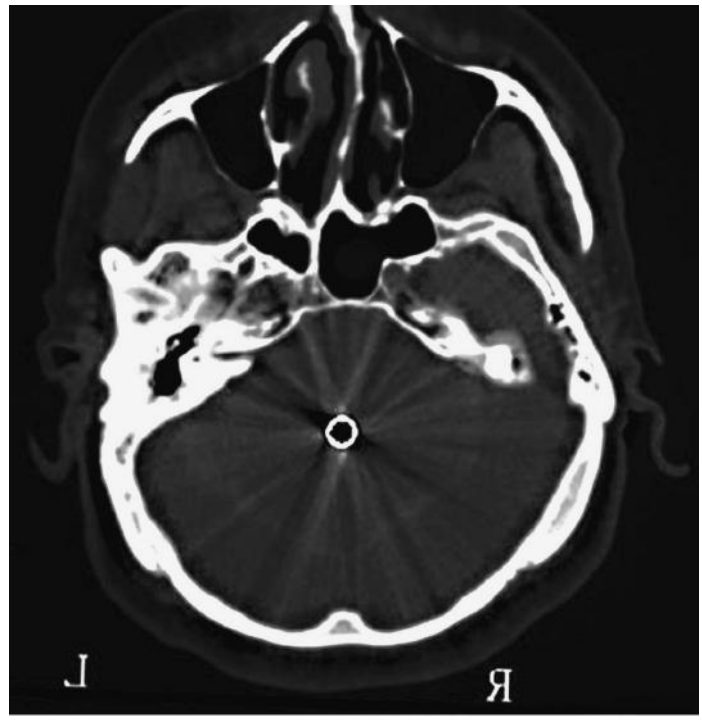
VASCULAR INJURY

Small entry wounds from shrapnel may mask severe vascular injuries (**Figure 7-5**). Compartment syndrome (see "Crush Injury and the Crush Syndrome," below) may develop and is difficult to diagnose, especially in patients receiving anesthesia. Carefully assess and document pulses and perfusion in affected limbs. **Observe for delayed presentation of compartment syndrome, and measure compartment pressure if any signs or symptoms develop.** Early angiography and intervention are indicated if pulses are lost.

EXTERNAL HEMORRHAGE

Bleeding from wounds is likely to be the most commonly encountered life-threatening finding. Whether venous or arterial, blood loss from multiple wounds (internal and external) may be sufficient to cause hypovolemic shock. Quickly control external bleeding with direct pressure. Military experience has shown that hemorrhage is the most common cause of preventable death in penetrating trauma.[9] Apply tourniquets for extremity hemorrhage whenever blood loss cannot be controlled with direct pressure, or if the resources required to maintain direct pressure are insufficient during either treatment or transportation. Tourniquets have been successfully used for up to 6 hours in battlefield situations.[23] Angiographic vascular occlusion is an attractive treatment option if the time and staff are available. Victims of blast mass casualty incidents may require massive amounts of blood and blood products.[24]

OCULAR INJURIES



Eye injuries from a blast wave may cause shearing damage to the orbit, but ocular injuries are from a combination of primary and secondary processes.[25] Ocular injuries include lid or brow lacerations, conjunctival lacerations, open globe injuries, orbital fractures, retinal detachment, retained intraocular foreign body, lens dislocation, vitreous hemorrhage, retinal tears and retinal detachment.[25] Eye examination is needed for all moderately to severely injured blast victims, and a poor initial visual acuity is not a guarantee of a poor final result.

DIAGNOSIS

Order diagnostic imaging judiciously in a mass casualty incident. Visualization of a metallic object on a single-plane radiograph is often inadequate for thorough evaluation, but it can direct the treatment team on the need for urgent surgery or for additional imaging. Use the FAST examination liberally. Plain chest radiographs, ultrasonography, and diagnostic peritoneal lavage are the most rapid studies used to evaluate for life-threatening injuries. Order laboratory tests sparingly.

TREATMENT

When blast injuries occur, they tend to be unexpected, occur outside of regular working hours, and often produce moderate to large numbers of simultaneously arriving casualties. Drills and checklists are critical for successful implementation of rarely used protocols. Checklists should be concise, never more than one to two pages, and available in a location known to everyone. Implement the hospital plan for management of mass casualty incidents.

A

B

FIGURE 7-4. **A.** CT scan image of a 17-year-old female patient injured in a terrorist bomb blast in Israel. This girl walked into the ED unassisted, was triaged "green," but deteriorated after 30 minutes. Fortunately the clinical deterioration was noted, she underwent emergent CT, and then extensive neurosurgical intervention. **B.** A 1-cm metal ball bearing was extracted. Prolonged rehabilitation was later required for residual brain damage. [Image used with permission of Tel Aviv Medical Center.]

Obtain details about the explosion from patients and rescue teams. **The nature and location of the blast, including size and type of charge, location in open or closed space, structural collapse, associated fire or smoke, and toxic agent release, will be helpful in making informed clinical decisions, especially with regard to disposition of moderately to severely injured casualties.**

Patient triage will be needed when multiple patients arrive. Station an experienced emergency physician or surgeon at the ED entrance to triage

FIGURE 7-5. Vascular injuries may occur with externally minor penetrating injury. This young woman was triaged "green." The significance of a small penetrating injury in her lower limb, one of many throughout her body, was initially misinterpreted, but she lost her pulses after 1 hour and was rushed to angiography and subsequent vascular surgical intervention. [Image used with permission of Tel Aviv Medical Center.]

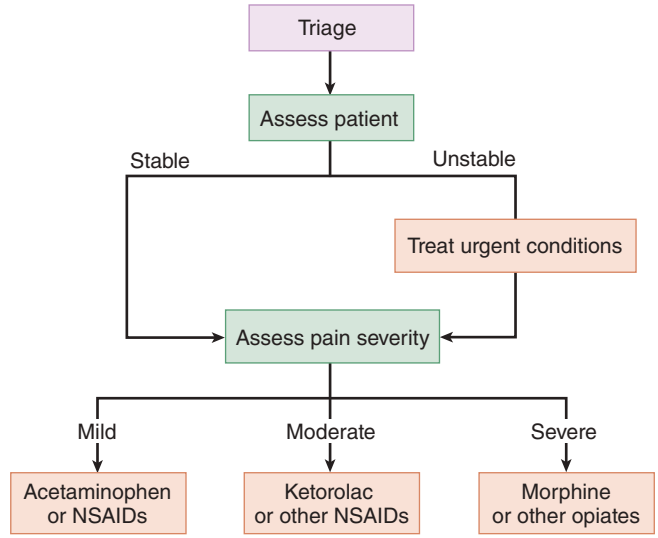


FIGURE 7-6. Algorithm for pain management in blast injury patients in the context of a multiple-casualty incident. NSAID = nonsteroidal anti-inflammatory drug.

patients to appropriate, predetermined locations in the ED or elsewhere in the hospital. Patients must be triaged to categories of urgency based on relevant criteria, such as those listed in **Table 7-1**. Many triage methods have been in use in various parts of the world, with varying success and scientific foundation.[2-7]

Apply the basic advanced trauma life support principles of primary and secondary surveys within the logistic limitations that may occur temporarily or permanently. Administer IV fluids and blood products judiciously. Preventing fluid overload is important for lung- and brain-injured patients. Activated factor VII administration or tranexamic acid may be considered in select cases of uncontrollable bleeding.

Copiously irrigate and disinfect wounds urgently, but definitive debridement and closure may wait a few hours. Temporary splinting, traction, and dressings are generally sufficient for initial management of musculoskeletal injuries. Consider prophylactic antibiotics for severely soiled wounds, penetrating abdominal and thoracic wounds, and open fractures, and in patients with diabetes or who are immunocompromised.

TABLE 7-1 Criteria for the Triage in Bomb Injuries

Severely Injured	Lightly Injured
Airway compromise	Minor wounds
Breathing difficulty	Burns, first or second degree
Hemodynamic instability	Isolated trauma to a limb
Altered level of consciousness	Anxiety states
Vascular trauma	Most walking patients
Extensive second- to third-degree burns	

Address pain management after life-threatening emergencies have been evaluated. Reserve opiates for patients with severe pain because opiate supplies may become limited (**Figure 7-6**).

Patients exposed to open-space explosions and who have no apparent significant injury, normal vital signs, and an unremarkable physical examination generally can be discharged after a few hours of observation. Asymptomatic patients may be discharged after 4 to 6 hours of observation. Admit all patients with significant burns, suspected air embolism, radiation or chemical contamination, abnormal vital signs, abnormal lung examination findings, clinical or radiographic evidence of pulmonary contusion or pneumothorax, abdominal pain, vomiting, hypoxia, or penetrating injuries to the thorax, abdomen, neck, or head to the hospital.

Patients appropriate for discharge need to be given proper follow-up instructions. Given the austerity of initial care and the propensity to miss injuries in a mass casualty incident, secondary assessments of all casualties should be done before discharge. Because symptoms of pulmonary contusion and intestinal hematoma may take 12 to 48 hours to develop, instruct all discharged patients to return for reevaluation if they develop breathing problems, abdominal pain, or vomiting. Provide relevant follow-up instructions in writing, including audiologic and ear, nose, and throat follow-up, wound care, immunization schedules, medications, psychological support, and social services.

SPECIAL POPULATIONS

PREGNANT WOMEN

Because the fetus is surrounded by amniotic fluid, direct injury to the fetus is uncommon. **Injuries to the placenta, however, are more common.** After life-threatening conditions have been stabilized, admit patients in the second or third trimester of pregnancy who have been exposed to blast injury to the labor and delivery area for continuous fetal monitoring and further testing and evaluation. Pelvic US, fetal nonstress test monitoring, and obstetrics consultation should always be obtained. Consider Rh immune globulin administration if the mother's blood type is Rh negative.

CHILDREN

Children may suffer significant tertiary blast injury because their lighter bodies are more easily hurled by the blast wind. Imaging, such as total-body CT, may be difficult to perform in anxious and frightened children. Children typically require sedation to facilitate imaging.

SPECIAL CONSIDERATIONS

STAFF SAFETY

Issues that may affect staff safety include: (1) possible infiltration of the ED by perpetrators intent on causing second explosions or attacks in the hospital; (2) unexploded explosives inadvertently brought into the ED; (3) transmissible disease in the setting of body fluid exposure or needle sticks during stressful, rapid work; and (4) contamination of victims by chemical, radiologic, and biologic hazards, either accidental or intentionally caused by the perpetrators.

FORENSIC ISSUES

Police and crime scene investigators, as well as counterterrorism and other security services, have legitimate interests in securing forensic and other information. Efforts should be made to accommodate them, but never at the expense of medical care. Prior coordination with all relevant authorities should establish protocols, such as who and how many persons from these agencies are allowed in, when, into which parts of the ED, who controls them, and who is empowered to limit their entry and work. As a rule, however, although a terrorist event is a crime, forensics in the hospital are of minor relevance compared with the actual crime scene. Investigators may wish to interrogate victims with minor injuries regarding the event and obtain shrapnel or clothing from patients for forensic analysis.

INFORMATION MANAGEMENT

Because blast injury is often part of a large event, information becomes a critical component of appropriate management. Such information concerns include: (1) clinical charting and other patient care–centered information, such as imaging; (2) command and control information, such as casualty flow data, resource management data, and interface with other agencies; (3) information provided to relatives; (4) information provided to the media; and (5) information recorded for quality improvement and research. An information center is an indispensable component of such events, providing relief for the relatives and also preventing them from crowding patient care spaces and impeding caregiver workflow.

CRUSH INJURY AND THE CRUSH SYNDROME

A crush injury occurs when a body part is subjected to a high degree of force or pressure, usually after being squeezed between two heavy or immobile objects. **Crush injury that produces ongoing ischemia of a fascial muscle compartment is termed *compartment syndrome*, defined as increased pressure within a confined space that leads to microvascular compromise and ultimately to cell death as a result of oxygen starvation.** Crush syndrome is the systemic manifestation of muscle cell damage resulting from pressure or crushing with or without subsequent compartment syndrome. This chapter discusses crush injury and treatment measures specifically in the context of mass natural disasters. Specific discussion of detailed physiology, compartment anatomy, and compartment pressure measurement is found in chapter 278, "Compartment Syndrome."

EPIDEMIOLOGY

Crush injuries may be seen in two different scenarios: in single-patient situations and in disasters of varying magnitude, like earthquakes or tsunamis. Catastrophes have occurred throughout history, but the recognition of crush syndrome in the twentieth century and the advent of effective treatment for some of the components of the systemic and local injury have made it one of the important aspects of the medical care of natural disaster victims. The increasing number of vehicular and workplace accidents has also led to a rise in the incidence of crush syndrome and in the importance of its timely recognition and treatment. In various reports, the incidence of crush syndrome and subsequent renal failure varies from 1% to 25%, probably resulting from reporting differences, the nature of the disaster, and the timeliness and effectiveness of the rescue efforts and medical care.[26]

Crush injuries are most commonly seen in the extremities, because crush of the trunk or head and neck is quickly lethal. There is a high incidence of associated injuries such as fractures, lacerations, and degloving injury.

PATHOPHYSIOLOGY

Injury to muscles, including crush and ischemia, causes rupture of the sarcolemma and the release of the intracellular contents of the myocytes into the surrounding tissues. Calcium ion is one of the most destructive components released from the myocytes, because calcium stimulates proteolytic enzymes and oxygen free radicals are released. This causes more myocyte destruction, and potassium, phosphate, myoglobin, creatine kinase, and uric acid leak into the bloodstream. Serum haptoglobin binds some of the myoglobin, but its binding capacity is quickly overwhelmed, and myoglobin causes direct kidney injury. Membrane damage to the myocytes and to the systemic capillary endothelium causes vascular volume loss and hypovolemia. Hyperkalemia and hypocalcemia may cause arrhythmias and cardiac arrest. Metabolic acidosis caused by hypovolemia and shock aggravates arrhythmogenicity. **Renal failure is the most serious complication of crush syndrome.** The pathogenesis of renal failure is multifactorial, including systemic hypoperfusion, renal vasoconstriction, nephrotoxicity from myoglobin, and uric acid and phosphate precipitation in the distal tubules. Low urine pH and renal vasoconstriction promote precipitation of nephrotoxins. Myoglobin is indirectly nephrotoxic through the formation of ferrihemate, which produces free hydroxyl radicals and, combined with lipid peroxidation, damages the kidney.[27]

Reperfusion syndrome is a paradoxical phenomenon of exacerbation of cellular dysfunction after restoration of blood flow to previously ischemic tissues. It involves biochemical and cellular changes causing oxidant production and complement activation, which culminates in an inflammatory response, mediated by neutrophils and platelets interacting with the endothelium. The inflammatory response has both local and systemic manifestations.[28] Systemic manifestations include hypotension, vasodilatation, hypovolemia, myocardial depression, hyperkalemia, and acidosis.

Normal muscle compartment pressure is <10 mm Hg. After crush injury, trauma to the microcirculation leads to edema formation, interstitial bleeding, stasis, and obstruction, and the myocytes are no longer able to retain intracellular water. Edema in a closed space causes increased pressure, which further collapses the microcirculation and potentiates the problem.[29] **Pressures >30 mm Hg produce muscle ischemia; irreversible nerve and muscle damage occurs after 4 to 6 hours.**

CLINICAL FEATURES

Obvious external signs of crush injury are usually evident, as is a suggestive history. Lacerations, degloving, deformity, pain, and ischemia may occur in varying degrees.

Compartment syndrome often presents with the five "P's": **pain, paresthesias, passive stretch, pressure, and pulselessness.** Pain is the most common and consistent symptom, described as diffuse and intense; exacerbated with movement, touch, or pressure; and out of proportion to physical examination findings.

Paresthesias are numbness, tingling, or burning sensations in the affected area. Severe pain results when muscles in the affected compartment are stretched.

The affected compartment is very tight to the examiner's touch and sometimes warm, and there are measurable increases in tissue pressure. Pulselessness occurs only in the late stages. Examining for a pulse, or its lack, is the least reliable because compartment syndrome is a disorder of the microvasculature; the major vessels are frequently unaffected.

Crush syndrome is due to the manifestations of muscle toxin release and hypovolemia. Hypovolemic shock may occur, aggravated by hyperkalemic, hypocalcemic, or acidemic cardiotoxicity. Thromboplastin release may cause disseminated intravascular coagulation, which is especially critical in the face of tissue damage, open wounds, or the need

for surgery. Renal failure may ensue quickly and is the primary cause of delayed death.[26]

DIAGNOSIS

Testing of the compartment pressure will confirm the diagnosis. A compartment pressure of >30 mm Hg is considered to be a positive test. Measurement is best accomplished with a dedicated device (Stryker STIC; Stryker Co., Kalamazoo, MI) or by inserting a saline-filled needle connected to an intravascular pressure measurement system (arterial or central venous pressure gauges) into each compartment and recording the pressures.[26] See chapter 278 for detailed description of compartment pressure measurement.

Crush syndrome is characterized by protean and rapid metabolic changes. Laboratory tests are crucial to help direct management. Serum creatine kinase levels may not necessarily predict disease severity and risk of renal failure, but they are a useful initial triage and subsequent follow-up tool. Pay close attention to serum potassium, calcium, phosphorus, pH, creatinine, hemoglobin, coagulation indices, and urine pH and electrolytes. A preplanned sequence of laboratory tests every 2 to 4 hours is useful, rather than sporadic checks. Urine collection for total electrolyte excretion and creatinine clearance calculations may be considered.[26]

TREATMENT

Establish two large-bore IV lines and administer normal saline with a 1- to 2-L bolus. Avoid Ringer's lactate and other potassium-containing fluids, because fatal hyperkalemia may occur, even in the absence of renal failure.[26] Initiate IV fluid rate at 1000 mL/h, and then reduce to 500 mL/h after 2 hours. Urine output should be approximately 200 to 300 mL/h (5 to 7 L every 24 hours) for an adult. Monitor serial serum potassium levels. Admit the patient to an intensive care unit setting to monitor fluid administration and electrolyte status.

FASCIOTOMY

In reports of mass casualties from earthquakes, most of the fasciotomy procedures were performed >12 hours after the time of trauma. Reviews of these cases showed high infection rates with increased mortality and amputations and poor long-term outcomes. Fasciotomy creates open wounds, which increases the risk for sepsis, amputation, hemodynamic instability, chronic nerve dysfunction, and death.[26] Most recommendations discourage the use of routine fasciotomy, particularly for crush wounds, and fasciotomy is only indicated for absence of distal pulses, a requirement for debridement of necrotic muscle, compartment pressures >30 mm Hg (measured within 6 hours of injury), and differences between compartmental pressure and diastolic blood pressure of >30 mm Hg.[26] If initial compartment pressures are normal and delayed compartment syndrome develops, fasciotomy may be needed, but infection rates have been reported to be high and prolonged, and profuse local bleeding may develop.

HYPERBARIC OXYGEN THERAPY

Hyperbaric oxygen therapy is a useful adjunct in the treatment of crush injury and compartment syndrome because it supplements oxygen availability to the hypoxic tissues in the early postinjury period.[29] With hyperbaric oxygen therapy at 2 atm, the blood oxygen content (oxygen carried by hemoglobin and plasma) is increased by 125% (by increasing plasma oxygen content), and the oxygen tension in plasma and tissue fluid is increased 10-fold compared to room air breathing.[29] Edema reduction secondary to oxygen-induced vasoconstriction is another beneficial effect of hyperbaric oxygenation. Hyperbaric oxygenation reduces blood flow by 10% to 20%, thereby reducing tissue edema caused by blood flow, but oxygen delivery to the tissues is increased because of higher tissue oxygen tensions.[29] The immediate effects of hyperbaric oxygen therapy are threefold: enhanced oxygen at the tissue level, increased oxygen delivery per unit of blood flow, and edema reduction. Long-term effects may include improved wound repair after fasciotomy, diminished infection rates, and improved outcome of skin grafts.[29]

SPECIAL POPULATIONS

Care of crush injury patients in the setting of mass casualty incidents is radically different than that of the individual victim. Extrication may be delayed, medical treatment during extrication may be unavailable, initial management may occur in makeshift or suboptimal conditions, and medical personnel may have little experience working under such conditions. Transportation to definitive care may be prolonged; critical equipment, such as dialysis machines, may be in short supply; and laboratory, monitoring, and intensive care facilities may be insufficient for the volume demands. Healthcare workers should anticipate these obstacles and develop flexible treatment protocols.

CHAPTER 8

Chemical Disasters

B. Zane Horowitz
Robert G. Hendrickson

INTRODUCTION AND EPIDEMIOLOGY

Although the term "agents of mass destruction" is often used in planning for terrorist events, in reality, few chemicals can be delivered by terrorists in the appropriate fashion to create large numbers of deaths.[1] However, chemical mass casualty events do occur. The setting may involve the release of industrial chemicals, such as the 1984 industrial accident in Bhopal, India, that caused more than 2500 deaths and 200,000 injuries from a methyl isocyanate release,[2] or a natural chemical incident, such as the emission of carbon dioxide in Lake Nyos, Cameroon, that was responsible for 1700 chemical asphyxiant deaths. Chemical terrorism may also occur through acts of willful deployment, as with the sarin release in the Tokyo subway in 1995 in which 12 people died and 5500 sought medical attention.

The emergency physician is most likely to encounter the accidental release of a chemical from a fixed industrial site or transportation accident. In 2005, a freight train collision in Graniteville, South Carolina, caused the release of chlorine gas that resulted in nine deaths and 511 ED visits.[2,3] Environmental contamination, even without injuries, may affect an entire community, including local emergency departments. In 2014, a previously little-known chemical named 4-methylcyclohexane methanol that was used in coal washing leaked into the Elk River in West Virginia, in proximity to the intake area for the water supply for nine counties that served 300,000 people. Although there were no injuries, emergency planners needed to supply clean water to the affected population. Providing risk management advice based on limited data on this chemical and the chemical's strong black licorice odor despite levels below the toxic concentration made it challenging to convince the citizens that the water was safe to use again.[4]

What has been learned from these incidents is that when chemicals are released, the agents create a penumbra effect, in which true chemical emergencies occur in the epicenter and a larger surrounding area of fear and panic arises in individuals with lower, usually nontoxic levels of exposure. **Planning for chemical disasters must take into account both the chemical emergency occurring near the center of any chemical release and the chaos that can ensue through fear of exposure.**[2,3] What makes these events overwhelming for an individual ED is the larger number of victims who are ambulatory, frightened, and make their own way to the hospital, bypassing any scene triage or decontamination.[5] Appropriate planning for management of this large, self-extricated population is paramount to the concept of disaster preparedness for chemical emergencies and perhaps even more important than specific antidotes for rare agents that might be encountered.

PRINCIPLES OF PHYSICS: SOLIDS, LIQUIDS, AND GASES

Solids have a fixed volume and shape and can be bulk solids, powders, dusts, or fumes.[6] Dust particles are visible if they are >100 μm in diameter; particles smaller than this size are imperceptible to the naked eye.[7] Most dust particles settle with time as the result of gravity; however, in a wind-blown environment or an explosion, they can be blown through the air and contaminate mucous membranes or be inhaled. Dust particles between 2.5 and 6.0 μm in diameter deposit in the bronchial mucosa, whereas particles smaller than 2.5 μm can reach the alveoli. Fumes are fine, solid particles created by either combustion or condensation and are smaller than 1 μm in diameter. Chemicals may adhere to fumes or dusts and be deposited in the lungs through inhalation.

Liquids have a fixed volume, but their shape conforms to both gravitation and container shape. They will flow downhill and can accumulate in clothing and shoes. A liquid forced through a small orifice under pressure can be aerosolized into fine liquid droplets (i.e., aerosols). Aerosols, like dust, will settle with gravity over time. A vapor may be a dispersion of a liquid or a volatile solid, like mercury. Vapors and aerosols may penetrate clothing, causing contact injury by soaking the underlying skin or reacting with moisture in mucous membranes.

A gas has a variable shape and volume and will diffuse to fill an enclosed space once released. Many compressed gases are stored as liquids in cylinders and are converted to a gas upon their release. Hazardous risk analysis should take into consideration misuse or theft of these compressed gas cylinders. An endothermic reaction may occur during release of a compressed gas, causing hypothermic skin injury. Gases can be inhaled into the lungs and cause local reaction, systemic toxicity, or, in some cases, delayed reactions deep in the pulmonary tree.

How deeply in the lungs a gas or vapor exerts its effects depends on its degree of water solubility. Highly water-soluble compounds react with water in our mucous membranes and can irritate the eyes and upper airway.[6] Examples of agents with this property includes ammonia and hydrogen chloride. These agents have good warning properties, allowing an awake and ambulatory individual to leave the area of exposure. Low water-soluble compounds may be less irritating, allowing greater duration of exposure and, therefore, greater pulmonary penetration. Phosgene is an example of a low-solubility gas; it has a pleasant smell like new-mown hay and penetrates deep into the alveoli where it slowly is converted to hydrochloric acid.

All liquids at temperatures between their freezing point and their boiling point are in equilibrium between the liquid itself and some amount of gas vaporized into the atmosphere. Below their freezing point, liquids become a solid and pose little risk of vaporization. Above their boiling point, they become a gas, and their vapor pressure equals the atmospheric pressure.[6] The higher the vapor pressure is for a substance, the more likely it is to volatilize into a gas. It is possible to calculate the concentration of a chemical as a vapor knowing its vapor pressure and the atmospheric pressure. This vapor concentration may be used to predict risk of toxicity based on established exposure limit guidelines.

HAZARDOUS MATERIALS EXPOSURE-LIMIT GUIDELINES

Several agencies have created exposure guidelines used for different purposes, of which a few may be useful in assessing health risks during an exposure. The American Conference of Governmental Industrial Hygienists has created threshold limit values for many substances.[8] This value is the maximum allowable airborne concentration of a substance that a worker can be exposed to for an 8-hour workday. Concentrations below this should be regarded as acceptable and safe.[6,8] The American Conference of Governmental Industrial Hygienists has also established a short-term exposure limit for substances to which an individual should not be exposed for >15 minutes.[8] The National Institute for Occupational Safety and Health has established an acute exposure limit called the *immediately dangerous to life or health* limit. This is the maximum environmental air concentration of a substance from which a person without protective equipment could escape within 30 minutes and not sustain irreversible health effects.[6] This applies only to acute health effects and does not take into account chronic health effects or carcinogenicity. The immediately dangerous to life or health level is meant to apply to the work environment and not a chemical accident, where the level of a substance measured in an environment is usually unavailable during an actual disaster and may change over time.

The Environmental Protection Agency created a three-tiered Acute Exposure Guideline Level (AEGL) that is applied to nonoccupational, one-time exposures in the general population.[9] AEGL-1 levels cause discomfort only; AEGL-2 levels cause irreversible, long-lasting effects; and AEGL-3 levels cause serious disease or death. Each level is further rated by time exposure for concentrations of exposure for 10 minutes, 30 minutes, 60 minutes, and 4 and 8 hours.

Exposures at or less than AEGL-1 limits require public health and emergency response agency efforts to educate the public about the minor effects expected to help minimize ED and physician visits. Access to areas with levels higher than AEGL-1 limits should be restricted. **Levels between AEGL-2 and AEGL-3 require accurate and specific information to be given to the public and generally would require people to shelter in place, seal their homes, and perform self-decontamination.**[9] Highly susceptible individuals, such as the elderly, those with lung disease, or the very young, may need priority evacuation and evaluation. Levels anticipated at or greater than AEGL-3 require evacuation, field decontamination, and triage.

SCENE HAZARDOUS MATERIALS RESPONSE

Each year, there are 15,000 to 19,000 hazardous materials (HAZMAT) events in the United States. Planning for chemical exposure events, whether terrorist or accidental, builds on our existing principles of HAZMAT response. Core concepts of planning are listed in **Table 8-1**.

COMMUNITY RISK ASSESSMENT

The Superfund Amendments and Reauthorization Act, also called the Emergency Planning and Community Right-to-Know Act, requires states to create state-level emergency response commissions and communities to form local emergency planning committees to prepare emergency response plans for chemical accidents. Chemical facilities are required to provide local emergency management agencies and local fire departments with annual inventory reports and information about hazardous chemicals. The Environmental Protection Agency maintains a national database containing a Toxics Release Inventory that mandates certain facilities to annually report the quantities of their emissions of toxic chemicals (http://www.epa.gov/tri and http://www.epa.gov/triexplorer/maps.htm). This information includes the chemical name, an estimate of the maximum amount of the hazardous chemical present at the facility at any time during the preceding calendar year, an estimate of the average daily amount of the hazardous chemical present at the facility during the preceding calendar year, a brief description of the manner of storage of the hazardous chemical, and the location within the facility of the hazardous chemical. **Table 8-2** lists the most common chemicals stored in the United States. Appropriate emergency planning would require a laborious review of these databases at each local level and is not often done with any assessment of vulnerability to release. Rather than expect an accurate accounting of local risk, each ED must be knowledgeable in the general principles

TABLE 8-1 Scene HAZMAT Planning Guidelines

of HAZMAT decontamination. An awareness of the clinical manifestations of the most common stored chemicals and the availability of just-in-time information sheets can supplement risk assessment in the real world.[10]

RECOGNITION OF AN EVENT

Most chemical releases are recognized early because many chemicals have early warning properties, including a noxious or unusual odor, or cause eye or upper airway irritation. Toxic exposures may produce rapid death at the site of the release. Sometimes, more subtle clues are present, such as large numbers of dead animals in an outdoor environment.

Most HAZMAT events occur in fixed industrial facilities, and many industries have monitors for leaks of chemicals at nontoxic threshold levels that have no warning properties. For example, the semiconductor manufacturing industry has monitoring sensors for many toxic semiconductor gases, such as arsine, and these are triggered at very low levels. However, these agents are gases and pose no risk of secondary contamination.

IDENTIFICATION OF THE SUBSTANCES INVOLVED

The most common agents released in the United States are the pulmonary irritants ammonia and chlorine. There are numerous resources for the identification of which substances are involved in a spill by a transportation accident or industrial site (**Table 8-3**).

Few of these resources will identify the amount, and none will have treatment recommendations. **Although it may be intuitive that an exact identification of a substance is critical to the disaster or HAZMAT process, in reality, it is more important to recognize the clinical syndromic manifestations of the victims.** It is not necessary at the scene to know which organophosphate is involved; it is more important to identify that the symptom complex of a cholinergic crisis is occurring. Similarly, early recognition of the pulmonary irritant effects of a highly water-soluble acid is usually more important than the concentration or the specific chemical identified. Ultimately, identification of the exact agent involved will need to be made. HAZMAT teams have several techniques to identify substances and usually have a standard procedure to enter and evaluate a building where an odor is detected. The treating physician should evaluate all presumptive initial identifications of substances with some caution.[3] **If the symptoms of the patient do not fit the initial chemical identification, then the accuracy of the identification should be called into question.** Experience with chemical events has sometimes revealed that the substance involved must be reidentified during the evolution of the incident, and sometimes, the initial determination of the chemical involved in the release is wrong.

ISOLATION AND SCENE CONTROL

Once a suspected chemical release occurs, the EMS response team must establish an incident command system; designation of hot, warm, and cold zones; and an isolation process. The immediate area where the suspected chemicals and victims of exposure are located is designated the hot zone. Only trained personnel in fully encapsulated protective gear should be allowed to enter. **Their primary role is rescue of victims by removing them from further exposure.** There is substantial risk of secondary contamination and, therefore, toxic effects for any rescuer or bystander who enters the hot zone without the proper protective gear.[11]

A surrounding corridor through which each victim is washed off and decontaminated is created outside the hot zone and is designated the warm zone (**Figure 8-1**). Basic treatment, such as opening obstructed airways, may occur simultaneously with decontamination. Once appropriately decontaminated, the patient can be transferred to the cold zone where a lower level of protective equipment is necessary and a very low risk of secondary contamination exists. With less cumbersome protective gear, reevaluation in the cold zone, triage, and initiation of treatment can occur (**Figure 8-2**).

DECONTAMINATION IN THE WARM ZONE

Primary contamination is caused by direct contact with the release. Both people and the environment may suffer primary contamination. Secondary contamination is the inadvertent contamination of rescue personnel through contact with a contaminated patient or environment. **Secondary contamination can be avoided by proper use of personnel protective equipment and adequate decontamination of adherent solids and liquids.** Some rare substances are excreted in sweat and exhaled. Close unprotected contact with wet skin, mouth-to-mouth ventilation, or mouth-to-mask ventilation could be a source of secondary contamination. Equipment can become secondarily contaminated and may be required to be taken out of service until appropriate decontamination is done. This equipment contamination can be something as simple as a stethoscope or as large as a fire truck. Organophosphates can be excreted in sweat and may adhere to leather. Care must be taken with first responders who may not have protective gear; their shoes, belts, and holsters need to be discarded because they cannot be effectively decontaminated and could potentially pose a risk to coworkers or their families at home.

After the victim is removed from the hot zone to the warm zone, the critical management issue is adequate decontamination. The first and most effective method of decontamination is removing clothing, brushing off solid particles, and washing and toweling the face.[11-13] **Water is the universal decontamination agent.** Some guidelines recommend decontamination for nerve agents and vesicants with dilute household bleach, but there is little evidence of superiority over plain water, and bleach is likely to be unavailable in sufficient quantities at the scene. In general, 5 minutes of decontamination with warm water in the warm zone is adequate for most ambulatory patients.[13] Warm water is used to prevent shivering. If the patient has had direct contact with either liquid or vapor, he or she must be hosed off with water, paying critical attention to occult areas where fluids can hide, such as the hair, skin folds, axilla, groin, toes, and eyes. Patients with severe symptoms may require rapid decontamination and simultaneous treatment in the warm zone.

STABILIZATION AND TRIAGE IN THE COLD ZONE

Triage patients in the cold zone. Safety requires the cold zone to be upwind and, if needed, uphill from the hot zone. Once decontaminated, stabilize patients and evaluate for syndromic symptoms and the need for antidotes. **Primary stabilization includes the establishment of airway, applying oxygen, and administering bronchodilators for bronchospasm.** The establishment of IV lines in a disaster or multiple-casualty incidents requires judgment of the need for fluid resuscitation and critical IV medications. Give priority for IV line placement to patients requiring benzodiazepines for stopping seizure activity,

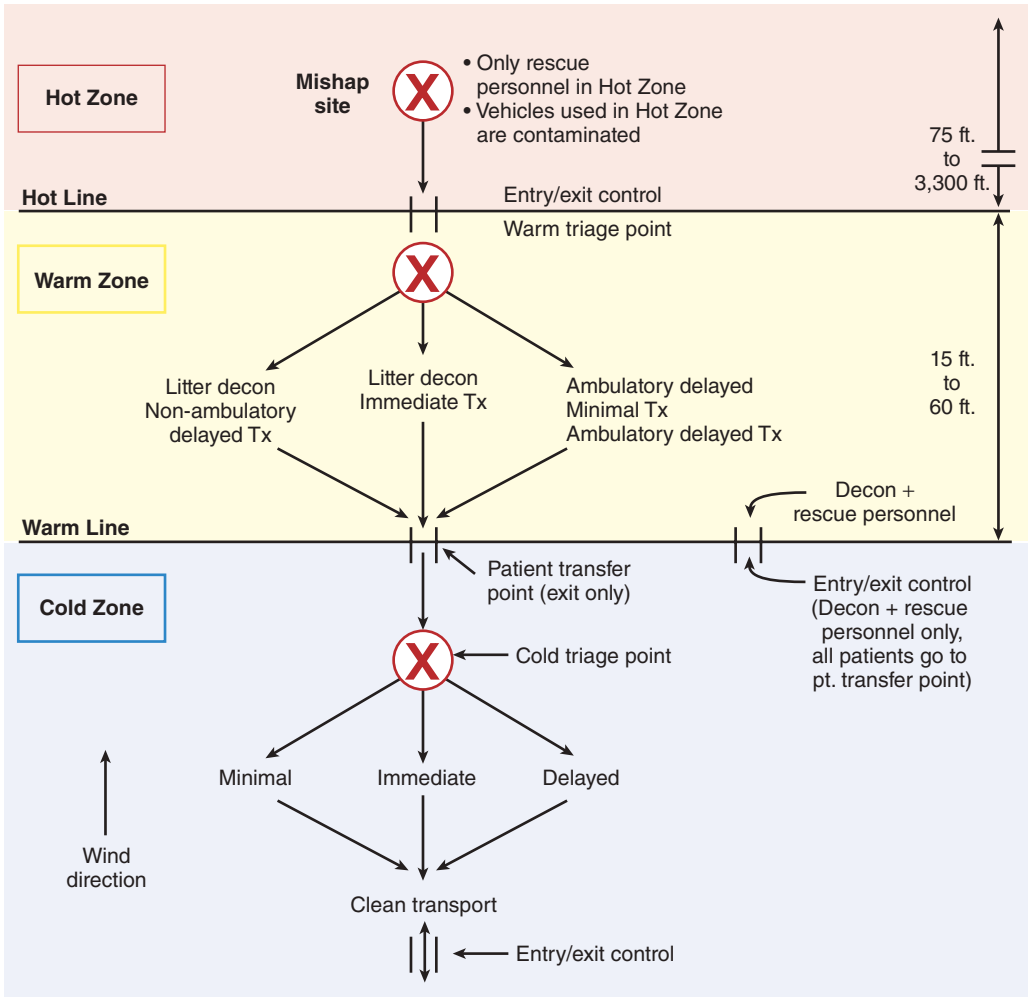

FIGURE 8-1. Control zones of a chemical event. decon = decontamination; pt. = patient; Tx = treatment.

treating cardiac arrhythmias with usual advanced cardiac life support medications, and volume resuscitation for hypotension. Only a few antidotes may truly be beneficial if given early, such as the cyanide antidote, hydroxocobalamin, or atropine for muscarinic effects of organophosphate exposure. The need for additional antidotes in the prehospital phase is unusual unless prolonged on-scene triage is likely to occur.

ED HAZMAT RESPONSE

Despite the best planned and drilled chemical emergency response plan, most individuals will self-rescue and make their way in an uncoordinated fashion to a healthcare facility, so potentially contaminated patients will find their way by private transportation to the ED.[3] In the Tokyo subway release of sarin, 85% of patients who presented to St. Luke's Hospital, the facility closest to the scene, arrived under their own accord.[14-16] Therefore, EDs cannot rely solely on the prehospital system to completely decontaminate and triage every patient. Each facility must consider their physical space and patient flow, create a hospital-based plan for chemical emergencies, and have a policy and training that allow for the identification of chemically exposed patients. There should be an organized plan to perform decontamination and mobilize a system for decontamination of multiple patients, and the plan and equipment must be practiced on a regular basis. Regardless of the specific type of equipment, EDs should have the ability to decontaminate large numbers of patients external to the ED with warm water and proper personal protective equipment. ED decontamination is performed far from the release of the chemical, is not in a warm zone, and does not require fully encapsulated supplied air gear. However, ED decontaminators should wear chemical-resistant covers for all body surfaces (e.g., chemical-resistant gloves, coveralls, and boots) and air-purifying respirator masks with filters that are designed for chemical threats.[11,13]

HIGH-RISK CHEMICALS (TABLE 8-4)

TOXIC INHALANTS

Toxic inhalants tend to interfere with one or more of the four phases of oxygen delivery. Gases that interfere with oxygen uptake by displacement of oxygen from air are **simple asphyxiants**. Interruption of pulmonary diffusion may occur with some of the less soluble irritant agents such as phosgene. Agents that may interrupt oxygen transport include carbon monoxide and the methemoglobin-forming agents. Agents that interfere with oxygen utilization at the cellular level, such as cyanide, azide, and sulfides, produce severe lactic acidosis.

DISPLACEMENT OF OXYGEN FROM AIR: SIMPLE ASPHYXIANTS

Simple asphyxiants create an oxygen-poor environment by displacing oxygen from air. Many inert gases fall into this category, such as carbon dioxide, hydrogen, nitrogen, the noble gases (helium, neon, argon, krypton, xenon, radon), and simple hydrocarbons such as methane, butane, and propane. An occupant confined in a closed unventilated space may die as the concentration of an asphyxiant gas builds up silently.

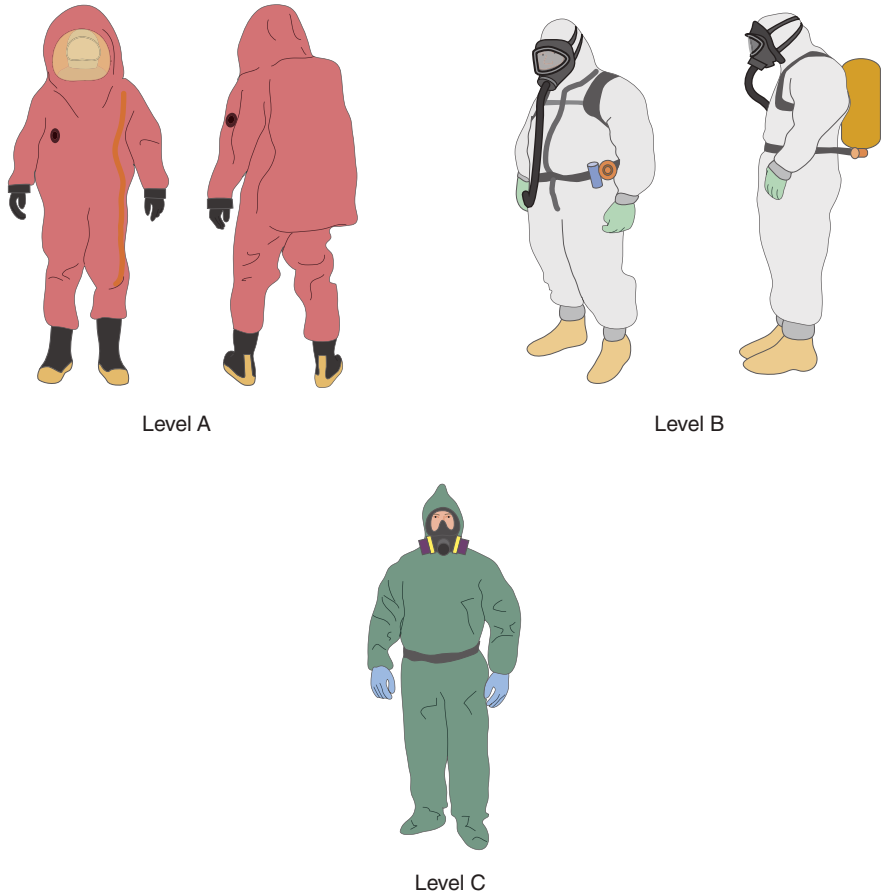

FIGURE 8-2. Personal protective equipment. Level A: Completely encapsulated protection. Requires use of self-contained breathing apparatus (SCBA) inside a chemical-resistant suit sealed at the face. Taped or suit-incorporated gloves and boots make this a completely sealed environment. Level B: Provides either an SCBA or a supplied air respirator and splash protection. The SCBA is worn outside the protective clothing and could expose this equipment to secondary contamination. There may be areas of the skin around the face mask of the SCBA where gas or vapor may penetrate. Level C: Either a gas-mask or air-purifying respirator and skin slash protection. This is the highest level of protection most hospital-based personnel should be trained to use.[12,13] [From U.S. Army Center for Health Promotion and Preventive Medicine Fact Sheet for Acute Exposure Guideline Levels. http://chppm-www.apgea.army.mil.]

TABLE 8-4 High-Risk Chemicals

	Simple Asphyxiants	Irritant Gases or Droplets	Agents that Interrupt Delivery of Oxygen to Tissues	Agents that Interfere with Oxygen Utilization in Mitochondria	Nerve Agents	Incapacitating Agents	Vesicants
Mechanism	Displace oxygen from air	React with H_2O in upper respiratory tract	Alter hemoglobin so it cannot transport O_2; or produce methemoglobin	Bind to cytochrome oxidase	Organophosphates, which bind to acetylcholinesterase	Immobilize victims in a variety of ways	Blistering to eyes, skin, mucous membranes, lungs
Agents	CO, H, N, methane, butane, propane	Ammonia, chloramine, SO_2, HCl, HFl, chlorine, phosgene	CO, methylene chloride, nitrites, benzocaine, phenazopyridine	Cyanide, HS, phosphine, sodium azide, CO	GA, GB (sarin), GD, VX, GF	Mace, narcotic vapors, LSD, BZ	Sulfur mustard, phosgene oxime, lewisite
Treatment	Remove from source, give O_2	Remove from source, give O_2, monitor pulmonary status; for HFl, monitor serum Ca	O_2, methylene blue	Hydroxocobalamin	Identify DUMBELS syndrome; atropine for muscarinic effects; 2-PAM for nicotinic effects, benzodiazepines for seizures; atrovent for wheezing; never give succinylcholine	Individualize for agent	Irrigate with water, supportive care; mustard agents can cause marrow suppression

Abbreviations: BZ = 3-quinuclidinyl benzilate; DUMBELS = defecation, urination, miosis, bradycardia/bronchospasm/bronchorrhea, emesis, lacrimation, and salivation; LSD = lysergic acid diethylamide; 2-PAM = pralidoxime.

For example, deaths have been reported in persons transporting dry ice in the back seat of an automobile with the windows closed. As the solid carbon dioxide sublimes from solid to gas, oxygen concentration drops, and the driver asphyxiates. When the concentration of any of these nonreactive gases increases, the fraction of inspired oxygen (F_{IO_2}) decreases. At an F_{IO_2} of <16%, air hunger, tachypnea, and changes in level of consciousness occur. At F_{IO_2} <10%, loss of consciousness, seizures, or vomiting may occur. Treatment is restoration of a higher F_{IO_2} with supplemental oxygen and correction of the problem that led to the exposure.[17]

IRRITANT AGENTS THAT INTERRUPT PULMONARY DIFFUSION

Irritant agents are classified according to their water solubility as high-, intermediate-, or low-solubility agents. Despite being often referred to as "irritant gases," many of these agents are actually liquid droplets suspended in the air. **Highly water-soluble agents react with water in the upper respiratory tract and produce immediate irritation and discomfort. The most common agent released in chemical events is the highly soluble pulmonary irritant ammonia.** Ammonia, used as an industrial refrigerant, is prototypical of a highly water-soluble vapor. The gas chloramine is created accidentally when bleach and ammonia cleaners are mixed together. Other chemicals with high water solubility include sulfur dioxide and hydrogen chloride. Hydrogen fluoride, in addition to being a highly water-soluble irritant vapor, also reacts with intercellular calcium, causing life-threatening calcium depletion and cardiac dysrhythmias. Because of the immediate discomfort caused by these agents, they have excellent warning properties to those exposed. These agents cause significant eye irritation and edema, burning in the throat, and, at higher concentrations, constriction of the upper airway.[6,17] Treatment is removal from the source, providing supplemental humidified oxygen, and monitoring pulmonary status. Hydrogen fluoride exposure also requires close monitoring of the serum ionized calcium level and administration of supplemental calcium IV.

The only agents classified as intermediate in solubility are chlorine and hydrogen sulfide. Chlorine was the first gas used in chemical warfare in the trenches during the First World War.[17,18] Chlorine is used for chlorinating water in swimming pools and as a disinfectant, making **chlorine releases the second most common hazardous material released. Chlorine reacts with water in the upper airways to produce hydrochloric and hydrochlorous acids.** Symptoms include burning of the conjunctiva, throat, and the bronchial tree. Because of its acrid odor, it has good warning properties. Higher concentrations can produce bronchospasm, lower pulmonary injury, and delayed pulmonary edema.

Phosgene, another chemical warfare agent used extensively in World War I, is prototypical of the minimally soluble agents.[17] At concentrations as low as 25 parts per million, it can be fatal after even brief exposures. It produces only minimal irritation to the eyes and upper airways and, in fact, has a pleasant odor of new-mown hay. However, it slowly hydrolyzes to hydrochloric acid and reacts in the alveoli to cause the delayed onset of severe acute lung injury. Treatment is directed at providing pulmonary monitoring, and the need for intubation and ventilator management is guided by clinical symptoms and radiographic findings of acute lung injury. Noncardiogenic pulmonary edema may require ventilation with positive end-expiratory pressure.

AGENTS THAT INTERRUPT OXYGEN TRANSPORT

Chemicals that react in the body to interrupt the delivery of oxygen do so by altering hemoglobin so that it is no longer capable of binding and transporting oxygen. Examples are carbon monoxide and methylene chloride, which is metabolized to carbon monoxide to generate carboxyhemoglobin. Certain other chemicals, including the nitrites, and some pharmaceuticals, such as benzocaine and phenazopyridine (Pyridium), may cause the iron moiety in hemoglobin to convert from divalent Fe^{2+} to trivalent Fe^{3+}. Hemoglobin with trivalent iron is called *methemoglobin*, and it is incapable of binding and transporting oxygen.[19] Symptoms of either exposure include those consistent with declining oxygenation. Headache, nausea, and fatigue occur at low levels; however, in those with critical fixed coronary artery lesions, angina may occur. Both carboxyhemoglobin and methemoglobin can be measured by co-oximetry on an arterial blood gas analyzer. Pulse co-oximeters are also available that detect both carboxyhemoglobin and methemoglobin and may be used by either prehospital agencies or in hospitals. Both hemoglobinopathies may be treated initially with high concentrations of oxygen. Methemoglobinemia may be treated with methylene blue, which acts as an electron donor and converts trivalent iron back to divalent iron.[19]

AGENTS THAT INTERFERE WITH CELLULAR OXYGEN UTILIZATION (CHEMICAL ASPHYXIANTS)

Chemical asphyxiants are agents that interfere with oxygen utilization at the electron transport chain in the mitochondria. **These agents include cyanide, hydrogen sulfide, phosphine, and sodium azide.**[20,21] Carbon monoxide also interferes with oxygen utilization, in addition to its effect on oxygen delivery. By binding to cytochrome oxidase a_3, these agents disrupt aerobic metabolism and create intracellular acidosis. Cyanogens have been developed for use in chemical warfare, and nitriles used in industry release cyanide.[21,22] Symptoms include headache, alteration of consciousness, seizures, and severe acidosis. Hydroxocobalamin was approved for use in the United States in 2006 for cyanide toxicity and for smoke inhalation and is administered as a 5-gram infusion.[22]

NERVE AGENTS

During World War II, scientists in Germany discovered and manufactured three nerve agents, classified as GA (tabun), GB (sarin), and GD (soman). In 1952, chemists in Great Britain and America manufactured the agents VX and GF.[23,24] Although the preferred terminology for these chemicals is organic phosphorus compounds, they are still referred to as organophosphates in most publications. These agents were chosen as chemical warfare agents over existing insecticides because they had greater CNS activity and higher lethality than many of the organophosphates and carbamates used for insect control.[23-27] With the advent of the Cold War, organophosphate production accelerated, with both the United States and Soviet Union developing large stockpiles of these agents.[24] Occasional accidents occurred, sickening soldiers handling these agents, and one chemical release of VX in Skull Valley, Utah, killed 6000 sheep.[28,29] In the 1980s, Iraq developed an extensive capability to manufacture and weaponize these gases and used both sarin and GF against both its own Kurdish people and the Iranians with whom it was engaged in a prolonged border war.[24] During the Syrian civil war in 2013, nerve agents were confirmed to be used as well, with over 800 civilian casualties.[30,31] Today, not only do many countries have the capability to manufacture these or similar agents, but terrorist groups have used them also. The Aum Shinrikyo cult used sarin in two separate attacks, one in Matsumoto in 1984, which killed seven people, and in a larger release in the Tokyo subway a year later that killed 12 people and sickened 5500 individuals.[14,16]

The organophosphate compounds inhibit several key enzymes by binding to them. They bind to acetylcholinesterase in a two-stage process. The first stage is reversible if the antidote pralidoxime (Protopam) is given.[26] The second stage (aging process) makes the enzyme unavailable to be regenerated by pralidoxime. Acetylcholinesterase breaks down the neurotransmitter acetylcholine. With this enzyme inhibited, acetylcholine remains at its postsynaptic receptor sites, causing excessive cholinergic stimulation. Within the parasympathetic nervous system, there are cholinergic receptors at muscarinic sites, such as tear glands, sweat glands, bronchial secretion glands, and the sinoatrial and atrioventricular nodes of the heart. **Overstimulation of these leads to the "DUMBELS" syndrome, a mnemonic for the following symptom complex: *d*efecation, *u*rination, *m*iosis, *b*radycardia/*b*ronchospasm/*b*ronchorrhea, *e*mesis, *l*acrimation, and *s*alivation.**[6]

The second location within the peripheral nervous system where cholinergic transmission is affected is the neuromuscular junction, or nicotinic receptor. **Excess cholinergic stimulation here causes the progression from muscular fasciculation to profound muscular weakness to complete paralysis in a dose-dependent fashion.** Early in the course, there can also be paradoxical hypertension and tachycardia, but

these both subside as the bradycardia from muscarinic receptors predominates in the clinical presentation.

The last location of importance for cholinergic stimulation is the brain, where excessive stimulation produces coma and seizures. Many organophosphates cross the blood–brain barrier freely, and the nerve agents in particular have potent CNS effects.

The treatment strategy for nerve agents must counteract cholinergic excess at all three of these receptor sites. **Atropine counteracts only the muscarinic effects. Pralidoxime counteracts the nicotinic effects. Benzodiazepines treat seizures.**[24,26] The indication for each of these agents varies with the clinical manifestations. For the patient with exposure in low concentrations, such as with vapor releases, only eye findings may develop. Pinpoint pupils, frequently with local pain, may be treated with any of the anticholinergic eye drops, scopolamine, or homatropine. If pulmonary symptoms are isolated to bronchospasm in the reactive airway disease–prone patient, ipratropium bromide (Atrovent) may be adequate. **Administer IV atropine to anyone experiencing hypersalivation, bronchial secretions, or bradycardia.**[25,26] Large doses of IV atropine, sometimes as much as 20 milligrams, may be needed.[26] This has been reported typically in ingestions but could be needed in liquid exposure to the nerve agents. High doses of atropine were not needed in the lower concentration exposures that occurred in the Tokyo subway incident.[14-16] **Titrate atropine administration to clearing of the excess secretions.** Pupil size and heart rate response are poor indicators of adequate atropinization in organophosphate exposure.

Pralidoxime reactivates the enzyme acetylcholinesterase at the neuromuscular junction. It can only reactivate the enzyme if the aging process has not occurred. How rapidly an agent ages varies from agent to agent; VX takes 24 hours, whereas soman takes only 5 to 8 minutes to age and create an irreversible bond.[26] The recommended initial dosage of pralidoxime is 1 to 2 grams IV slowly over 20 to 30 minutes.[24-26] **In a large event with multiple casualties, half this may be given to spread the antidote to the maximal number of patients.** Many patients with neuromuscular weakness will eventually require intubation and mechanical ventilation. Succinylcholine should not be used, if at all possible, because it is metabolized by the same enzymes inhibited by the organophosphates. **The onset of action of succinylcholine will be the same (usually <90 seconds), but the duration of action of this drug will be prolonged to several hours.**[32] Seizures, when they occur, may be refractory and, in combination with diaphragmatic paralysis, will lead to respiratory arrest. Use any of the IV benzodiazepines to treat seizures. Phenytoin and fosphenytoin are not effective for seizure control.

Patients with minor symptoms, such as eye findings only, may be observed for a 6- to 8-hour period and released if no further symptoms occur.[15] Admit any patient who received pralidoxime to an intensive care unit and give either a continuous infusion of pralidoxime at 500 milligrams/h or intermittent bolus dosages of 1 to 2 grams every 6 hours.[14,24]

INCAPACITATING AGENTS

The incapacitating agents are a diverse group of chemicals that immobilize victims.[13] Although riot control agents, such as Mace (Mace Security International, Horsham, PA), are not classically defined in this category, they can be considered incapacitating and are generally nonlethal. Narcotic vapors have also been used, such as the fentanyl derivatives used by Russia when they stormed the Moscow theater in 2002 where terrorists were holding hostages. The potent fentanyl derivatives, carfentanil and remifentanil, may have been mixed with a halothane-like anesthetic agent.[33] Despite the intent of this mixture to immobilize those inside the theater, lack of coordinated rescue efforts and late use of the antidote naloxone led to >100 causalities. 3-Quinuclidinyl benzilate is a long-acting potent anticholinergic agent. The U.S. Army developed it in the 1960s; exact information on how it was used is difficult to substantiate.[24] 3-Quinuclidinyl benzilate causes a severe and prolonged anticholinergic delirium similar to diphenhydramine or atropine. Other agents intended to immobilize victims have been experimented with, such as lysergic acid diethylamide, benzodiazepines, α_2-agonists, vomiting agents, and other exotic agents.

TABLE 8-5 Indications of a Possible Biotoxin Exposure

Occurrence of a disease or syndrome that rarely occurs naturally
Multiple victims of a similar disease with no classic risk factors
Epidemiology suggesting a point source or localized exposure
Possible animal and human morbidity in the same area
High mortality in an otherwise healthy population

VESICANTS

Sulfur mustard was first deployed by Germany in 1917 near Ypres, Belgium, the site of their release of chlorine as a chemical weapon 2 years earlier.[34,35] Vesicant agents were used extensively as military weapons by both sides in World War I and in a variety of regional wars leading up to and during World War II (Ethiopia, Manchuria).[24] The largest number of casualties from sulfur mustard came with the explosion of the Liberty ship *John Harvey*, during World War II in Bari, Italy, where 617 sailors sustained burns from sulfur mustard.[36,37] During the 1980s sulfur mustard was used in the Middle East (Iraq against Iran and the Kurds, Egypt against Yemen); 12 of these patients were transported to Germany, and their therapy was described in detail.[35] A small number of spills have occurred since in the United States at chemical weapons storage facilities.[36] **Vesicants cause damage to eyes, skin, mucous membranes, and potentially the lungs if exposed to high concentrations.** Sulfur mustards [bis(2-chloroethyl) sulfide] make up the most common vesicants used, although the nitrogen mustards were also produced, but never used militarily.[34] Other vesicant agents are phosgene oxime, a solid that liquefies at 35°C (95°F); this agent does not cause blisters but produces severe skin erythema.[24,36] Lewisite, an arsenical compound that smells like geraniums and that was developed in 1918, too late for use in World War I and thus never deployed, is also included in this category.[36] Both lewisite and phosgene oxime produce symptoms on immediate contact.[35-37] Sulfur mustard skin symptoms are delayed in onset for 4 to 8 hours, leading to blistering similar to second-degree burns within 2 to 18 hours of initial exposure.[34] Ocular damage from vapor exposure to all these agents is common, leading to incapacitation of the victims exposed. Corneal vesicle formation and sloughing of epithelium occur. The primary goal of therapy is copious irrigation with water to dilute and remove the chemical, and then monitoring the patient with serial eye examinations, pulmonary monitoring, and careful attention to skin care. The mustard agents may produce a systemic toxicity, with marrow suppression as a delayed component presenting with a falling white blood cell count and increased risk of infection 3 to 5 days after exposure.[35]

BIOTOXINS

The biotoxins differ from biologic agents in that the toxins do not replicate in the body and a sufficient dose needed to cause disease must be delivered. These agents produce unusual symptoms, some with delayed onset. Clues to biotoxin exposure are presented in **Table 8-5**.

With many biotoxins, the lethal dose in 50% of exposed subjects (LD_{50}) is quite low (**Table 8-6**), allowing small amounts to potentially be made into a high-risk weaponized aerosol and dispersed intentionally.[24]

TABLE 8-6 Lethality of Biotoxins

Agent	LD_{50} (micrograms/kg)
Botulinum toxin	0.001
Tetanus toxin	0.002
Staphylococcal enterotoxin B	0.02
Diphtheria toxin	0.10
Ciguatoxin	0.4
Ricin	3.0
Tetrodotoxin	8.0
Saxitoxin	10.0
Trichothecene toxin	1200

Abbreviation: LD_{50} = lethal dose in 50% of exposed subjects.

BOTULINUM TOXIN

Inhalational botulism has been described in humans only after an accidental laboratory exposure. It is estimated that the LD_{50} for inhalation botulism is 1 to 3 nanograms/kg.[24] Three days after performing an autopsy on a lab animal that died of botulism, three technicians developed tightness in the throat, difficulty swallowing, and symptoms characterized as a cold without a fever. They developed ocular paresis, rotatory nystagmus, dilated pupils, dysarthria, ataxia, and generalized weakness. All recovered within 2 weeks with antitoxin treatment.[24] Diagnosis requires the recognition of the clinical presentation, with early subtle cranial nerve palsies, typically presenting with difficulty swallowing, palsies of extraocular muscles, and trouble speaking.[38] **Treatment with antitoxin will prevent progression of the disease but will not reverse paralysis once it occurs. Administer the antitoxin based on clinical suspicion as early as possible; do not wait for the results of laboratory tests.** The heptavalent antitoxin against all subtypes of botulism is available by contacting the Centers for Disease Control and Prevention.[38] Give one vial of antitoxin IV in suspected cases of botulism. Supportive care, including mechanical ventilation, is frequently needed and may be required for 90 days or more in cases presenting with diaphragmatic paralysis before receiving the antitoxin.[38] Antibiotics only have a role in wound botulism and are not indicated in inhalational botulism.

RICIN

Ricin toxin gained notoriety when it was used as the agent to assassinate Bulgarian activist Georgi Markov. At autopsy, a pellet containing ricin was removed from a small wound in the back of his leg. The pellet was fired from a specially designed umbrella into his leg while he waited at a London bus stop.[24] Ricin is a toxin derived from the castor bean, *Ricinus communis*.[39] Ricin is not toxic by ingestion and must either be injected or inhaled as an aerosolized powder to produce disease. Ricin is taken up by cells in many tissues and causes destruction of RNA, leading to cell death. With inhalation exposure, pulmonary symptoms occur after about an 8-hour postexposure delay. Inflammation, exudates, and pulmonary edema occur, producing a necrotizing pneumonitis. After parenteral administration, local pain occurs, followed in a few hours by weakness and flu-like symptoms. Fifteen to 24 hours later, nausea, vomiting, fever, and localized lymphadenopathy proximal to the injection site may occur. After 48 hours, a sepsis-like syndrome occurs with hypotension, leukocytosis, disseminated intravascular coagulation, and multiorgan system failure (involving the liver, kidneys, heart, lungs, and GI hemorrhage). In Georgi Markov's case, death occurred by deterioration to complete atrioventricular dissociation.[24] The differential diagnosis includes other causes of sepsis, but in the setting of an intentional attack, staphylococcal enterotoxin B must also be considered. Diagnosis may be confirmed by an enzyme-linked immunosorbent assay. Contact the Centers for Disease Control and Prevention in any suspicious case. Aggressive supportive care in an intensive care unit is warranted for all cases.

CHAPTER 9

Bioterrorism

Anthony G. Macintyre
Joseph A. Barbera

INTRODUCTION AND EPIDEMIOLOGY

An adequate response to a bioterrorist event of any magnitude requires early recognition and effective coordination of many disparate health and medical entities beyond the ED. Although the emergency physician plays a critical role in these types of events, many other essential functions must be addressed by individuals and organizations representing public health, mental health, law enforcement, emergency management, and others.

A bioterrorist incident is the release, or the threat of a release, of a biologic agent among a civilian population for the purpose of creating fear, illness, and death. Such an occurrence is a low-probability, high-impact incident. For example, in the U.S. anthrax dissemination incident, the U.S. Postal Service was used to deliver letters containing spores of *Bacillus anthracis*. Although the environmental contamination was widespread, only 22 diagnosed cases of anthrax infection occurred: 11 cases of inhalational and 11 cases of cutaneous anthrax. Five patients died as a direct result of the anthrax exposure.[1] Communities on the Eastern Seaboard of the United States were severely affected, with thousands of people receiving prophylaxis for anthrax.[2] Fear then spread across the nation, as concern increased for a wider delivery of anthrax. Much of this national anxiety may have been exacerbated by the perception of an inadequate public health response capability, with the deficiencies demonstrating a critical need to integrate acute care medicine and the public health response.

Biologic agents are classified into two groups: biologically produced toxins and infectious organisms. Biologic toxins usually act as chemical agents in their human impact. The recognition and response requirements for these are very similar to those for chemical incidents. Infectious agents are subdivided into two categories: contagious (propagating person to person) and noncontagious. Contagious agents have additional ramifications, both for protection of the healthcare workforce as well as propagation of the disease beyond the initially exposed population. The contagious agents of greatest concern, such as smallpox, plague (pneumonic), and certain viral hemorrhagic fevers, are person-to-person infectious through airborne or droplet transmission. Suspected biologic agents causing illness should be treated as contagious until demonstrated otherwise.

AGENTS OF CONCERN

Certain characteristics make individual organisms particularly attractive as weapons for generating widespread fear, illness, and death among civilian populations. The Centers for Disease Control and Prevention identified select organisms and the diseases they cause as the priority for focused preparation.[3] Infectious agent selection was based on four general criteria:

1. Potential for public health impact
2. Delivery potential (an estimation of the ease for development and dissemination, including the potential for person-to-person transmission of infection)
3. Public perception (fear) of the agent
4. Special requirements for public health preparedness (diagnostic, logistic, etc.)

The selected agents were then ranked in three categories, based on their overall potential for adverse public health impact (**Table 9-1; Figures 9-1 to 9-3**). **Class A agents have the most severe potential and include viruses and bacteria such as variola major (smallpox), *B. anthracis* (anthrax), and *Yersinia pestis* (plague). Class B agents are considered to have less potential for causing widespread illness and death, and Class C agents are those that, as technology improves, could emerge as future threats.** More common pathogens could be used to cause intentional injury and death, and the intentional etiology of the infections may be apparent only through epidemiologic cohort evaluation. This chapter focuses on Class A agents, but applies also to a range of additional bacteria and viruses that, although not on the Centers for Disease Control and Prevention list, could have a similar human impact if used in a nefarious manner (e.g., hanta virus).

CLINICAL FEATURES: RECOGNITION OF A BIOTERRORISM INCIDENT

Unless the release of an agent is openly announced or the terrorist is caught in the process of delivering the agent, initial indications of attack may be subtle. **Early symptoms of most agents of concern are not**

TABLE 9-1 Infectious Agents of Concern as Defined by the Centers for Disease Control and Prevention

Biologic Agent	Disease Caused	Incubation Period	Signs and Symptoms
Class A agents			
Variola major	Smallpox (Figure 9-1)	7–14 d	Initially fever, severe myalgias, prostration; followed within 2 d by papular rash on the face spreading to extremities (affecting palms and soles) and then to trunk (lesser extent than chickenpox); lesions progress at same rate, becoming vesicular and then pustular with subsequent scab formation
Bacillus anthracis	Cutaneous anthrax (Figure 9-2)	Usually 1 d, up to 2 wk reported	Macule or papule enlarging into eschar with surrounding vesicles and edema; sepsis possible, less common
	GI anthrax	Usually 1–7 d	Abdominal pain, vomiting, GI bleeding progressing to sepsis; mesenteric adenopathy on CT
	Oropharyngeal anthrax	Usually 1–7 d	Sore throat, ulcers on base of tongue, marked unilateral neck swelling
	Inhalational anthrax (Figure 9-3)	Usually <1 wk, 43 d reported at Sverdlovsk[4]	First stage is nonspecific (fever, dyspnea, cough, headache, vomiting, abdominal pain, chest pain); second stage (dyspnea, diaphoresis, shock); hemorrhagic mediastinitis with widened mediastinum on x-ray
Yersinia pestis	Bubonic plague	2–8 d	Initially fever, chills, painful swollen lymph node(s); node progresses to bubo (sometimes suppurative)
	Pneumonic plague	2–3 d	Fever, chills, cough, dyspnea, nausea, vomiting, abdominal pain; clinical condition consistent with gram-negative sepsis
	Primary septicemic plague	2–8 d	The clinical condition is consistent with gram-negative sepsis, disseminated intravascular coagulation (secondary septicemic plague may occur after bubo formation)
Clostridium botulinum	Foodborne botulism	1–5 d	GI symptoms followed by symmetric cranial neuropathies, blurred vision, progressing to descending paralysis
	Inhalational botulism*	12–72 h	Symmetric cranial nerve palsies followed by descending paralysis
Francisella tularensis	Tularemia	1–21 d	Depends on route of exposure: all usually involve abrupt nonspecific febrile illness; inhalation exposure progressing to pleuropneumonitis; cutaneous exposure developing glandular or ulceroglandular lesions; ingestion developing oropharyngeal lesions/tonsillitis
Filoviruses and arenaviruses (Ebola virus)	Viral hemorrhagic fevers	2 d–3 wk, depending on virus	Initial nonspecific febrile illness, sometimes with rash; progresses to bloody vomiting, diarrhea, shock
Class B agents			
Coxiella burnetii	Q fever	2–3 wk	Fever, myalgias, headache, 30% develop pneumonia, rarely lethal (2%)
Brucella spp.	Brucellosis	2–4 wk	Fever, myalgias, back pain; CNS infections and endocarditis possible
Burkholderia mallei	Glanders	10–14 d	Local infection: ulcers, suppurative; pneumonia, pulmonic abscesses, sepsis possible
Burkholderia pseudomallei	Melioidosis	2 d to years reported	Local infection: nodule; pneumonia, pulmonic abscesses, sepsis
Alpha viruses (Venezuelan equine encephalitis, Eastern equine encephalitis, Western equine encephalitis)	Encephalitis	Variable	Fever, headache, aseptic meningitis, encephalitis, focal paralysis, seizures
Rickettsia prowazekii	Typhus fever	7–14 d	Fever, headache, rash
Toxins (ricin, *Staphylococcus*, enterotoxin B)	Toxic syndromes	—	—
Chlamydia psittaci	Psittacosis	6–19 d	Fever, headache, dry cough, pneumonia, endocarditis
Food safety threats (*Salmonella* spp., *Escherichia coli* O157:H7)	—	—	—
Water safety threats (*Vibrio cholera, Cryptosporidium parvum*)	—	—	—
Class C threats			
Emerging threat agents (Nipah virus, hantavirus)	—	—	—

*Inhalational botulism may not be preceded by GI symptoms. Inhalational and foodborne botulisms are caused by botulinum toxin, not the bacteria itself.

Note: Incubation periods should be interpreted with some caution. Data in some instances are limited and in others may be based on natural outbreaks. Intentional releases or engineered organisms could cause variations in expected disease parameters.

readily distinguished from more common, less threatening illnesses. Fever, myalgias, and malaise could be the initial presenting symptoms of a victim of bioterrorism (anthrax and others) or of influenza, parainfluenza, or many common illnesses. This is more than a theoretical risk, as demonstrated when some agents of concern have been documented to occur in the nonbioterrorism setting.[5] During the anthrax dissemination incident in 2001, several anthrax-infected postal workers were evaluated by physicians early in their illness. Their relatively nonspecific symptoms were attributed to other causes, and they were discharged home without antibiotic therapy.[6] Two postal workers in this cohort died from inhalational anthrax. The similarity in early symptoms also creates another response issue: once an attack becomes public, patients with any

FIGURE 9-1. Smallpox.

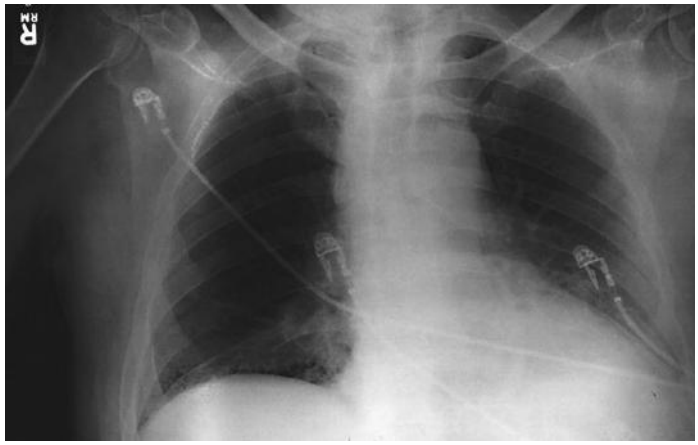

FIGURE 9-3. Chest radiograph with widened mediastinum characteristic of inhalational anthrax.

of those common symptoms or concerns about exposure may seek rapid evaluation in EDs, clinics, or private offices. Extreme patient volume and diagnostic challenge should be anticipated.

The recognition of a biologic attack could occur through several pathways:

1. A patient presents with signs, symptoms, or real-time diagnostic results that obviously indicate a suspect disease process.
2. A patient presents with protean symptoms, but an astute clinician establishes enough criteria (e.g., suspicious historical information, signs, symptoms, short-turnaround laboratory results, public health corroborative information) to designate the patient as a presumptive case until diagnostic confirmation can be accomplished.
3. Patient is evaluated and admitted or released but not suspected as being a victim of bioterrorism. That patient's course then unexpectedly worsens, or diagnostic test results (e.g., blood cultures, immunoassays), even postmortem, subsequently establish a diagnosis.
4. Multiple patients present over a defined period with similar symptoms or historical characteristics, with the cohort pattern raising practitioner suspicions that prompt a report to public health. Further investigation, through environmental and diagnostic testing and/or public health investigation of the cohort, establishes the cause.
5. Public health surveillance systems establish unusual patterns of signs, symptoms, or disease in the community and investigate further to establish the etiology.

FIGURE 9-2. Ulcer and eschar of cutaneous anthrax.

6. Sampling technologies (of which there are numerous types related to different jurisdictions and agencies) detect the release of an agent of concern in the community.

Based on the few historical cases, the first three scenarios may be the most likely ways in which a bioterrorist event would be detected. Scenario 3 is how the inhalational anthrax index case was initially diagnosed in Florida during the fall of 2001.[7] The initial inhalational anthrax infection in a postal worker was recognized as in scenario 2. Thus, the emergency physician should have an operational knowledge of the biologic agents of concern or understand where to readily access this information. This knowledge should include basic pathologic principles for each agent, modes of dissemination and transmission, disease signs and symptoms, recommended diagnostic testing, recommended treatment (medications, immunizations, or prophylaxis), and infection control practices (Table 9-1 and **Table 9-2**).[8]

DIAGNOSIS

Real-time diagnostic studies to reliably confirm or exclude the presence of potential agents of concern are not available for all Centers for Disease Control and Prevention–designated agents (this actually does not differ from most common infectious processes). In some cases, specialized confirmatory testing by state or federal laboratories may be required (e.g., through the Laboratory Response Network),[10] and methodologies are rapidly evolving. Therefore, clinicians should command sufficient knowledge to initiate available and appropriate test ordering, medical interventions, and reporting when they are **suspicious** of a patient's clinical presentation. The public health authorities with jurisdiction over the involved communities should be consulted early for current diagnostic recommendations and further testing (both patient and environmental).

Be prepared to appropriately respond to notification of a potential disease by another health or medical professional (public health authority, laboratory technician, radiologist, pathologist, or medical examiner). Carefully query the reporting source for pertinent specific information before considering further actions such as those delineated below. Questions to be asked include the methodology of the testing that produced the concern (specimen collection technique and the sensitivity and specificity of the test procedure) and the time until confirmatory test results become available.

Situations that are much more common and pose a great challenge to ED operations are those in which patients present after having been exposed to an unidentified substance (e.g., white powder), with circumstances that raise suspicion for terrorism (e.g., threatening letter, high-profile location, a "very important person"). The source substance may not have been properly evaluated or secured, and any recommended treatment necessarily will involve coordination with outside agencies, especially public health and law enforcement. If no environmental or

TABLE 9-2 Class A Agents: Treatment, Prophylaxis, and Vaccination

Biologic Agent	Vaccination	Prophylaxis	Treatment
Variola major	Vaccinia vaccination: currently not recommended for general public use because of its association with limited numbers of deaths and complications in immunocompromised individuals and those with eczema; useful in preventing disease if given within 4 d of exposure	Vaccinia immune globulin: best given within 2–3 d of exposure; limited supplies are available; consider giving to those exposed who have contraindications to vaccine. Several antivirals are under investigation for postexposure prophylaxis.	Supportive.
Bacillus anthracis	Anthrax vaccination: five-part series vaccination at 0 and 4 wk and then at 6, 12, and 18 mo; annual boosters required; currently not available to the public (offers have been made to the first responder community); efficacy in preventing inhalational anthrax demonstrated in animal models	Ciprofloxacin or doxycycline for 60 d is preferred, but alternatives exist. In addition, amoxicillin and penicillin V potassium for penicillin-susceptible strains; 60-d term established by using latency period for last infection occurring at Sverdlovsk[4]; consider concurrent 3-dose vaccination.* NOTE: 60-d regimen recommended whether vaccinated before event, receiving postexposure vaccination, or no vaccination.[9]	Three-drug IV regimen for presumed or proven meningitis concurrent with illness. Two-drug regimen for illness with meningitis ruled out (see Hendricks et al[9] for specifics). Consider antitoxin administration for systemic anthrax infection (either raxibacumab or anthrax immune globulin).
Yersinia pestis	Killed whole bacilli vaccine no longer available by producers; vaccine had efficacy in preventing bubonic disease but not the pneumonic form	Ciprofloxacin or doxycycline; alternative: chloramphenicol; prophylaxis for 10 d.	Streptomycin or gentamicin preferred choices; alternatives: doxycycline, ciprofloxacin, chloramphenicol.
Clostridium botulinum	Vaccine not available to the public: pentavalent toxoid of C. botulinum toxin types A–E; three-part series with yearly booster	Not applicable.	Antitoxin: requires procurement through local public health agency (state or the Centers for Disease Control and Prevention); antitoxin may preserve remaining neurologic function but does not reverse paralysis; may require prolonged, assisted mechanical ventilation and supportive care.
Francisella tularensis	Live attenuated vaccine was under investigation but now discontinued in United States	Ciprofloxacin or doxycycline for 14 d.	Streptomycin or gentamicin preferred choices; alternatives: doxycycline, ciprofloxacin, chloramphenicol.
Filoviruses (e.g., Ebola virus) and arenaviruses	Not applicable	Not applicable.	Supportive therapy; ribavirin may have applicability in arenaviruses.

*Not approved by the U.S. Food and Drug Administration but potentially available under Emergency Use Authorization.

NOTE: Due to multiple ongoing efforts, some new or adjusted therapies may be available in the near future. Readers are encouraged to check peer-reviewed literature because this is a dynamic field. Specific recommendations exist for some agents and may entail use of therapies traditionally reserved for nonpregnant adults. In some cases, these entail use under Emergency Use Authorization, which is beyond the scope of this chapter.

agent testing was performed, one may attempt to obtain confirmatory studies through the local public health authorities if the substance remains available. Otherwise, the difficult task of stratifying patient exposure risk is necessary, using arguably nonspecific factors such as patient demographics and the specific characteristics of the incident (e.g., white powder found in a local business vs a high-level federal official's office). The public health authorities with jurisdiction over the involved communities should be consulted early in the process, ideally by using a preplanned notification process and decision support tools. When testing has been performed by others, the emergency clinician should request specific information on the testing methodology and judge the reliability of the test procedure. For example, anthrax environmental testing may be performed with a wide range of procedures, including immune-based assays, assays based on polymerase chain reaction, and confirmatory culture testing.[11] Older immune-based assays caused numerous instances of false-positive environmental tests, which were subsequently reported in the media and created serious public concern during and after the 2001 anthrax incident. Clearer understanding of the sensitivity and specificity of these tests could have assisted in interpretation and representation of results.[12]

Methods for potentially detecting a biologic event include the recognition of unusual epidemiologic phenomena such as a high incidence of nonspecific illness, clusters or large numbers of rapidly fatal cases, and steep infection curves identified through public health surveillance systems.[12]

Much effort in the United States has been focused on developing broad-based public health surveillance systems for detection of disease. The surveillance systems currently in use or under development are based on collecting and analyzing public health information and/or patient diagnostic information in specific communities. It is intuitive that this may be further enhanced by the widespread adoption of electronic medical records. Information is sought from many disparate sources, including hospitals, clinics, nursing homes, pharmacies, emergency medical service systems, independent laboratories, medical examiners, and general businesses (e.g., absenteeism rates). Information collected from EDs often is based on symptom complexes (syndromic surveillance). The City of New York Department of Health and Mental Hygiene has operated this type of surveillance system since the late 1990s, which has more recently capitalized on the use of electronic medical records.[13,14]

Air sampling systems to detect inhalation agents have been implemented in some communities and for specific agencies or facilities across the United States. The most well-known is the BioWatch program, which uses strategically placed sensors in specific communities. These sensors operate on the principle of drawing air samples across filters that are subsequently analyzed for some agents of concern.[15,16]

INITIAL RESPONSE TO A BIOTERRORISM INCIDENT

Every receiving facility and ED should have standard operating procedures to manage a bioterrorism threat or actual incident. These should be incorporated into the all-hazards emergency operations plan, with bioterrorism-specific procedures in an attached incident-specific annex. The initial response to a suspected or confirmed bioterrorist event should involve many different hospital departments plus agencies outside the hospital. Initial actions taken by the emergency physician can be pivotal in the success of the hospital performance and the overall community response.

When bioterrorism is confirmed or suspected, critical initial notifications and prompt emergency operations plan activation should include:

1. Activation of processes and procedures (including preplanned surge capacity configuration) as appropriate and as listed in incident-specific annexes to the emergency operations plan
2. Implementation of appropriate infection control procedures (which may extend to how patients are received in the ED), with provision of protective equipment for patients and healthcare workers[17]

TABLE 9-3 Guidelines for Initial Public Health Reporting

1. Diagnosed or suspected agent of concern
2. Whether it is a presumed or confirmed diagnosis (and method for "confirmation")
3. Patient demographics (including occupation)
4. Recent history of travel or participation in special events by the patient(s) (mass gatherings, high-profile events, or at-risk activities)
5. Patient condition
6. Initial testing performed and further diagnostic testing being conducted
7. Treatment being provided
8. Public health assistance required (including environmental and additional patient testing)
9. Preferred method of contacting hospital or treating physicians for follow-up

3. Notification of key departments, including hospital administration, infection control and infectious diseases, security, environmental services, and the hospital laboratory
4. Information flow to all hospital personnel regarding the suspected agent, its characteristics (including potential for person-to-person transmission), and actions to protect the staff
5. Coordination of hospital media messages to external entities (other hospitals, public health, emergency management) to avoid dissemination of conflicting information
6. Notification of the appropriate public health agency, with confirmation that law enforcement was notified by them

Initial information that should be conveyed to the public health department is listed in **Table 9-3**. Ideally, the hospital emergency operations plan fully integrates the hospital into the community response, which is critical for successful bioterrorist incident response.[18]

The local department of health then has the responsibility to notify regional or state public health departments and the Centers for Disease Control and Prevention. With some agents and/or situations, the U.S. Department of Health and Human Services would notify the World Health Organization, because the potential impact could be global and this reporting is mandatory under International Health Regulations administrated by the World Health Organization (the United States is a signatory to International Health Regulations).[19] Public health officials also have the responsibility for notifying local law enforcement and the Federal Bureau of Investigation.

INTEGRATION WITH THE LOCAL HEALTH DEPARTMENT

In any suspected or confirmed case of bioterrorism, the emergency physician can expect to interface with multiple diverse agencies in an ongoing fashion, the most critical of which is the local public health department. In most communities, public health epidemiologists are assigned the task of defining the size and scope of an incident, the at-risk population, and other incident parameters. This type of information becomes critical to acute care clinicians, other medical care providers, and hospitals in the evaluation and treatment of patients and in anticipating medical surge and continuity of operations requirements. Challenges, such as the evaluation of minimally symptomatic individuals or the evaluation of large volumes of patients, can be facilitated by receiving clear and concise information from public health. **The most important assistance public health can provide to all clinicians is in the development of a community-wide patient evaluation and treatment protocol.** Evaluation and treatment protocols provide criteria to stratify individual and population risk for exposure and guide steps for specific evaluation and treatment. The protocol also should include recommended testing, treatment, patient instructions, tracking of at-risk cohorts, and public education.

A single evaluation and treatment protocol provides a uniform method across a community to evaluate patients presenting with possible exposure. This is important not only for individual practitioners but also for the public. During the 2001 anthrax incident, the initial epidemiologic investigation in the Washington metropolitan area used nasal swabs in suspect exposures. This practice was misunderstood by some clinicians and the public as having individual diagnostic utility when, in fact, it was merely an epidemiologic surveillance tool. Anxiety and confusion resulted when individuals received nasal swabbing at some healthcare locations and were (correctly) told it was not useful for diagnosis at other medical facilities. Because no early standardized protocol was developed by the public health system, hospitals implemented their own individual protocols to limit variation between clinicians practicing within individual hospitals. The resultant variability between institutions, however, caused great consternation for patients and, subsequently, for providers.

Critical information that the public health system should also provide includes a clear and concise case definition for the particular agent in question. **A case definition imparts definitive clinical and diagnostic criteria for an individual patient.** Within the case definition, criteria should be supplied that define "presumptive" or "suspect" cases for patients awaiting confirmatory testing. This kind of tool is simple and allows practitioners to officially designate victims as "confirmed" or "presumptive/suspected" for the target illness. Similarly delineated "exposure" categories are helpful in providing criteria for stratifying risk by designating "confirmed" or "presumptive" (suspected) exposure.

INTEGRATION WITH OTHER RESPONSE ASSETS

Requests for assistance or for resources not available within an individual hospital should be coordinated through the hospital administration to other hospitals (through mutual aid mechanisms), the local department of health, and/or the local emergency management agency. From there, requests may be transmitted to the regional, state, or federal levels.[18]

TREATMENT

General treatment principles for victims of bioterrorism should be understood by the practitioner. Specific therapies for individual Class A agents are listed in Table 9-2. From a population perspective, morbidity and mortality are primarily minimized by preventing exposure and providing prophylaxis and immunization as appropriate, and then by treating the infected, symptomatic patients. Treatment may involve specific pharmaceuticals or general supportive care. Depending on the agent involved, prophylaxis or immunization of the hospital staff may be warranted. **Prophylaxis, immunization, or treatment may be indicated even without obvious signs of disease or definitive information about exposure.** This makes the practitioner heavily reliant on the public health sector to stratify patient risk based on exposure and to provide evidence-based prophylaxis and treatment. With specific agents (e.g., anthrax), large community-based efforts have been developed with federal support related to the dispensing of postexposure prophylaxis (i.e., Medical Counter Measures).[20]

MEDICAL SURGE

One of the critical issues in providing treatment to victims of bioterrorism is the development of adequate medical surge.[18] This issue is complicated by current healthcare industry practices that minimize staff, maintain just-in-time inventory, and limit hospital bed capacity. Medical surge capacity is developed by first maximizing individual healthcare facility capacity and capabilities (through an effective emergency operations plan) and then by coordinating regional resources to address and match patient needs to available resources. The development of emergency healthcare coalitions is supported by federal funding through the national Hospital Preparedness Program, in part to achieve this surge requirement through information dissemination and effective mutual aid. State and federal assistance should also be included in planning but not relied upon for at least the first 48 hours.

Federal agencies distinguish medical *surge capacity* from *surge capability*, which similarly can pose challenges.[18] *Medical surge capability* refers to the ability to manage patients requiring unusual or very specialized medical evaluation and care. It is intuitively obvious, for example, that even one patient presenting with signs and symptoms of smallpox would present highly unusual challenges affecting any hospital's continuity of operations.

DISEASE CONTAINMENT

Infection control guidelines for the diagnosed or suspected agent should be put into practice. This is essential to protect clinicians, hospital staff,

visitors, and other patients. It is also critical in maintaining the ability of the hospital to continue its regular medical commitment to the community. The Association for Professionals in Infection Control and Epidemiology has published guidelines for hospital infection control in response to a bioterrorist event.[21] Most agents of concern require only standard precautions (gloves, mucous membrane protection when potential for splashing exists, and a gown when the potential exists for soiling), but meticulous attention to detail is required. The more troubling agents are those that are contagious through airborne or droplet transmission. Disease containment for a case of pneumonic plague requires droplet protection and patient isolation. Smallpox requires airborne and contact precautions and, therefore, full patient isolation. If a contagious disease is spreading within the community, procedures must be instituted to screen everyone entering the healthcare facility (e.g., staff, patients, visitors, delivery personnel) for active disease. This screening should ideally take place in an appropriately established "facility" before entering or immediately upon entry into the hospital building.

Isolation of large numbers of infectious patients may be necessary. Current hospital configurations often prohibit large-scale containment of patients in official isolation rooms, but entire wings could be adapted (using fire doors and manipulation of ventilation/air pressure within hospital smoke compartments) to serve as isolation wards. Plans to provide adequate separation from other, noninfected patients, to designate and train specific staff to care for these patients, and to furnish proper personal protective equipment should be developed in the emergency operations plan annex.

Another important initial consideration for ED personnel is whether patient decontamination is indicated. **Decontamination is a consideration only if a patient presents shortly after acute exposure to a substance suspected or confirmed as a biologic agent, in contrast to the presentation of the patient who has already developed symptoms of an infectious disease.** If a realistic concern exists, simply disrobing the patient and showering with soap and warm water should be adequate decontamination, but this must be accomplished in a controlled environment before patient entry into the healthcare facility. Clothing and personal belongings should be secured to assist with the public health and law enforcement investigations. Decontamination agents, such as diluted bleach, should be avoided, due to their potential for harm and the lack of demonstrated clinical or protective efficacy.[22,23]

SUPPLY MANAGEMENT

Just-in-time inventory practices may limit the amount of vaccine, antibiotics, and other pharmaceuticals and supplies available. Vendors for emergency back-up supplies and equipment are commonly shared by multiple institutions, each counting the vendor's back-up cache as their own. Having a community-wide mutual aid system between all the hospitals promotes appropriate sharing of critical supplies, equipment, and staff during an emergency. If prescriptions are being written for antibiotics, the local pharmacies' on-hand supply should be considered (an issue during the anthrax incident in 2001). Writing short-course prescriptions with procedures to provide completion of the medication regimen may be indicated until adequate supplies are available, but this strategy should be implemented on a region-wide basis to not place an individual practitioner's patients at increased risk. Integration of Strategic National Stockpile supplies into a medical community has specific requirements that are available for review through the Centers for Disease Control and Prevention and requires specific planning by the community emergency management and public health agencies.[18]

PATIENT MANAGEMENT

In unusual and very threatening situations such as bioterrorism, addressing the requirements of each patient encountered and maximizing efficiency can markedly facilitate the overall processing of victims. For those patients who are potentially exposed but not physically ill, the patient interaction may require sophisticated explanations as to why the individual is or is not receiving a particular therapy. Preprinted instructions (indicating category of risk stratification and why the patient was placed in that category) can increase efficiency and be helpful for patients being treated and released. These instructions should clearly indicate how the disease is transmitted, measures that prevent spread, and early signs and symptoms of disease with appropriate steps if they should occur. Appropriate follow-up should be established (in a large-scale incident, this may not be with a primary care physician but through a public health venue). It is important to note any change in the epidemiology of the incident (e.g., a new site tests positive for the agent) or if new information becomes available on the etiologic agent itself (e.g., antibiotic resistance patterns). Patients may need to be rapidly re-contacted to change therapy. Proper record keeping and organization of charts based on assigned risk category can assist with this process. Entering all patients into a reliable long-term surveillance database should be a task for the public health agency, but hospitals and EDs could facilitate this process.

For agents of concern that have an available vaccine, such as anthrax and smallpox, in a preincident setting, recommendations are to withhold vaccination for the general public.[23,24] Anthrax vaccination requires a series of five injections followed by yearly updates. A 2003 initiative to vaccinate healthcare workers and willing civilians against smallpox was discontinued after only a minority of the target cohort actually accepted vaccinations. The risk of potential life-threatening side effects, such as generalized vaccinia and potential cardiac sequelae, complicates the recommendations for smallpox vaccination in the absence of known disease.[25]

Therapeutics recommended for some bioterrorism agents are normally not approved for children or for pregnant or lactating women. In many situations, these recommendations are relaxed (e.g., Emergency Use Authorization) when the risk of infection and its consequences exceeds the risks of the medication or vaccine. In addition, some unique treatments (e.g., ciprofloxacin for anthrax prophylaxis in children) have received U.S. Food and Drug Administration approval.

CHAPTER 10

Radiation Injuries

Annette M. Lopez
Jennifer A. Stephani

INTRODUCTION

Radiation exposure may either be accidental or intentional. The year 2015 marked the 70th anniversary of the bombing of Hiroshima and Nagasaki, with nearly 200,000 acute deaths and untold numbers with chronic disability. Accidental exposures can occur during transport, storage, or working with radioactive materials or with errors in dosing radiotherapy. Most civilian incidents involve industrial exposures from sealed radiation sources.[1] The Fukushima Daiichi nuclear disaster resulted in about 1000 disaster-related deaths; however as of this writing, no deaths were related to radiation exposure.[2]

The largest reported accidental exposure took place in Goiania, Brazil in 1987. An "orphaned" cesium-137 radiosource was left in place at an abandoned radiotherapy institute. Individuals looking for scrap metal removed the source and dismantled it. They proceeded to sell it to a junk dealer, who observed the material glowing in the dark. Due to this unique characteristic, he distributed it to family and friends, who quickly became ill with acute radiation syndrome. At the conclusion of this event, there were 112,000 individuals evaluated for exposures, 249 who were contaminated, 20 who required hospital admissions, and four who died.[3,4]

A famous case of malicious intentional exposure involved Alexander Litvinenko, a former KGB agent who had defected to England. In 2006, after a meeting with former co-workers, he suffered a protracted gastrointestinal illness with associated leukopenia. On the day of his

death, elevated levels of polonium-210 were identified, confirming his death from radiation exposure. Investigations into his murder revealed that there are had been rehearsals in multiple areas of England leading to contamination.[5] The public health response that followed found that there were 1693 local and international individuals who were potentially exposed during such rehearsals.[6,7]

Radiologic dispersal devices, or "dirty bombs," combine radioactive materials with conventional explosives in attempts to disperse "hot material" over an unsuspecting population. The intended use of these devices is to generate some injuries, but the true goal is to generate massive panic and hysteria, overwhelm local resources, affect the local economy, and lead to prolonged clean-up efforts.[4]

FUNDAMENTALS OF RADIATION PHYSICS

Radiation energy includes the entire electromagnetic spectrum: from low-energy, long-wavelength, and low-frequency *nonionizing radiation*, such as radio waves and microwaves, to high-energy, short-wavelength, and high-frequency forms of *ionizing radiation*. Ionizing radiation has enough energy to remove an electron from an atom and generate charged particles. Sources of ionizing radiation are: alpha particles, beta particles, neutrons, and sole energy waves that include x-rays and gamma rays.[8]

Alpha and beta particles and positrons are charged particles that directly interact with electrons of the atom. Neutrons are not charged, and they lead to expulsion of other particles after interactions with the atomic nuclei, so neutrons indirectly generate charged atoms. Gamma and x-rays are electromagnetic waves that destabilize the atomic nucleus and lead to the expulsion of ionized particles (**Table 10-1**).

ALPHA PARTICLES

Alpha particles have relatively large size (two protons and two neutrons), have limited travel potential, and are unable to penetrate the outer layers of the skin. Thus, alpha particles are easily shielded with a piece of paper. Exposure to alpha particles only leads to pathology in the setting of ingestion, inhalation, or absorption. Detection can be problematic because common Geiger counters do not detect alpha particles without a special attachment.[8]

BETA PARTICLES

Beta particles are much smaller (a single electron) than alpha particles. Small size allows for greater penetration ability. Beta radiation can travel several meters in air, penetrates approximately 8 mm into exposed skin, and can cause serious burns. Beta radiation is a hazard if internally deposited. Most radioisotopes decay by beta radiation followed by gamma emission.[8]

POSITRONS

Positrons are positively charged beta particles that are emitted from the atomic nuclei. They are the antiparticles to the electron, and interactions with electrons lead to the generation of highly energetic photons that requires shielding with lead, steel, or concrete. Positron sources are commonly used in medical procedures such as positron emission tomography scanning.[8]

NEUTRONS

Neutrons are uncharged particles that are capable of generating radiation via alterations of the atomic nuclear proton-to-electron ratio. These particles are capable of traveling large distances and require the use of helium, water, and paraffin as shielding. Neutron exposures are rare and tend to be limited to nuclear fallout, research, industry, and weapons manufacturing.[8]

GAMMA RAYS AND X-RAYS

Gamma rays and high-energy x-rays are able to travel meters in the air and can penetrate centimeters into human tissue. Shielding materials must be very dense, such as concrete or lead. Individuals exposed to high doses of these sources are at high risk of developing acute radiation syndrome.[8]

BIOLOGIC EFFECTS OF IONIZING RADIATION

Ionizing radiation leads to cellular effects at both high and low levels of exposure. At high doses, ionizing radiation causes cell death. At lower doses, it interrupts cellular reproduction through inhibition of mitosis, resulting in cellular injury with delayed onset of effects.[9]

Radiosensitivity refers to the response of cells to radiation injury. Rapidly dividing cells with short life spans are the cells most vulnerable to radiation injury, because they are quickly depleted and new cells are unable to replete the population.[4]

MEASURING RADIATION

There are many ways in which radiation can be measured: dose given, exposure received, absorbed dose, or activity generated. Many conventional units may be used, and confusion can arise between interchanging units. See **Table 10-2** for more information on units of measure.

RADIATION MONITORING EQUIPMENT

Just as there are many radiation units, there are many ways to monitor radiation exposures. Commonly used equipment includes dosimeters and survey meters (**Table 10-3**). In the setting of radiation emergencies, both of these devices should be available to ED staff. Staff should wear dosimeters because of their small size and ability to measure and record an individual's cumulative exposure doses. In contrast, rate meters are survey instruments that record the amount of radiation in an area over a particular time course and are best suited to monitor environmental contamination.

ALLOWED ANNUAL DOSE OF RADIATION

Radiation exposures are an unavoidable hazard of living on our planet. Common sources of unavoidable radiation include cosmic and

TABLE 10-1 Types of Radiation

Type (Symbol)	Charge	Penetration	Shield	Hazard	Source
Alpha	+2	Few centimeters in air	Paper, keratin layer of skin	Internal contamination only; requires special detection devices	Heavy radioisotopes (e.g., plutonium, uranium, radon)
Beta	−1	~8 mm into skin	Clothing	External (skin) and internal contamination	Most radioisotopes decay by beta followed by gamma emission
Positron	+1	~8 mm into skin	Lead, steel or concrete	Interacts with electrons and releases photons of energy	Medical tracers
Neutron	0	Variable	Material with high hydrogen content	Whole-body irradiation	Nuclear power plants, particle accelerators, weapons assembly plants
Gamma and x-rays	0	Several centimeters in tissue	Concrete, lead	Whole-body irradiation	Most radioisotopes decay by beta followed by gamma emission

TABLE 10-2 Radiation Units of Measure

Description	Conventional Units	SI Unit	Conversion
Activity	Curie	Becquerel	1 Bq ~2.7 × 10^{11} Ci
Units of activity describe the amount of radioactivity present.			1 Ci ~3.7 × 10^{10} Bq
Exposure	Roentgen	Coulomb per kilogram	1 R = 2.58 × 10^{4} cP/kg
Units of exposure measure the amount of x-ray or gamma radiation that produces a given number of ionizations in air.			
Absorbed dose	rad	Gray	1 rad = 0.01 Gy
Units of absorbed dose can be applied to any type of radiation and reflect the energy imparted to matter.			1 Gy = 100 rad
Dose equivalent	Roentgen equivalents man	Sievert	1 rem = 0.01 Sv
Units that provide a common scale of measure for the different types of radiation.			1 Sv = 100 rem

Abbreviation: SI = International System of Units.

solar rays, naturally occurring elements such as radon and uranium, and even some of the carbon in our bodies. The background radiation dose of individuals living in the United States is approximately 6.2 mSv (620 mrem).[10] The International Commission on Radiological Protection, the National Commission on Radiological Protection and Measurements, and the Health Physics Society have set the annual radiation dose limit for the general public at 1 mSv per year (100 mrem) over natural background radiation. See **Table 10-4** for selected approximate levels of radiation exposure.

LETHAL DOSE OF RADIATION

The $LD_{50/60}$ from exposure to ionizing radiation is defined as the dose of penetrating ionizing radiation that will result in the deaths (lethal dose) of 50% of the exposed population within 60 days without medical treatment. Regarding human survival, the most commonly cited value is an $LD_{50/60}$ of approximately 3.5 to 4.5 Gy (350 to 450 rad).[8] In the setting of supportive medical therapy, including antibiotics, blood products, and reverse isolation, the value is 4.8 to 5.4 Gy (480 to 540 rad). During mass exposures where resources may be limited to basic first aid, the $LD_{50/60}$ falls to approximately 3.4 Gy (340 rad). The use of stem cell transplantation and hematopoietic growth factor administration has theoretically increased the $LD_{50/60}$ to 11 Gy (1100 rad).[11]

TABLE 10-3 Radiation Monitoring Equipment

Equipment Type	Device	Common Type of Measurement	Units Commonly Recorded
Dosimeter	Thermoluminescent dosimeter or film badge	Cumulative dose of beta, x-ray, and gamma	Roentgen equivalents man or sieverts
Dosimeter	Pocket dosimeter	Cumulative exposure to x-ray and gamma	Milliroentgen
Survey meter	Geiger-Müeller tube	Low exposure rates of x-ray, gamma, and beta*	Counts per minute†
Survey meter	Ion chamber	Higher exposure rates of x-ray and gamma	Milliroentgen per hour

*With special instrument probes, alpha radiation can also be detected.

†2500 counts per minute equal approximately 1 mR/h.

TABLE 10-4 Selected Approximate Levels of Radiation Exposure

Natural background radiation	620 mrem/y (U.S. average)
Chest x-ray (effective dose)	10 mrem
Abdominal x-ray	120 mrem
Lumbar spine x-ray	70 mrem
CT head	200 mrem
CT chest	700 mrem
CT abdomen or pelvis	1000 mrem
Jet travel	1 mrem per 1000 miles traveled
Annual radiation dose limit (public)	100 mrem/y*
Occupational exposure limit	5000 mrem/y
Lethal dose in 50% of exposed subjects within 60 d (3.5–4.5 Gy)	350,000–450,000 mrem (350–450 rad†)

*over natural background radiation.

†1 rem (dose equivalent) = 1 rad (absorbed dose or exposure).

CLINICAL EFFECTS OF RADIATION

LOCAL RADIATION INJURY

Most radiation accidents are due to local radiation injury from partial-body exposure. Partial-body irradiation rarely causes systemic manifestations; rather, it leads to a dose-dependent *cutaneous* involvement. Typically, the injury in the first week tends to be asymptomatic, although there may be transient erythema (6 Gy/600 rad), hyperesthesia, and itching. The second week is characterized by the development of erythema that progresses to hair loss (3 Gy/300 rad). The development of skin tenderness, swelling, and pruritus heralds the third week after exposure. Within the fourth week, the wound will develop dry (10 to 15 Gy/1000 to 1500 rad) or wet (15 to 20 Gy/1500 to 2000 rad) desquamation and/or ulceration (>25 Gy/2500 rad).[12]

Skin findings may be indistinguishable from thermal burns. Radiation injuries are hallmarked by episodes of transient erythema and delayed onset of prolonged and severe pain. As long as the exposure is less than 50 Gy (5000 rad), these injuries develop over a much longer time period than thermal burns. When doses exceed 50 Gy, these injuries will progress similarly to thermal burns, and the onset of pain will occur immediately. Surgical intervention such as resection and grafting may be required.

ACUTE RADIATION SYNDROME

Acute Radiation Syndrome occurs after a significant exposure to penetrating ionizing radiation within a 24-hour time period (**Table 10-5**). It

TABLE 10-5 Acute Radiation Syndrome

Approximate Dose	Onset of Prodrome	Duration of Latent Phase	Manifest Illness
>2 Gy (200 rad)	Within 2 d	1–3 wk	Hematopoietic syndrome with pancytopenia, infection, and hemorrhage; survival possible
>6 Gy (600 rad)	Within hours	<1 wk	GI syndrome with dehydration, electrolyte abnormalities, GI bleeding, and fulminant enterocolitis; death likely
>20–30 Gy (2000–3000 rad)	Within minutes	None	Cardiovascular/CNS syndrome with refractory hypotension and circulatory collapse; fatal within 24–72 h

should be expected in cases in which a whole-body gamma dose exceeds of 2 Gy (200 rad). External sources of alpha and beta radiation are unable to penetrate the body, although internal contamination may lead to this syndrome. Neutron sources, although rarely encountered, can also lead to acute radiation syndrome.

Acute radiation syndrome develops in four distinct phases: prodrome, latent phase, manifest-illness, and recovery. The initial **prodrome** involves the transient autonomic nervous system response to the exposure. It is directly related to the dose received. High doses cause acute and severe symptom onset, whereas lower doses may lead to prolonged onset and milder symptoms. Nausea, vomiting, anorexia, and diarrhea may be accompanied by hypotension, pyrexia, diaphoresis, cephalgia, and fatigue.

The prodrome is followed by the **latent phase**, a symptom-free interval whose duration depends on the received dose. Larger doses result in a shorter duration of this phase. Doses less than 4 Gy are associated with a period that may last 1 to 3 weeks, whereas in doses greater than 15 Gy, this phase may only last a few hours.

The **manifest-illness phase** is subdivided into three dose-dependent syndromes that are hallmarked by the affected organ system. The syndromes are not independent of one another, and there is synergy and overlap leading to the clinical manifestations. The final stage is **recovery**.

Hematopoietic Syndrome The hematopoietic system is the first organ system that demonstrates injury when doses exceed 1.5 Gy. The prodromal phase of this subsyndrome occurs within hours to a few days from the exposure, resolves within 48 hours, and is followed by a latent phase that on average lasts 1 to 3 weeks.

Radiation damages the bone marrow stem cells and destroys circulating hematopoietic cells, particularly lymphocytes (**Figure 10-1**). Because of the preferential destruction of lymphocytes, the peripheral lymphocyte count is currently the best marker to grade the extent of the injury. Granulocytes and platelets are also affected. However, being markers of inflammation, their counts rise in the immediate time period following the exposure, and later decline and reach a nadir within 30 days of the injury. Red blood cells are also affected but not to the same extent of the other lines due to the lack of nuclear material. Morbidity and mortality depend on associated pancytopenia, immunosuppression, and hemorrhage. Aggressive medical management with blood products and growth factors may increase survival.

GI Syndrome Doses greater than 6 Gy (>600 rad) cause the GI syndrome. Nausea, vomiting, and diarrhea develop within hours of exposure. This is followed by a short latent phase lasting up to 1 week. The manifest-illness phase is characterized by the recrudescence of severe nausea, vomiting, diarrhea, and abdominal pain. The initial insult leads to the apoptotic death of the GI mucosa, with associated insult to the underlying stem cells responsible for their replenishment. Impaired mucosal integrity causes massive fluid and electrolyte losses and allows the translocation of enteric flora into the bloodstream. Fulminating enterocolitis results.

Cardiovascular and CNS Syndrome The last subsyndromes of the manifest-illness phase are the cardiovascular and CNS syndromes, resulting from doses greater than 20 to 30 Gy (>2000 to 3000 rad). There is immediate hypotension, prostration, nausea, vomiting, and explosive bloody diarrhea. Hypotension is persistent and unresponsive to treatment. CNS symptoms manifest within hours and include seizures, lethargy, disorientation, ataxia, and tremors. The lymphocyte count, the quickest marker available to determine the extent of injury, very quickly falls to near-zero levels. Death from circulatory collapse ensues within 72 hours.

EMERGENCY RESPONSE PLANNING

Emergency response plans should involve multiple community-wide organizations, including hospitals, EDs, public safety, public health, and emergency management officials. Every EMS system should have a prehospital plan for the evacuation of victims from a radiation disaster. Every hospital is required by The Joint Commission to have a written protocol detailing instructions for receiving and treating radiation victims. Hospitals should stage regular disaster drills and train personnel in decontamination procedures, use of personal protective equipment, and radiologic monitoring. Planning templates exist to assist hospitals in developing appropriate radiation emergency response plans.[13,14]

PREHOSPITAL EMERGENCY MEDICAL MANAGEMENT

Emergency responders should rapidly establish incident command in a situation involving radioactive materials. Personal protective equipment and respiratory protection should be used as the situation dictates. Care and transportation of seriously injured victims should not be delayed, even if the patient is contaminated. In medically stable patients, perform radiation monitoring and decontamination at the scene.

ED NOTIFICATION AND PREPARATION

First responders must communicate with hospitals prior to arrival to allow adequate preparation. Provide incident information such as circumstances of the event, number of victims, type of radiologic insult, and identification of radioactive material (if known). Coexisting medical conditions and traumatic injuries need to be reported. Extent of completed patient decontamination should also be relayed. The hospital disaster plan should include steps that need to be initiated by the ED upon notification to prepare for a radiologic event (**Table 10-6**).

The hospital protocol should instruct ED personnel how to contact predetermined local radiation specialists and health physics professionals. These specialists may assist by monitoring radiation doses of personnel,

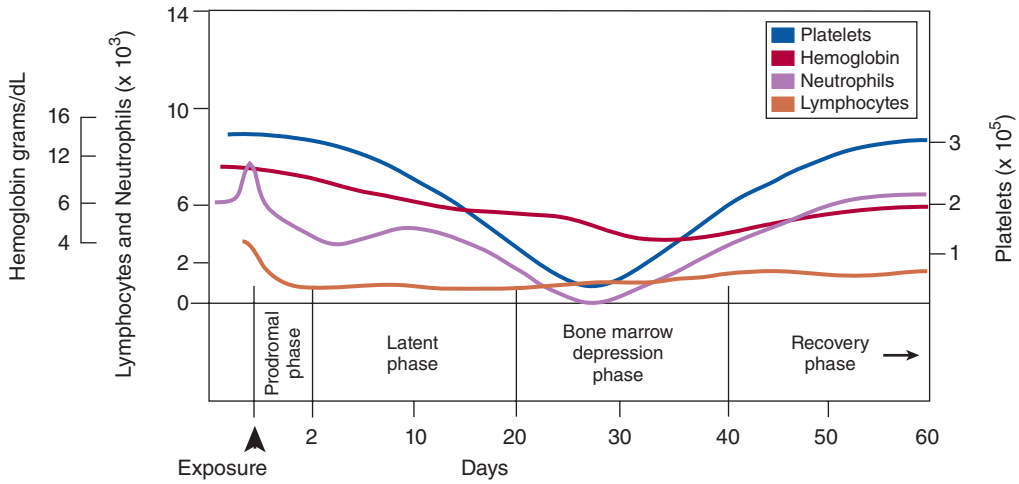

FIGURE 10-1. Typical hematologic course and clinical stages after sublethal (~3 Gy/300 rad) exposure to total-body irradiation.

TABLE 10-6 ED Preparation

Initiate hospital disaster plan.
Mobilize hospital radiation experts (radiation safety officer, nuclear medicine and radiation oncology experts and staff).
Request dosimeters for staff and radiation monitoring and survey instruments.
Prepare the ED.
Establish an ad hoc triage area based on the location designated in the hospital disaster plan.
Establish a "contaminated" area and "clean" area separated by a buffer zone using ropes, tape, and signs to designate areas.
Remove contaminated outer garments when leaving contaminated area and have your body surveyed with a radiation meter prior to leaving the area.
Cover floors with plastic or paper secured with heavy tape.
Remove pregnant women, nonessential personnel, and nonessential equipment.
Request extra gloves, other medical supplies, and extra large plastic bags for disposal.
Use standard precautions to protect staff.
Staff should wear a water-resistant gown, cap, and shoe covers to keep contaminants off skin and clothes.
Double glove with inner glove taped in place, changing the top pair after handling contaminated items and between patients.
N95 masks, if available, are recommended, but surgical masks should be adequate.
Survey hands and clothing at frequent intervals with a radiation meter.
Dosimeters, if available, should be worn at the collar, under protective clothing.

surveying personnel and areas for contamination, directing contamination control and decontamination efforts, and disposing of contaminated wastes. If radiation monitors are not available, patients should undergo decontamination and then be surveyed for residual contamination when monitoring equipment is available.

TRIAGE PRINCIPLES

When there are multiple victims, field triage protocols will designate patients as minor, delayed, immediate, or deceased depending on physical trauma or burns. Do not alter triage principles based solely on radiation exposure. **Because radioactive contamination is never immediately life-threatening, do not delay treatment of life-threatening injuries for radiologic surveying.** Morbidity and mortality from ionizing radiation injuries increase dramatically in the face of physical trauma, thermal burns, and other significant medical conditions. In a mass-casualty event that could include blast injuries in addition to radiologic insult, resources may be limited and will require a coordinated approach to develop the best management plan.

TREATMENT

Because most radiation injuries are not immediately life-threatening, there is usually time to determine whether the patient was irradiated, externally contaminated, or internally contaminated. Early treatment decisions are based on the signs and symptoms evident in the first 24 to 48 hours and corresponding laboratory test results.[15,16] **Figure 10-2** illustrates the medical treatment prioritization for those exposed to and/or contaminated with radioactivity.

DECONTAMINATION OF EXTERNALLY CONTAMINATED PATIENTS

It is highly unlikely that the radioactivity from a contaminated patient would pose a significant risk to healthcare personnel. However, the goal of decontamination measures is to decrease total exposure of the patient and staff, by minimizing radiation exposure from a source external to the body to a level that is as low as reasonably achievable (**Table 10-7**). This is accomplished by minimizing time of exposure and the quantity of radioactive materials in the area, as well as maximizing distance and shielding from the source.[16,17]

ACUTE RADIATION SYNDROME

Direct treatment of the irradiated patient toward alleviating the symptoms of the prodromal phase. Pain can be managed with acetaminophen and opioids. Because the patient may be at risk for significant GI bleeding if the exposure dose is more than 5 to 6 Gy, avoid using nonsteroidal anti-inflammatory agents.[8] Administer antiemetics for nausea and vomiting. Ondansetron or other 5-hydroxytryptamine-3 antagonists are effective.[18] Use antidiarrheal agents as needed.

Complete laboratory testing as soon as possible. Biologic dosimetry uses laboratory analyses (e.g., rate and nadir of lymphocyte depletion) and clinical signs to estimate absorbed dose. Cytogenetic analysis for chromosomal aberrations (dicentrics) is the gold standard for biodosimetry. Contact the Radiation Emergency Assistance Center/Training Site for assistance with obtaining chromosomal testing.

Perform a targeted history and physical exam. Note time of onset of all symptoms, especially vomiting and diarrhea, which are important in biologic dosimetry. Observe for abnormal vital signs suggestive of acute radiation syndrome, including fever, hypotension, tachycardia, and tachypnea. Monitor for impaired level of consciousness, ataxia, motor or sensory deficits, reflex abnormalities or papilledema, abdominal tenderness, and GI bleeding.

Obtain a baseline CBC with differential and absolute lymphocyte count in the ED and check a CBC every 6 hours for 24–48 hours. Monitor the CBC for progressive declines in lymphocytes as an indicator of total dose. Also obtain a baseline serum amylase and C-reactive protein, because dose-dependent increases are expected after 24 hours in a significant exposure. If vomiting and diarrhea occur in the first 2 to 3 hours (dose estimated to >2 Gy), consider the need for human leukocyte antigen typing in anticipation of pancytopenia requiring further management. This could include administration of blood products, cytokines, colony-stimulating factors, bone marrow cells, or stem cell transplant.[19] The goal is to bridge cytopenic gaps and manage subsequent infections. Patients may require antibiotics, antifungals, and antivirals during their course.

Monitor patients with large exposures who survive the acute phase for severe infectious and metabolic complications. Treat multiorgan failure from a large radiation exposure with standard supportive measures.[20]

LOCAL RADIATION INJURY

Analgesia is important in the early management of cutaneous radiation injury. Cutaneous radiation injury differs from thermal burns in that the cutaneous injury continues to evolve and may not be visible to the naked eye. The primary goal of treatment is interruption of radiation-induced inflammation in the dermis. Perform traditional burn care, including burn dressings, surgical debridement, and grafting, when indicated. Consider applying topical steroids to control local inflammation[16] and giving vitamin A, C, and E supplementation, and pentoxifylline to decrease blood viscosity and increase blood flow.[17] Systemic steroids are not recommended.[20] Although inpatient treatment may not be always be required, close follow-up is essential given the potential for ongoing evolution of cutaneous injury.

INTERNALLY CONTAMINATED PATIENTS

Internal contamination generally does not produce early symptoms but should be considered if persistently high radiation survey readings are notedand with all nose or mouth contamination cases. Obtain a 24-hour urine collection for possible radionuclide identification. Collect other specimens depending on exposure with or without contamination (**Table 10-8**). Consult radiation experts for treatment with cathartics, activated charcoal, gastric lavage, and radionuclide-specific decorporation agents (**Table 10-9**). Duration of therapy is based on dose estimations from radiochemical measurements of urine and fecal samples.

PRENATAL EXPOSURES

Fetal sensitivity to radiation depends on a number of factors, including radiation dose and gestational age. The radiation dose to the fetus may not be the same as the dose to the mother, because the fetus is shielded

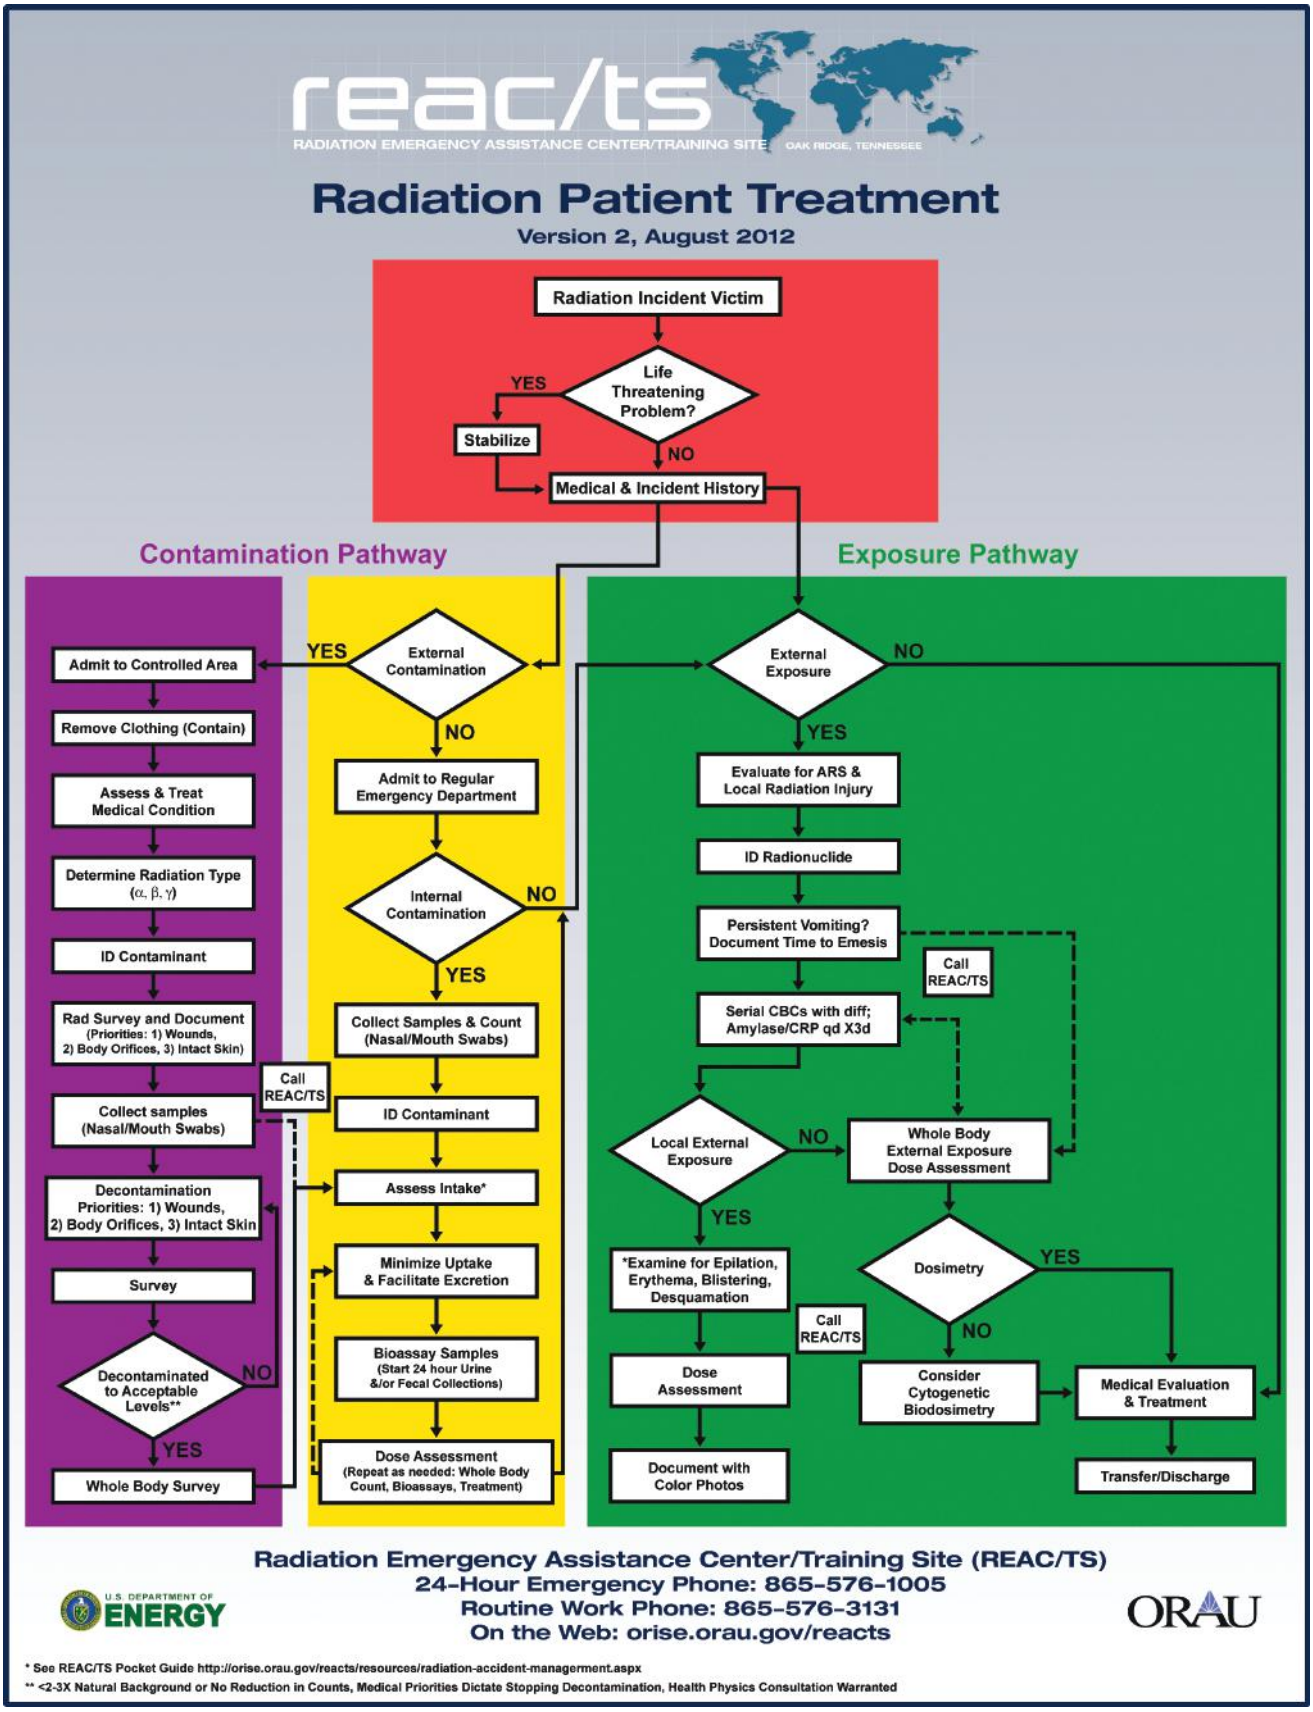

FIGURE 10-2. Medical treatment flow diagram for those exposed to or contaminated with ionizing radiation. TABLE 10-7 Steps of Patient Decontamination

Assess external contamination.
Contact radiation safety officer.
Assess contamination with radiation survey meter (Geiger counter).
Evaluate for radioactive shrapnel. Easily accessible pieces should be removed with a forceps and placed in a lead container.
Document contamination pattern on a body diagram.
Swab each nostril separately to estimate level of internal contamination of the lungs.
Decontaminate whole body.
Carefully cut and roll clothing away from the face to contain contamination.
Double bag clothing and label as hazardous waste.
Wash wounds first with saline or water.
If facial contamination is present, rinse as appropriate.
Gently cleanse intact skin and avoid scrubbing.
Repeat patient scan with radiation survey meter. Repeat washing until radiation is <2 times background. Avoid scrubbing.
Cover wounds with waterproof dressing.

TABLE 10-9 Internal Contamination Treatment

Radionuclide	Ionizing Radiation	Treatment	Mechanism of Action	Usual Administration
Iodine (I-131)	β, γ	Potassium iodide	Block thyroid uptake	130 milligrams PO for adults
Plutonium (Pu-239)	α	Ca-DTPA or Zn-DTPA	Chelation	1 gram in 250 mL NS or 5% dextrose in water over 60 min
Tritium (H-3)	β	Water	Dilution	Oral: 3–4 L a day for 2 wk
Cesium (Cs-137)	β, γ	Prussian blue	Decrease GI uptake	1 gram in 100–200 mL water three times a day for several days
Uranium (U-235)	α	Bicarbonate	Urine alkalinization	2 ampules in 1 L NS at 125 mL/h

Abbreviations: DTPA = diethylenetriamine pentaacetate; NS = normal saline.

in part by the uterus and surrounding tissues. External exposure of alpha and beta particles is unlikely to reach the fetus, but gamma and x-rays directed toward a pregnant woman's abdomen could harm the fetus. In addition, internal contamination could expose the fetus to higher radiation, because the radioactive material could accumulate in the bladder of the pregnant woman.

The health effects of radiation on the fetus are dependent on the gestational age. Before about 2 weeks of gestation, there is an all-or-none phenomenon, and if the exposure does not result in death of the embryo, no observable effects would be expected. An exposure of greater than 0.1 Gy is expected to be lethal, resulting in resorption of the conceptus. From 2 to 8 weeks, organogenesis occurs. During this time, the embryo is at risk for congenital malformations and growth retardation. In cases of substantial exposures, there is a significant risk of major malformations of the neurologic and motor systems. After 8 weeks of gestation, most organogenesis is complete with the exception of the CNS. Exposures during this period have an increased risk of mental retardation and miscarriage. Throughout gestation, an exposure of less than 0.05 Gy would not be expected to produce an increased risk of noncancer health effects. Consult with radiation medicine physicians regarding fetal dose estimation and risk assessment counseling for the expecting parents.[21] For additional discussion, see chapter 99, Comorbid Disorders in Pregnancy.

TABLE 10-8 Specimens for Medical Assessment

Specimen/Type of Analysis	Reason	Mechanism
Suspected radiation exposure		
Check a CBC every 6 hours for 24–48 hours	Establish baseline and assess lymphocyte depletion as an early predictor of dose.	Venipuncture
Serum amylase and CRP, repeat daily for 3 days	Parotid glands are sensitive to radiation; amylase will rise if exposed to >0.5 Gy.	Venipuncture
Blood: chromosomal analysis (dicentrics)	Gold standard for estimating dose.	Venipuncture. Call REAC/TS for assistance.
Urine: routine urinalysis	Establish baseline kidney function, especially if internal contamination is suspected.	Clean catch
Suspected external contamination		
Swabs of body orifices and samples from dressings/wounds	Assess internal contamination and identify radionuclide.	Use separate saline or water-moistened swabs to wipe the inside of each nostril, ear, and mouth.
Suspected internal contamination		
Urine bioassay: 24-h specimen; repeat for 4 d	Radionuclide identification.	Standard specimen containers
Consider feces bioassay in consult with radiation expert		

CRP = C-reactive protein; REAC/TS = Radiation Emergency Assistance Center/Training Site.

SOURCES OF ASSISTANCE

Two organizations provide medical advice for the treatment of radiation casualties. The Radiation Emergency Assistance Center/Training Site, sponsored by the Department of Energy and managed by the Oak Ridge Institute for Science and Education, provides training programs, consultation assistance, and treatment capabilities, and can dispatch an emergency response team of health professionals to assist at an accident site. After initial treatment and decontamination actions are complete, the Radiation Emergency Assistance Center/Training Site may also accept severely contaminated or irradiated patients for transfer to its facilities for more definitive care.

Radiation Emergency Assistance Center/Training Site (REAC/TS)
Oak Ridge Institute for Science and Education
P.O. Box 117, MS 39, Oak Ridge, TN 37831-0117
865-576-3131 (daytime phone; ask for REAC/TS)
865-576-1005 (24-hour emergency number)

Another organization available for consultation is the Medical Radiobiology Advisory Team, sponsored by the Department of Defense and managed by the Armed Forces Radiobiology Research Institute.

Medical Radiobiology Advisory Team
Armed Forces Radiobiology Research Institute
National Naval Medical Center
8901 Wisconsin Avenue, Building 42
Bethesda, MD 20889-5603
301-295-0316
301-295-0530 (24-hour emergency number)

The US Department of Health & Human Services sponsors the Radiation Emergency Medical Management (REMM) Guidance on Diagnosis & Treatment for Health Care Providers. Information can be found at http://www.remm.nlm.gov.

Resuscitation

CHAPTER 11

Sudden Cardiac Death

Joseph P. Ornato

INTRODUCTION AND EPIDEMIOLOGY

This chapter focuses on the epidemiology and pathophysiology of sudden cardiac death in adults and strategies for prevention and treatment. Discussions of sudden infant death syndrome and cardiac arrest in children are found in chapter 126, Congenital and Acquired Heart Disease, and chapter 127, Syncope, Dysrhythmias, and ECG Interpretation in Children. Chapters 22 and 23 discuss basic and advanced life support, respectively. Chapters 23 and 33 discuss defibrillation and cardioversion, and cardiac pacing, respectively.

Sudden, unexpected out-of-hospital cardiac arrest occurs in approximately 382,800 adult Americans each year.[1] Estimated national survival of EMS-treated cardiac arrest cases is 11.4%, yielding an estimated overall out-of-hospital cardiac arrest survival rate of 6.8% (EMS-treated plus deceased-on-EMS-arrival cases).[1] There is substantial variability in the odds for survival across various geographic locations.[2]

Most episodes of sudden cardiac death occur in the home, although victims who experience cardiac arrest in a public place have a much better chance of survival.[3] The initial recorded cardiac arrest rhythm is more likely to be ventricular fibrillation when cardiac arrest occurs in a public location rather than in the home, likely because patients who experience cardiac arrest in the home are typically older and more likely to have one or more chronic diseases that limit or exclude participation in activities outside the home.[3] Sudden cardiac death is 30% to 80% higher among residents in the lowest compared with the highest socioeconomic quartile.[4] This association is likely due to lifestyle and healthcare disparity issues.

There is a circadian pattern of sudden cardiac death and acute myocardial infarction,[5,6] and both are most likely to occur within the first few hours after awakening from sleep, when there is increased sympathetic stimulation. β-Blockade provides some protection from sudden cardiac death, particularly in patients with known coronary artery disease who have had myocardial infarction and have a low ejection fraction.[7]

There are two peaks in the age-related prevalence of sudden cardiac death: infancy (representing sudden infant death syndrome) and age greater than 45 to 50 years, with 60% in males.[4] There are multiple known factors contributing to the likelihood of sudden cardiac death (**Table 11-1**).

Coronary artery disease (which is often undiagnosed before the event) is the major cause of sudden cardiac death in adults and is present in 80% of cases, followed by cardiomyopathy (10% to 15%) and other miscellaneous conditions (e.g., hereditary channelopathies, valvular disease, congenital anomalies), which account for most of the remaining 5% to 10% of cases.[4]

PATHOPHYSIOLOGY

CORONARY ARTERY DISEASE

Coronary atherosclerosis is present on autopsy in 80% of sudden cardiac death victims.[8] Coronary artery disease is also found in 70% to 80% of cardiac arrest victims who survive and undergo coronary angiography.[9-12] Approximately one third have evidence of acute plaque rupture in areas of long-segment coronary stenosis.[10,11] A documented initial cardiac arrest rhythm of ventricular fibrillation (or shockable rhythm if an automated external defibrillator was applied) suggests that an acute coronary syndrome is the cause, since ventricular fibrillation is noted in the majority of cases in which a coronary occlusion is found on angiography.[9-12] However, ventricular fibrillation is present in only 23% of all cardiac arrests.[13]

SEVERE LEFT VENTRICULAR DYSFUNCTION

Severe left ventricular dysfunction with a reduced ejection fraction is currently the best available predictor of sudden death risk.[4] Patients with an ejection fraction ≤35% are the primary candidates for an implantable cardioverter-defibrillator. However, almost half of sudden deaths occur in individuals with normal left ventricular function.

CARDIOMYOPATHY

Cardiomyopathy with reduced left ventricular function, regardless of cause or presence of decompensated heart failure, is another predictor of sudden cardiac death. Dilated ventricles promote dispersion of ventricular depolarization and/or repolarization, allowing "islands" of ventricular tissue to depolarize and repolarize at different rates. The lack of homogeneity in electrical activation and recovery fosters the development of circus movement reentry, which can initiate and sustain ventricular tachyarrhythmias. Myocardial ischemia and/or infarction can also transiently diminish the homogeneity of left ventricular depolarization and repolarization. Left ventricular hypertrophy (often a result of hypertension and/or valvular heart disease) or conduction disturbances (left or right bundle-branch block or a nonspecific intraventricular conduction disturbance) can create similar functional disturbances.

In-hospital cardiac arrest patients with heart failure are more likely to have ventricular fibrillation as the initial documented cardiac arrest rhythm compared with non–heart failure patients.[14] New York Heart Association functional class II (symptoms with moderate exertion) and III (symptoms with mild exertion) patients are at higher risk of sudden cardiac death than death from pump failure, whereas class IV patients (symptoms at rest) are more likely to die of pump failure than sudden cardiac death.[5,15]

Hypertrophic cardiomyopathy is characterized by unexplained left ventricular hypertrophy associated with nondilated ventricular chambers.[16] The disorder can cluster in families, and the risk of sudden cardiac death increases at a rate of approximately 1% per year.[16] **Hypertrophic cardiomyopathy is the most common cardiovascular cause of sudden cardiac death in young athletes, accounting for one third of such events**, and its presence disqualifies affected individuals from competitive sports.[16] Implantable cardioverter-defibrillator placement is recommended for individuals with prior documented cardiac arrest; ventricular fibrillation; hemodynamically significant or nonsustained ventricular tachycardia; patients with a first-degree relative who has had sudden cardiac death; one or more recent, unexplained episodes of **syncope**; a maximum left ventricular wall thickness ≥30 mm; an abnormal blood pressure response to exercise in the presence of other sudden death risk factors or modifiers; or high-risk children with unexplained syncope, massive left ventricular hypertrophy, or family history of sudden cardiac death.[16]

Arrhythmogenic right ventricular cardiomyopathy is a hereditary form of cardiac muscle disease that is characterized by right-sided heart failure, ventricular arrhythmias of right ventricular origin (i.e., ventricular

tachycardia with a left bundle-branch block morphology), syncope, and sudden cardiac death.[17,18] **The electrocardiogram typically shows T-wave inversion in the right precordial leads (V_{1-3}).** Severe right heart failure develops in the majority of cases. Patients suspected of having this disorder should be referred for cardiology evaluation. Implantable cardioverter-defibrillator placement is often the treatment of choice since β-blockers and other antiarrhythmics do not usually prevent symptomatic ventricular arrhythmias in these patients.[17]

CONGENITAL HEART DISEASE

Congenital heart disease occurs in approximately 0.8% of all live births.[19] Because many children with congenital heart disease survive to adulthood as a result of improvements in cardiac surgery, sudden cardiac death is a frequent cause of later morbidity and mortality. Congenital heart defects commonly associated with sudden cardiac death in children and adults are listed in **Table 11-2**.[19]

The most frequent coronary artery anomaly associated with sudden cardiac death is anomalous origin of the left coronary artery from the pulmonary artery syndrome, which results in the left coronary artery traversing between the aorta and main pulmonary artery. This disorder is being diagnosed more frequently in adults by cardiac CT and MRI.[20] Ischemic symptoms, ventricular arrhythmias, and sudden death can be triggered during exercise as a result of increasing venous return, which dilates the main pulmonary artery and compresses the anomalous coronary artery in the space between the aorta and main pulmonary artery. Treatment is surgical correction.

The greatest risk of sudden cardiac death in children and adults with congenital heart disease exists in those with left heart obstructive lesions (e.g., aortic stenosis, aortic coarctation) and cyanotic defects (e.g., Ebstein's anomaly, corrected transposition of the great vessels, tetralogy of Fallot).[19] Most sudden death events in this population occur during exercise, with half of cases resulting from ventricular fibrillation.[19] Nonventricular arrhythmias (e.g., sinus node dysfunction, atrioventricular block, supraventricular tachyarrhythmias) are also common, even after surgical correction.[19]

Transposition of the great arteries
Ebstein's anomaly
Single ventricle

VALVULAR HEART DISEASE

Hemodynamically severe aortic stenosis can cause effort-induced dyspnea, myocardial ischemia, and ventricular arrhythmias, which can trigger syncope and sudden cardiac death. The most common causes of aortic stenosis are a congenitally bicuspid aortic valve that typically calcifies and narrows its orifice in mid-adulthood or sclerosis/calcification of a tricuspid aortic valve, which can occur in individuals who are older than 70 or 80 years of age. **A harsh, late-peaking systolic murmur at the upper-right sternal border with radiation to the neck is a typical finding in hemodynamically significant aortic stenosis.**

CARDIAC PACEMAKER AND CONDUCTING SYSTEM DISEASE

Sick sinus syndrome affects the heart's primary pacemaker and can cause intermittent lightheadedness, syncope, or sudden cardiac death. Although it is more common with advancing age, primary electrical failure of the heart can occur in infants and children. The cause is unknown, but pathologic studies reveal histologic degeneration of the sinoatrial node. In addition, the disorder often involves the atrioventricular node and the conduction tissue between the sinoatrial and atrioventricular nodes. Therefore, sick sinus syndrome should be thought of as a diffuse degenerative disease of the heart's electrical generation and conduction system. Idiopathic sclerodegeneration of the AV node and the bundle branches (Lenègre's disease) or invasion of the conduction system by fibrosis or calcification spreading from adjacent cardiac structures (Lev's disease) can lead to bradyasystolic heart block with or without cardiac arrest. In rare cases, a clinical presentation resembling the sick sinus syndrome can occur when the heart's electrical system is affected by systemic disease, vascular compromise, or tumor. Symptomatic bradycardia is treated with pacemaker placement.

HEREDITARY CHANNELOPATHIES

Sudden Arrhythmic Death Syndrome **The sudden arrhythmic death syndrome is characterized by sudden cardiac death occurring out of hospital in relatively young adults (mostly men), often during sleep or at rest, usually without any premonitory symptoms (including syncope) and with no anatomic abnormality identified at autopsy.**[18,19] Genetic disorders are associated with sudden arrhythmic death syndrome, and many cases can be identified clinically based on their characteristic electrocardiogram patterns.

Ion Channel Disease **Cardiovascular and genetic examination of first-degree relatives can identify an inherited form of heart disease known as a "channelopathy" or "ion channel disease" in almost half of cases.** Ion channel flux is responsible for the initiation, propagation, and repolarization of the cardiac action potential. Ion channel disease is

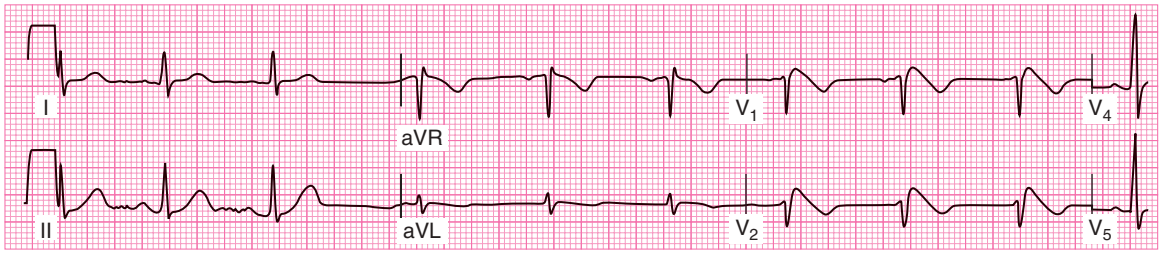

FIGURE 11-1. Brugada's syndrome. Twelve-lead electrocardiogram typical of Brugada's syndrome shows characteristic downsloping ST-segment elevation in leads V_1 and V_2 and QRS morphology resembling a right bundle-branch block.

caused by mutations in the genes that encode the proteins responsible for forming and interacting with the specialized sodium, potassium, and calcium ion channels within the heart.[21] There are many known ion channelopathies, modulated by a variety of causative gene defects that can have variable phenotype penetration in a given family. Genetic testing is used to screen family members for a known mutation. Common subtypes are listed in **Table 11-1**.

Brugada's Syndrome **Brugada's syndrome most commonly affects men and consists of a prominent J-wave with a characteristic downsloping ST-segment elevation in electrocardiogram leads V_{1-3} (Figure 11-1).** This electrocardiogram pattern resembles a right bundle-branch block and is associated with a 40% to 60% incidence of life-threatening ventricular arrhythmias (particularly polymorphic ventricular tachycardia that degenerates into ventricular fibrillation) and sudden cardiac death. The syndrome exhibits an autosomal dominant inheritance that results in total loss of function of the sodium channel or in acceleration of recovery from sodium channel activation.[22] **Brugada's syndrome is common in Southeast Asia (where it is called sudden unexplained nocturnal death syndrome), in the Philippines (*bangungut,* "to rise and moan in sleep"), in Japan (*pokkuri,* "sudden and unexpectedly ceased phenomena"), and in Thailand (*lai tai,* "death during sleep"). It is crucial for emergency physicians to identify this condition from its characteristic electrocardiogram pattern, because the risk of sudden cardiac death is high and can be prevented by internal cardioverter-defibrillator placement.[23]**

Early Repolarization Syndrome **Early repolarization syndrome** is present in 1% to 2% of adults (mostly males) and has long been considered to be a benign variant of normal ventricular repolarization.[24] Its prevalence is higher (10%) in general athletes and reaches as high as 100% in top-performing, endurance-trained individuals.[25] Classic electrocardiogram diagnostic criteria are a prominent, notch-like J wave on the QRS down-slope, followed by upsloping ST-segment elevation (**Figure 11-2**). These changes are seen most prominently in the mid to lateral precordium but can also occur just laterally or inferiorly. There is commonly reciprocal ST-segment depression in aVR. Rapid ventricular pacing or exercise usually normalizes these changes.

There may be similarity or overlap between Brugada's and early repolarization syndromes, but as of this writing, the clinical significance of early repolarization syndrome has not been established.[24] Both syndromes are often familial and more prominent in males, and drugs alter their characteristic electrocardiogram patterns (sodium channel blockers and β-blockers increase, and isoproterenol decreases the ST-segment elevation).[26,27] At this time, cardiology referral might only be warranted in the case of a teenager or young adult with syncope of unknown origin or with a family history of sudden cardiac death at an early age and with an electrocardiogram pattern of early repolarization.

Long QT Syndrome **The long QT syndrome is characterized by prolongation of the corrected QT interval (QT_c), syncope, and sudden death caused by torsade de pointes and ventricular fibrillation.[21]** The QT_c can be calculated by Bazett's equation:

$$QT_c = \frac{QT_m}{\sqrt{R-R}}$$

where QT_c is the corrected QT interval in seconds, QT_m is the measured QT interval in seconds, and R-R is the interval between any two consecutive R waves on the electrocardiogram in seconds. Because the QT interval is heart-rate dependent, the formula "corrects" the measured QT interval to a heart rate of 60 beats/min (at which the R-R interval is 1 second). Because the square root of 1 = 1, the QT_c equals the QT_m at a heart rate of 60 beats/min (at which the normal QT interval limits are 0.35 to 0.44 second).

Prolongation of the QT_c represents dispersion in ventricular repolarization and can be hereditary or acquired (caused by hypokalemia, hypomagnesemia, hypocalcemia, anorexia, ischemia, central nervous system pathology, terfenadine-ketoconazole combinations, or certain antipsychotic or antiarrhythmic drugs).[21,28] Hereditary long QT syndrome can have an autosomal recessive (Jervell and Lange-Neilsen

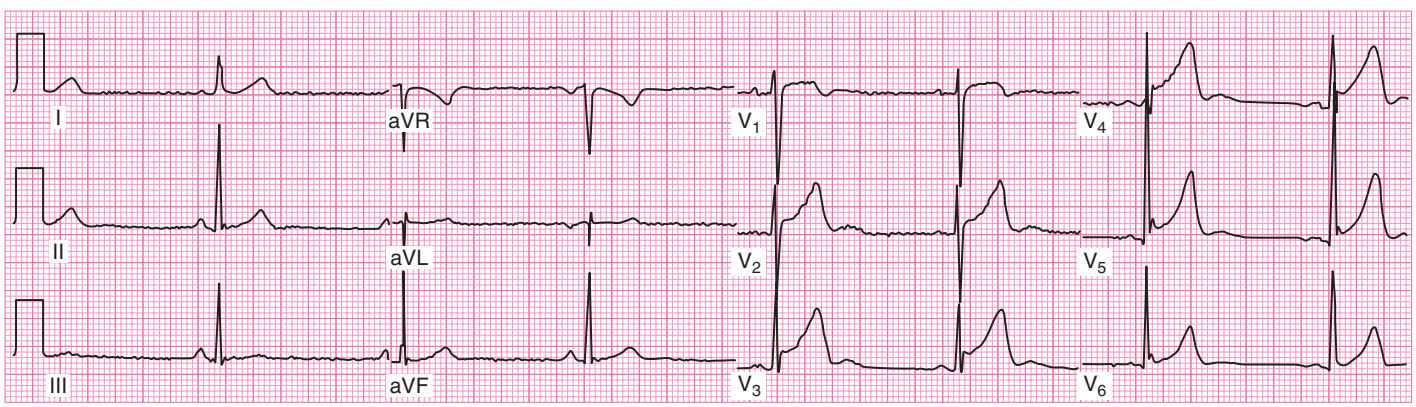

FIGURE 11-2. Early repolarization syndrome. Note in V_5 the prominent notch-like J wave on the QRS downslope, and the upsloping ST-segment.

syndrome with nerve deafness) or dominant (Romano-Ward syndrome without nerve deafness) mode of inheritance.[21] **Management of patients with long QT syndrome involves avoidance of QT-prolonging drugs (an up-to-date list can be found at http://www.azcert.org) and high-intensity sports, as well as cardiology/electrophysiology referral.[21]** A β-blocker is typically prescribed as prophylaxis against sudden cardiac death. Long QT syndrome patients who have syncope, torsade de pointes, or ventricular fibrillation despite β-blocker therapy are candidates for implantable cardioverter-defibrillator placement.[29]

Short QT Syndrome **An abnormally short QT_c (i.e., <0.34 second) can be secondary to hypercalcemia, hyperkalemia, acidosis, systemic inflammatory syndrome, myocardial ischemia, or increased vagal tone or can be inherited in an autosomal dominant genetic pattern.[30]** The genetic variety, dubbed the "short QT syndrome" (SQTS), is associated with atrial arrhythmia, including atrial fibrillation, syncope, polymorphic ventricular tachycardia, ventricular fibrillation, and sudden cardiac death.[30] Early repolarization, especially in the inferolateral leads, is noted in 65% of patients.[31] These individuals should also be referred for cardiology/electrophysiology evaluation and are candidates for cardioverter-defibrillator placement if syncope or life-threatening ventricular arrhythmias are documented.[30]

Catecholaminergic Polymorphic Ventricular Tachycardia Catecholaminergic polymorphic ventricular tachycardia (CPVT) is another genetically determined disorder involving defective myocardial cellular calcium handling. Affected individuals have exercise- and stress-related ventricular tachycardia, syncope, and sudden cardiac death, usually in childhood or early adulthood. Although there are no characteristic abnormalities in the electrocardiogram pattern, a significant number of affected individuals have sinus bradycardia that is not otherwise explainable. Almost half of these individuals carry a diagnosis of epilepsy as the cause of their recurrent syncope before the true cause (i.e., catecholaminergic polymorphic ventricular tachycardia) is identified.[32] β-blockers are the mainstay of prophylaxis, with implantable cardioverter-defibrillator placement as the next step if syncope recurs.[32]

PREVENTION OF SUDDEN CARDIAC DEATH

Unfortunately, the majority of sudden cardiac death victims cannot be identified in advance. Prodromal symptoms in the days to weeks preceding cardiac arrest are common but are usually too nonspecific to be of important predictive value.[33] The most common premonitory symptoms reported by sudden cardiac death survivors or family members of victims are chest discomfort, dyspnea, and "not feeling well."

Various tests have been used to try to "risk stratify" potential sudden cardiac death patients, but none are sensitive or specific enough to be useful. Tests include invasive and noninvasive assessment of left ventricular ejection fraction, coronary angiography, ambulatory electrocardiogram monitoring, exercise testing, detection of ventricular late potentials by using signal averaging, programmed ventricular stimulation of the heart to test the inducibility of ventricular tachyarrhythmias, assessment of heart rate variability, and T-wave alternans (alternating T-wave amplitude from beat to beat on the electrocardiogram, which is only visible with special recording equipment).[34] **The only opportunity for prevention is to recognize signs and symptoms of the syndromes that place a patient at higher risk of sudden cardiac death and to admit or refer such patients for proper evaluation and prophylaxis.**

ANTIARRHYTHMIC DRUG AND DEVICE THERAPY

The Cardiac Arrhythmia Suppression Trial showed that potent class I sodium channel–blocking antiarrhythmic drugs (encainide, flecainide, and moricizine) are proarrhythmic and paradoxically increase the odds of developing sudden cardiac death, as compared with placebo, in patients at relatively low risk for death.[35] The benefits of β-blockade, sotalol, and amiodarone in decreasing mortality from sudden cardiac death pale in comparison with the protective effects of the implantable cardioverter-defibrillator in high-risk patients,[36] including those who have been resuscitated from ventricular fibrillation or cardioverted out of sustained ventricular tachycardia.[37] Although these devices are expensive to insert, their effectiveness over conventional therapy results in a cost of less than $30,000 per year of life saved, which makes them relatively cost-effective for implantation in high-risk individuals.

SUDDEN CARDIAC DEATH RESCUE

The outcome of resuscitation is influenced strongly by the patient's initial cardiac rhythm. In most cases in which the event has been captured during monitoring, the initiating event is either pulseless ventricular tachycardia that degenerates rapidly to ventricular fibrillation or "primary" ventricular fibrillation.[38]

EMS and in-hospital resuscitation systems are the most effective means currently known to rescue patients from sudden cardiac death. Survival from pulseless ventricular tachycardia or ventricular fibrillation is inversely related to the time interval between its onset and termination. Survival is optimal when both CPR and advanced cardiac life support, including defibrillation and drug therapy, are provided early. Community resuscitation strategies should include provision of early CPR, early activation of the EMS system, early defibrillation (including public access defibrillation), early advanced cardiac life support, and regionalized systems of post-resuscitation care.[39,40]

See Chapters 22, 23, and 24 Basic Cardiopulmonary Resuscitation and Defibrillation and Cardioversion, and Advanced Cardiac Life Support, respectively, and Chapter 18, Cardiac Rhythm Disturbances, for detailed discussion of resuscitation pharmacotherapy.

Bystanders who witness the event can improve a victim's chances for survival significantly by alerting the emergency response system promptly. The best survival is attained in EMS systems that can provide early defibrillation to a large percentage of patients. In most cases, this is most cost-effectively accomplished by a tiered response system, in which large numbers of rapid first responders are trained and equipped to provide first aid, CPR, and early defibrillation using an automated external defibrillator. The Public Access Defibrillation randomized clinical trial showed that laypersons trained and equipped to use automated external defibrillators in public places can double survival to hospital discharge compared with that which can be achieved by layperson rescuers who can only perform CPR while awaiting EMS arrival.[41] These results have been confirmed in an analysis of 13,769 out-of-hospital cardiac arrest registry cases.[42]

PULSELESS VENTRICULAR TACHYCARDIA/VENTRICULAR FIBRILLATION

The likelihood of survival is relatively high if the initial rhythm is ventricular tachycardia or ventricular fibrillation (particularly if the ventricular fibrillation is "coarse," the arrest is witnessed, and prompt CPR and defibrillation are provided). If the initial rhythm is not ventricular tachycardia or ventricular fibrillation, survival is typically <5% in most reported series. Asystolic patients whose cardiac arrest is unwitnessed rarely survive to hospital discharge neurologically intact. The only common exceptions are witnessed cardiac arrest patients whose initial asystole is a result of increased vagal tone or other relatively easily correctible factors, such as hypoxia of brief duration.

PULSELESS ELECTRICAL ACTIVITY

Some sudden cardiac death events begin with a bradyarrhythmia or an organized rhythm without a pulse (e.g., pulseless electrical activity). *Bradyasystole* in adults is defined as a ventricular rate <60 beats/min or periods of absent heart rhythm (asystole). Bradyasystolic rhythms other than asystole can be accompanied by a pulse, or there can be no discernible pulse with each QRS (i.e., pulseless electrical activity). Bradyasystole *with* a pulse is often accompanied by a significant decrease in cardiac output, leading to hypotension and/or syncope. Bradycardia *with or without* a pulse occurs frequently during cardiac arrest, either as the initial rhythm, during the course of resuscitation, or after electrical defibrillation. Obviously, asystole occurs eventually in all dying patients. **To ensure that ventricular fibrillation is not masquerading as asystole, rescuers can switch to another lead whenever a "flat line" is recorded on the electrocardiogram during resuscitation or use US if available.**

TABLE 11-3 Common Causes of Bradyasystolic Arrest
Myocardial ischemia or infarction
Sick sinus syndrome
Asphyxiation (including near-drowning)
Hypoxia
Hypercarbia
Stroke
Opiates, β-blockers, calcium channel blockers, adenosine, or parasympathetics

Primary bradyasystole occurs when the heart's electrical system fails to generate and/or propagate an adequate number of ventricular depolarizations per minute to sustain consciousness and other vital functions. Secondary bradyasystole is present when factors external to the heart's electrical system cause it to fail (e.g., hypoxia). Common causes of bradyasystolic arrest are listed in **Table 11-3.**

One of the most baffling mysteries of bradyasystolic cardiac arrest relates to myocardial mechanics. Bradyasystole, unlike ventricular fibrillation, is accompanied by very little myocardial oxygen consumption in animal models. Because of this, myocardial high-energy phosphate stores should decay relatively slowly during bradyasystole. This should theoretically result in a high incidence of return of spontaneous circulation after restoration of a more normal rhythm (e.g., with the early use of electrical pacing). It is unclear why conventional treatment of bradyasystolic cardiac arrest with atropine, epinephrine, or electrical pacemakers rarely results in survival to hospital discharge. Return of spontaneous circulation is infrequent, and long-term neurologically intact survival is rare in bradyasystolic cardiac arrest.

Other factors must play a determining role in the pathophysiology and subsequent outcome of bradyasystolic cardiac arrest. Bradyasystolic arrest is not just a disorder of rhythm generation or propagation; it is a perplexing syndrome characterized by such rhythm disturbances accompanied, in many cases, by profound depression of myocardial and vascular function. Suspected causes include endogenous myocardial depressants (including down-regulation of catecholamine receptors and/or toxic influences of intense sympathetic stimulation), neurogenic influences, postischemic myocardial stunning, and/or free radical injury.

It is important to differentiate pulseless electrical activity from conditions in which the rescuer is unable to detect a pulse, but there is unmistakable evidence that there is adequate blood pressure and cardiac output to maintain vital organ perfusion (e.g., a conscious patient with profound vasoconstriction caused by hypothermia, or "pseudo pulseless electrical activity").[43]

TABLE 11-4 Conditions That Cause Pulseless Electrical Activity
Hypovolemia
Tension pneumothorax
Pericardial tamponade
Pulmonary embolism
Massive myocardial dysfunction due to ischemia or infarction, myocarditis, cardiotoxins, etc.
Drug toxicity (e.g., β-blockers, calcium channel blockers, tricyclic antidepressants)
Profound shock
Hypoxia
Acidosis
Severe hypercarbia
Auto positive end-expiratory pressure
Hypothermia
Hyperkalemia
Pseudo pulseless electrical activity

The underlying physiologic cause of pulseless electrical activity is a marked reduction in cardiac output due to either profound myocardial depression or mechanical factors that reduce venous return or impede the flow of blood through the cardiovascular system. Common conditions that can cause pulseless electrical activity are shown in **Table 11-4**. The management of patients with pulseless electrical activity is directed at identifying and treating the underlying cause or causes.

CHAPTER 12

Approach to Shock

Bret A. Nicks
John Gaillard

EPIDEMIOLOGY

The exact number of cases of shock that present to the ED in the United States is difficult to ascertain due to the insensitivity of clinical parameters, current definitions, and lack of a central database repository. Previous estimates propose that more than 1 million cases of shock are seen in the ED each year in the United States.[1] These estimates are largely based on the assumption that hypotension, defined as a systolic blood pressure <90 mm Hg, is consistent with shock in adults. Using this definition, the incidence of patients with hypotension that present to American EDs is approximately 5.6 million cases per year.[2]

Mortality depends on the inciting event. Septic shock has an estimated mortality of 40% to 60%.[3] Cardiogenic shock has an estimated mortality of 36% to 56%.[4] Approximately 30% to 45% of patients with septic shock and 60% to 90% of patients with cardiogenic shock die within 1 month of presentation.[3,4] With a greater recognition and improved treatment, mortality from neurogenic shock has been reduced significantly. The definition of and treatment approach to shock continue to evolve, but the initial approach to a patient in shock follows similar principles, regardless of the inciting factors or cause.

Patients present to the ED in varying stages of critical illness and shock. These stages are confounded by age, comorbidities, and delays in presentation. A focus on early recognition, rapid diagnosis, and empiric resuscitation is essential. Therapy and patient stabilization may need to occur simultaneously with evaluation.

PATHOPHYSIOLOGY

Shock is a state of circulatory insufficiency that creates an imbalance between tissue oxygen supply (delivery) and oxygen demand (consumption) resulting in end-organ dysfunction. Reduction in effective perfusion may be due to a local or global delivery deficiency or utilization deficiency with suboptimal substrate at the cellular or subcellular level.[5] The mechanisms that can result in shock are frequently divided into four categories: (1) hypovolemic, (2) cardiogenic, (3) distributive, and (4) obstructive.

FACTORS AFFECTING CARDIAC OUTPUT

An understanding of the mechanisms of oxygen delivery and consumption is foundational to the treatment of shock. While the physiology is complex, familiarity with the basic principles, equations, and their interactions is essential (**Tables 12-1 and 12-2**). As noted in the cardiac output (CO) equation, CO is determined by heart rate and stroke volume. Stroke volume is dependent on preload, afterload, and contractility. The mean arterial pressure (MAP) demonstrates the impact that CO has on MAP (which can also be estimated with the formula: 2 × diastolic blood pressure + systolic blood pressure/3). This is important because there is a MAP threshold below which oxygen delivery is decreased. Systemic

TABLE 12-1 Physiologic Equations

Parameter	Equation Specifics
Cardiac output	Cardiac Output = Heart Rate × Stroke Volume CO = HR × SV
Mean arterial pressure	Mean Arterial Pressure = Cardiac Output × Systemic Vascular Resistance MAP = CO × SVR
Oxygen delivery	Oxygen Delivery = Cardiac Output × Arterial Oxygen Content $Do_2 = CO \times [(1.39 \times Hb \times Sao_2) + (Pao_2 \times 0.0031)]$ Do_2 is the amount of O_2 delivered to the tissues per minute. A normal value is 1000 mL O_2 per minute.
Arterial oxygen content	Arterial Oxygen Content = Amount of Oxygen in the Blood $Cao_2 = (1.39 \times Hb \times Sao_2) + (Pao_2 \times 0.0031)$
Oxygen consumption	Oxygen Consumption = Cardiac Output × (Arterial O_2 Content – Venous O_2 Content) $\dot{V}o_2 = CO \times (Cao_2 - Cvo_2)$ Alternative equation: $\dot{V}o_2 = CO \times Hb \times 1.39 \times (Sao_2 - Smvo_2)$ The amount of O_2 consumed by tissues each minute is equal to the difference in O_2 delivered to tissues and the O_2 returning from tissues to the heart. A normal value is about 250 mL O_2 per minute. Note that this formula ignores the small contribution from dissolved oxygen.
Shock index	Shock Index = Heart Rate ÷ Systolic Blood Pressure SI = HR/SBP A normal value is 0.5–0.7. A persistent elevation of the shock index (>1.0) indicates an impaired left ventricular function (as a result of blood loss or cardiac depression) and carries a high mortality rate.

Abbreviations and units: Hb = hemoglobin in grams/dL; HR = heart rate per min; Pao_2 = partial pressure of oxygen in arterial blood in mm Hg; Sao_2 = oxygen saturation expressed as a fraction of 1.0, rather than a percentage; SBP = systolic blood pressure in mm Hg; $Smvo_2$ = mixed venous oxygen saturation expressed as a fraction of 1.0, rather than a percentage; SV = stroke volume in mL; SVR = systemic vascular resistance in mm Hg·min/L.

TABLE 12-2 Abbreviations and Definitions of Hemodynamic Parameters

Cao_2	Arterial oxygen content
CI	Cardiac index (cardiac output/body surface area)
CO	Cardiac output
Cvo_2	Venous oxygen content
CVP	Central venous pressure
Do_2	Systemic oxygen delivery
DBP	Diastolic blood pressure
Hb	Hemoglobin
MAP	Mean arterial pressure
MODS	Multiorgan dysfunction syndrome
$Paco_2$	Partial pressure of arterial carbon dioxide
Pao_2	Partial pressure of arterial oxygen
Sao_2	Arterial oxygen saturation
$Scvo_2$	Central venous oxygen saturation from the superior vena cava
$Smvo_2$ (Svo_2)	Mixed venous oxygen saturation from the pulmonary artery
SBP	Systolic blood pressure
SI	Shock index
SIRS	Systemic inflammatory response syndrome
SVR	Systemic vascular resistance
$\dot{V}o_2$	Systemic oxygen consumption

vascular resistance (SVR) directly impacts MAP, but also impacts afterload and thus CO. The physiologic mechanism of oxygen delivery to peripheral tissues (Do_2) is described in the oxygen delivery equation. Recognize that blood pressure is not represented in this equation. Patients in shock may initially have normal blood pressures (cryptic shock), yet have other objective signs of shock (see "Clinical Features" below). It is from these basic equations that the concept of preload influencing stroke volume, which itself influences CO and Do_2, has become fundamental in shock management.

Tissue oxygenation is predicated on CO being sufficient enough to deliver oxygenated hemoglobin to the tissues. CO is dependent on the interplay of cardiac inotropy (speed and shortening capacity of myocardium), chronotropy (heart contraction rate), and lusitropy (ability to relax and fill heart chambers). Determinants of inotropy include autonomic input from sympathetic activation, parasympathetic inhibition, circulating catecholamines, and short-lived responses to an increase in afterload (Anrep effect) or heart rate (Bowditch effect). Increases in the inotropic state help to maintain stroke volume at high heart rates.[6] Under certain conditions, such as shock states, higher levels of epinephrine will be produced and reinforce adrenergic tone. Epinephrine levels are significantly elevated during induced hemorrhagic shock, but these levels subsequently reduce to almost normal levels after adequate blood pressure is restored.[7] Previous studies have also shown that an acidotic milieu, which is common in shock, further compromises ventricular contractile force and blood pressure.[8] Chronotropy and lusitropy are both influenced by sympathetic input. Norepinephrine interacts with cardiac β_1-receptors, resulting in increased cyclic adenosine monophosphate. This leads to a process of intracellular signaling with an increased chronotropy and sequestration of calcium, leading to myocardial relaxation.[6]

LACTIC ACID

When compensatory mechanisms fail to correct the imbalance between tissue supply and demand, anaerobic metabolism occurs and results in the formation of lactic acid. Lactic acid is rapidly buffered, resulting in the formation of measured serum lactate. Normal venous lactate levels are less than 2.0 mmol/L. Most cases of lactic acidosis are a result of inadequate oxygen delivery, but lactic acidosis occasionally can develop from an excessively high oxygen demand (e.g., status epilepticus). In other cases, lactic acidosis occurs because of impaired tissue oxygen utilization (e.g., septic shock or the postresuscitation phase of cardiac arrest). Elevated lactate is a marker of impaired oxygen delivery or utilization and correlates with short-term prognosis of critically ill patients in the ED.[7]

COMPENSATORY MECHANISMS AND THEIR FAILURE

Shock provokes a myriad of autonomic responses, many of which serve to maintain perfusion pressure to vital organs. Stimulation of the carotid baroreceptor stretch reflex activates the sympathetic nervous system triggering (1) arteriolar vasoconstriction, resulting in redistribution of blood flow from the skin, skeletal muscle, kidneys, and splanchnic viscera; (2) an increase in heart rate and contractility that increases CO; (3) constriction of venous capacitance vessels, which augments venous return; (4) release of the vasoactive hormones epinephrine, norepinephrine, dopamine, and cortisol to increase arteriolar and venous tone; and (5) release of antidiuretic hormone and activation of the renin-angiotensin axis to enhance water and sodium conservation to maintain intravascular volume.[8]

These compensatory mechanisms attempt to maintain Do_2 to the most critical organs (heart and brain), but blood flow to other organs, such as the kidneys and GI tract, may be compromised. The cellular response to decreased Do_2 (adenosine triphosphate depletion) leads to ion-pump dysfunction, influx of sodium, efflux of potassium, and reduction in membrane resting potential. As shock progresses, the loss of cellular integrity and the breakdown in cellular homeostasis result in cellular death. These pathologic events give rise to a cascade of metabolic features including hyperkalemia, hyponatremia, azotemia, hyper- or hypoglycemia, and lactic acidosis.

TABLE 12-3 Clinical Features of Systemic Inflammatory Response Syndrome (SIRS)

Two or more of the following features are required to make a diagnosis of SIRS:
Temperature >38°C (100.4°F) or <36°C (96.8°F)
Heart rate >90 beats/min
Respiratory rate >20 breaths/min (or carbon dioxide tension <32 mm Hg)
WBC count >12.0 × 10^9/L, <4.0 × 10^9/L, or >10% immature forms or bands

In the early phases of shock, these physiologic changes may produce a clinical syndrome called the systemic inflammatory response syndrome or SIRS (**Table 12-3**).

As systemic inflammatory response syndrome progresses, shock ensues, followed by the multiorgan dysfunction syndrome, which is manifested by renal failure, respiratory failure, myocardial depression, liver failure, and then disseminated intravascular coagulation. The fulminant progression from systemic inflammatory response syndrome to multiorgan dysfunction syndrome is determined by the balance of anti-inflammatory and proinflammatory mediators and the level of inadequate tissue perfusion (**Figure 12-1**).

CATEGORIES OF SHOCK

The four categories of shock can be described in terms of their respective physiologic changes and common causes, recognizing that overlap is common (**Table 12-4**). **Hypovolemic shock** occurs when decreased intravascular fluid or decreased blood volume causes decreased preload, stroke volume, and CO. Severe blood loss (hemorrhage) can cause decreased myocardial oxygenation, which decreases contractility and CO. This action may lead to an autonomic increase in the SVR.

TABLE 12-4 Categories of Shock

Type	Hemodynamic Changes	Etiologies
Hypovolemic	Decreased preload, increased SVR, decreased CO	Hemorrhage, capillary leak, GI losses, burns
Cardiogenic	Increased preload, increased afterload, increased SVR, decreased CO	MI, dysrhythmias, heart failure, valvular disease
Obstructive	Decreased preload, increased SVR, decreased CO	PE, pericardial tamponade, tension PTX
Distributive	Decreased preload, increased SVR, mixed CO	Sepsis, neurogenic shock, anaphylaxis

Abbreviations: CO = cardiac output; MI = myocardial infarction; PE = pulmonary embolism; PTX = pneumothorax; SVR = systemic vascular resistance.

Hypovolemic shock can also occur due to volume loss from other etiologies. In **cardiogenic shock**, the left ventricle fails to deliver oxygenated blood to peripheral tissues due to variances in contractility, as well as preload and afterload. Myocardial infarction is the most common cause of cardiogenic shock. Dysrhythmias are another common cause because they can lead to a decreased CO. Bradyarrhythmias result in low CO, and tachyarrhythmias can result in decreased preload and stroke volume. **Obstructive shock** is due to a decrease in venous return or cardiac compliance due to an increased left ventricular outflow obstruction or marked preload decrease. Cardiac tamponade and tension pneumothorax are common causes. In **distributive shock**, there is relative intravascular volume depletion due to marked systemic vasodilatation. This is most commonly seen in septic shock. Compensatory responses to decreased SVR may include increased CO (increased contractility and heart rate) and tachycardia. The concurrent decreased SVR results in a decreased preload and may hinder CO

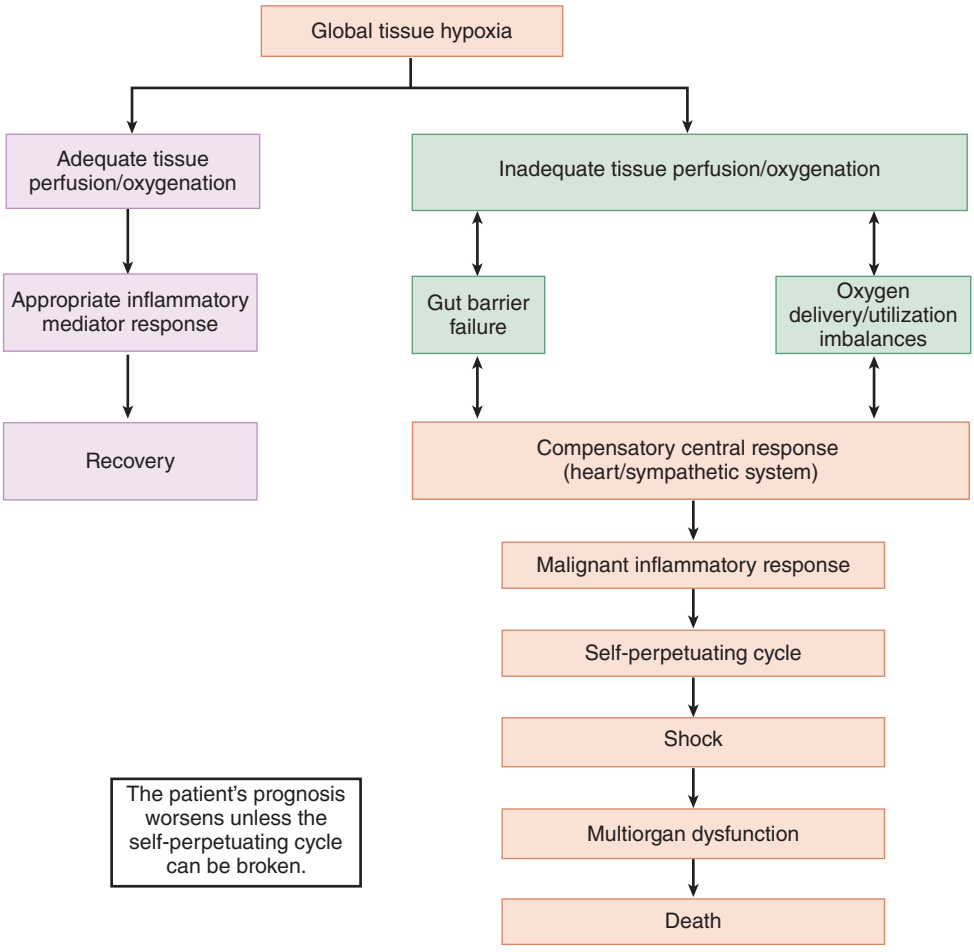

FIGURE 12-1. The pathophysiology of shock, the systemic inflammatory response syndrome, and multiorgan dysfunction.

overall. In sepsis, up to 40% of patients may have a transient cardiomyopathy characterized by decreased contractility and increased mortality.[3,4] Anaphylaxis, adrenal insufficiency and neurogenic shock are additional causes of distributive shock.

CLINICAL FEATURES

HISTORY AND COMORBIDITIES

While the clinical presentation of a patient in shock and the underlying cause may be quite apparent (e.g., acute myocardial infarction, anaphylaxis, or hemorrhage), it may be difficult to obtain a history from patients in shock. Assistance with medical history from EMS, family, or other sources may help determine the cause of shock, especially if the patient has comorbidities. Some patients in shock may have few symptoms other than generalized weakness, lethargy, or altered mental status. If the patient is unresponsive, consider trauma as a primary or secondary complication.

PHYSICAL EXAMINATION

Shock is usually associated with systemic arterial hypotension—systolic blood pressure <90 mm Hg. Blood pressure is the product of flow and resistance (MAP = CO × SVR). Blood pressure may not drop if there is an increase in peripheral vascular resistance in the presence of decreased CO with inadequate tissue hypoperfusion, making blood pressure an insensitive marker for global tissue hypoperfusion. **Shock may occur with a normal blood pressure, and hypotension may occur without shock.** No single vital sign is diagnostic of shock, and blood pressure is particularly insensitive in the presence of peripheral vascular disease, tachycardia with a small pulse pressure, or cardiac dysrhythmias. Composite physical findings are useful in the assessment of shock (**Table 12-5**).

TABLE 12-5 Composite Physical Examination Findings in Shock

Temperature	Hyperthermia or hypothermia may be present. Endogenous hypothermia (hypometabolic shock) must be distinguished from exogenous environmental hypothermia.
Heart rate	Usually elevated; however, paradoxical bradycardia can be seen in shock states due to hypoglycemia, β-blocker use, and preexisting cardiac disease.
Systolic blood pressure	May actually increase slightly when cardiac contractility increases in early shock and then fall as shock advances.
Diastolic blood pressure	Correlates with arteriolar vasoconstriction and may rise early in shock and then fall when cardiovascular compensation fails.
Pulse pressure	Increases early in shock and decreases before systolic pressure begins to drop.
Mean arterial blood pressure	Often low, <65 mm Hg.
CNS	Acute delirium or brain failure, restlessness, disorientation, confusion, and coma secondary to a decrease in cerebral perfusion pressure
Skin/capillary refill	Pallor, pale, dusky, clammy, cyanosis, sweating, altered temperature, and increased capillary refill time of >2–3 s.
Cardiovascular	Neck vein distention or flattening depending on the type of shock. Tachycardia and arrhythmias. An S_3 may result from high-output states. Decreased coronary perfusion pressures can lead to ischemia, decreased ventricular compliance, increased left ventricular diastolic pressure, and pulmonary edema.
Respiratory	Tachypnea, increased minute ventilation, increased dead space, bronchospasm, and hyper- or hypocapnia with progression to respiratory failure.
Splanchnic organs	Ileus, GI bleeding, pancreatitis, acalculous cholecystitis, and mesenteric ischemia can occur due to low flow states.
Renal	Reduced glomerular filtration rate. Renal blood flow redistributes from the renal cortex toward the renal medulla leading to oliguria.
Metabolic	Hyperglycemia, hypoglycemia, and hyperkalemia. As shock progresses, metabolic acidosis occurs with concurrent attempted respiratory compensation.

DIAGNOSIS

LABORATORY EVALUATION

No single laboratory value is sensitive or specific for shock. Laboratory studies are driven by the clinical presentation and the presumptive cause. Common studies are listed in **Table 12-6**. Arterial blood gases are useful to assess acid–base status and ventilation and oxygenation concerns, whereas a venous blood gas is limited to acid–base information. A rise in serum lactate correlates with mortality in many shock states;[7] typically this is due to anaerobic metabolism, but nonhypoxic causes of lactic acidosis due to cellular dysfunction occur in shock states. Serial lactate assessments may be indicated because lactate clearance is associated with improved outcomes in septic shock and may assist with resuscitation.[9] A wide range of laboratory abnormalities may be encountered in shock, but most abnormal values merely point to the particular organ system that is contributing to, or being affected by, the shock state.

TABLE 12-6 Initial Diagnostic Studies to Evaluate a Patient in Shock*

CBC with differential
Electrolytes, glucose, calcium, magnesium, phosphorus
BUN, creatinine
Serum lactate
ECG
Urinalysis
Chest radiograph
Coagulation studies: prothrombin time, PTT, INR
Arterial blood gas (measured pH, carbon dioxide, and oxygen levels)
Hepatic function panel
Cultures: blood, urine, suspicious wounds, quantitative sputum culture
Culture
Cortisol level
Pregnancy test
CT of chest/abdomen/pelvis as indicated history, physical exam

*Ordering of the listed tests should be individualized by patient presentation and history.

IMAGING

Chest X-Ray The portable anteroposterior view chest x-ray is often used in the evaluation of unstable patients to avoid transporting the patient during resuscitation. While limitations exist, evaluation of the heart size, presence of pulmonary edema, free air under the diaphragm, pneumothorax, infiltrates, or effusions may provide useful clinical information.

US Bedside US assessment is an important tool for developing a differential diagnosis, assessing volume status, defining cardiac function, and assisting with procedures. Various US methods are described to determine overall volume status by assessing right-sided filling pressures, including measuring inferior vena cava respiratory variation, end-expiratory vena cava respiratory variation, and other methods. Defining the degree of hypovolemia is inexact.

Bedside cardiac US to assess left ventricular ejection fraction can assist with determining the cause of shock. Emergency physicians trained in focused bedside cardiac US can provide an estimated ejection fraction with high relative correlation to cardiologists.[10]

US may also be used to assess for vascular emergencies. Identifying an abdominal aortic aneurysm on US may lead to further evaluation.

Additional US protocols, such as the Abdominal and Cardiac Evaluation with Sonography in Shock protocol and the Rapid Ultrasound in Shock protocol, have been formulated using many of the aforementioned concepts. The Abdominal and Cardiac Evaluation with Sonography in Shock protocol looks at cardiac function, inferior vena cava dynamics, pulmonary congestion, sliding and consolidation, abdominal free fluid, abdominal aortic aneurysm, and leg venous thrombosis to assist in differential diagnosis generation or narrowing.[11] The Rapid Ultrasound in Shock exam involves a three-part bedside physiologic assessment simplified as the pump (cardiac), the tank (volume status), and the pipes (arterial and venous).[12,13] However, as with any US intervention, operator competency and available resources are essential.

CT Although CT is an accurate and noninvasive approach for detecting internal pathology, patients must travel from the ED to the radiology suite, which may be unadvisable in unstable shock. The potential benefits of CT must be weighed against the associated risks, including concerns about renal function due to hypovolemia and contrast-induced nephropathy. CT scans without IV contrast will add some information to the clinical picture, although not to the degree of a scan with IV contrast.

HEMODYNAMIC MONITORING

Hemodynamic monitoring helps assess the severity of shock and the response to treatment. Monitoring capabilities should initially include pulse oximetry, electrocardiographic monitoring, and noninvasive blood pressure monitoring. In the critical care arena, intra-arterial blood pressure monitoring, end-tidal carbon dioxide monitoring, central venous pressure, and central venous oxygen saturation from the superior vena cava ($Scvo_2$) monitoring are frequently used. When obtaining central access, the average access time, number of attempts, and mechanical complications are reduced when a US-assisted approach is used.[14]

EARLY TREATMENT

Comprehensive and timely ED care can significantly decrease the predicted mortality of critically ill patients in as little as 6 hours of treatment.[15] Application of an algorithmic approach to optimize hemodynamic end points with early goal-directed therapy in the ED reduced mortality by 16% in patients with severe sepsis or septic shock in 2001.[16] That original study, the Surviving Sepsis Campaign that followed,[17] and other algorithmic efforts[18] have changed the approach to sepsis and shock care on a worldwide basis. Two large, multicenter, randomized controlled trials published in 2014 failed to show additional benefits to a rigid algorithmic approach.[19,20] However, we attempt to present below the most beneficial aspects of shock care demonstrated by the medical progress of the last 15 years. **The *ABCDE* tenets of shock resuscitation are establishing *a*irway, controlling the work of *b*reathing, optimizing the *c*irculation, assuring adequate oxygen *d*elivery, and achieving *e*nd points of resuscitation.[21]**

ESTABLISHING THE AIRWAY

Airway control is best obtained through endotracheal intubation. Sedatives used to facilitate intubation may cause arterial vasodilatation, venodilation, or myocardial suppression and may result in hypotension. Positive-pressure ventilation reduces preload and CO. The combination of sedative agents and positive-pressure ventilation will often lead to hemodynamic collapse. To avoid this unwanted situation, initiate volume resuscitation and vasoactive agents before intubation and positive-pressure ventilation.

CONTROLLING THE WORK OF BREATHING

Control of breathing is required when significant tachypnea accompanies shock. Respiratory muscles are significant consumers of oxygen during shock and contribute to lactate production. Mechanical ventilation and sedation allow for adequate oxygenation, improvement of hypercapnia, and assisted, controlled, synchronized ventilation. All of these treatments decrease the work of breathing and improve survival. When starting mechanical ventilation on a patient, it is essential to consider the patient's compensatory minute ventilation prior to intubation to ensure appropriate initial settings are selected. After a patient is placed on mechanical ventilation, obtain an arterial blood gas to evaluate acid–base status, oxygenation, and ventilation. Neuromuscular blocking agents should be considered to further decrease respiratory muscle oxygen consumption and preserve Do_2 to vital organs, especially if patients are severely hypoxemic due to acute respiratory distress syndrome.[22]

OPTIMIZING THE CIRCULATION

Fluids Circulatory or hemodynamic stabilization begins with intravascular access through large-bore peripheral venous lines. The Trendelenburg position does not improve cardiopulmonary performance compared with the supine position. It may worsen pulmonary gas exchange and predispose to aspiration. Passive leg raising above the level of the heart with the patient supine may be effective. If passive leg raising results in an increase in blood pressure or CO, fluid resuscitation is indicated.[23]

Fluid resuscitation should begin with isotonic crystalloid.[24] The amount and rate of infusion are determined by an estimate of the hemodynamic abnormality. Most patients in shock have either an absolute or relative volume deficit. The exception is the patient in cardiogenic shock with pulmonary edema. Administer fluid rapidly (over 5 to 20 minutes), in set quantities of 500 or 1000 mL of normal saline, and reassess the patient after each bolus. Patients with a modest degree of hypovolemia usually require an initial 20 to 30 mL/kg of isotonic crystalloid, as is suggested in the 2012 Surviving Sepsis Campaign Guidelines; however, there are few data to support this uniform recommendation, and fluid volume should be individualized to each patient.[25] More fluids are needed for profound volume deficits. It is common for patients in septic shock to receive 6 L of crystalloid in the first 24 hours of hospital care. For large fluid volumes, consider using lactated ringer's or plasmalyte to avoid hyperchloremic metabolic acidosis.[26,27]

Central venous access may aid in assessing volume status (preload) and monitoring $Scvo_2$. It is also the preferred route for the long-term administration of certain vasopressor therapy. However, there is no need for universal central access in patients with septic shock, and the need for central access should be individually determined.[20]

Vasopressors Vasopressors are used when there has been an inadequate response to volume resuscitation or if there are contraindications to volume infusion.[25] Vasopressors are most effective when the vascular space is "full" and least effective when the vascular space is depleted. Patients with chronic hypertension may be at greater risk of renal injury at lower blood pressures; however, in others, there appears to be no mortality benefit in raising MAP above the 65 to 70 mm Hg range.[28,29]

Vasopressor agents have variable effects on the α-adrenergic, β-adrenergic, vasopressin, and dopaminergic receptors (**Table 12-7**). Although vasopressors improve perfusion pressure in the large vessels, they may decrease capillary blood flow in certain tissue beds, especially the GI tract and peripheral vasculature. If multiple vasopressors are used, they should be simplified as soon as the best therapeutic agent is identified. In addition to a vasopressor, an inotrope may be needed to directly increase CO by increasing contractility and stroke volume.

ASSURING ADEQUATE OXYGEN DELIVERY

Control of oxygen consumption ($\dot{V}o_2$) is important in restoring the balance of oxygen supply and demand to the tissue (oxygen consumption equation). A hyperadrenergic state results from the compensatory response to shock, physiologic stress, pain, and anxiety. Shivering frequently results when a patient is unclothed for examination and then left inadequately covered in a cold resuscitation room. The combination of these variables increases $\dot{V}o_2$. Pain further suppresses myocardial function, further impairing Do_2 and $\dot{V}o_2$. Providing analgesia,

TABLE 12-7 Commonly Used Vasoactive Agents (all vasopressors increase myocardial oxygen demand; most should be titrated to desired effect)

Drug	Dose	Action	Cardiac Contractility	Vasoconstriction	Vasodilation	Cardiac Output
Dobutamine	2.0–20.0 micrograms/kg/min	β_1, some β_2 and α_1 in large dosages	++++	+	++	Increases
Side effects and comments	Inotrope only; Causes tachydysrhythmias, occasional GI distress, hypotension in volume-depleted patients; has less peripheral vasoconstriction than dopamine; can cause fewer arrhythmias than isoproterenol					
Dopamine	0.5–20 micrograms/kg/min	α, β, and dopaminergic	++ at 2.5–5 micrograms/kg/min	++ at 5–20 micrograms/kg/min	+ at 0.5–2.0 micrograms/kg/min	Usually increases
Side effects and comments	Tachydysrhythmias; a cerebral, mesenteric, coronary, and renal vasodilator at low doses; Surviving Sepsis Campaign second line, lot of overlap with α/β/dopaminergic receptors and dose; can be given through a peripheral IV					
Epinephrine	2–10 micrograms/min	α and β	++++ at 0.5–8 micrograms/kg/min	++++ at >8 micrograms/kg/min	+++	Increases
Side effects and comments	Causes tachydysrhythmia, leukocytosis; increases myocardial oxygen consumption; may increase lactate; no real maximum dose					
Isoproterenol	0.01–0.05 micrograms/kg/min	β_1 and some β_2	++++	0	++++	Increases
Side effects and comments	Inotrope; causes tachydysrhythmia, facial flushing, hypotension in hypovolemic patients; increases myocardial oxygen consumption; never use alone in shock					
Norepinephrine	0.5–50 micrograms/min	Primarily α_1, some β_1	++	++++	0	Slightly increases
Side effects and comments	Useful when loss of venous tone predominates; first-line agent for most situations; should be given through a central line					
Phenylephrine	10–200 micrograms/min	Pure α	0	++++	0	Decreases
Side effects and comments	Reflex bradycardia, headache, restlessness, excitability, rarely arrhythmias; can be used on patients in shock with tachycardia or supraventricular arrhythmias; not good comparatively for septic shock					
Vasopressin	0.01–0.04 units/min	Directly stimulates V_1 receptor on smooth muscle	0	++++	0	0
Side effects and comments	Primarily vasoconstriction; usually started at max dose and not titrated					

Note: 0 = no effect; + = mild effect; ++ = moderate effect; +++ = marked effect; ++++ = very marked effect.

muscle relaxation, warm covering, anxiolytics, and even paralytic agents, when appropriate, decreases this inappropriate systemic oxygen consumption.

Once blood pressure is stabilized through optimization of preload and afterload, Do_2 can be assessed and further manipulated. Restore arterial oxygen saturation to ≥91%. In shock states, consider a transfusion of packed red blood cells to maintain hemoglobin ≥7 to 9 grams/dL.[25] If CO can be assessed, it should be increased using volume infusion or inotropic agents in incremental amounts until venous oxygen saturation (mixed venous oxygen saturation [$Smvo_2$] or $Scvo_2$) and lactate are normalized.

Sequential examination of lactate and $Smvo_2$ or $Scvo_2$ is a method to assess adequacy of a patient's resuscitation. Continuous measurement of $Smvo_2$ or $Scvo_2$ can be used in the ED, although recent literature questions the need for this in resuscitation management.[20] A variety of technologic tools may be used to assess tissue perfusion during resuscitation.[30–35] These technologies may be available in some EDs, but it is essentially standard of care in intensive care units. Transfer of the patient to the intensive care unit should not be delayed so that monitoring devices can be placed in the ED.[15,36]

END POINTS OF RESUSCITATION

The goal of resuscitation is to use hemodynamic and physiologic values to guide therapy in order to maximize survival and minimize morbidity. No therapeutic end point is universally effective, and only a few have been tested in prospective trials, with mixed results.[20,28,29] Hypotension at ED presentation is associated with poor outcomes.[37] Noninvasive parameters, such as blood pressure, heart rate, and urine output, may underestimate the degree of remaining hypoperfusion and oxygen debt, so the use of additional physiologic end points may be informative.[20,28,29,37] A goal-directed approach of MAP >65 mm Hg, central venous pressure of 8 to 12 mm Hg, $Scvo_2$ >70%, and urine output >0.5 mL/kg/h during ED resuscitation of septic shock has been shown to decrease mortality, but which of the metrics accounts for the mortality decrease remains in question.[16,19,20,25] Source control, whether with infection, hemorrhage, or other state of shock, is essential in the initial stages of management. If shock or hypotension persists, reassessment at the patient's bedside is essential while considering the important issues in **Table 12-8**.

CONTROVERSIES OF TREATMENT

FLUID THERAPY

Rapid restoration of fluid deficits modulates inflammation and, if the condition progresses to shock, decreases the need for subsequent vasopressor therapy, steroid administration, and invasive monitoring (e.g., pulmonary artery catheterization and arterial line placement).[25,38] Although there is general agreement that volume therapy is an integral component of early resuscitation, there is a lack of consensus for the type of fluid, standards of volume assessment, and end points. **Table 12-9** compares the most commonly used fluid therapies.[39–43]

Colloids are high-molecular-weight solutions that increase plasma oncotic pressure. Colloids can be classified as either natural (albumin) or artificial (starches, dextrans, and gelatins). Due to their higher molecular weight, colloids stay in the intravascular space significantly longer than crystalloids. The intravascular half-life of albumin is 16 hours versus 30 to 60 minutes for normal saline and lactated

TABLE 12-8 Questions to Answer if There Is Persistent Shock or Hypotension

Equipment and monitoring
Is the patient appropriately monitored?
Is there an equipment malfunction, such as dampening of the arterial line or disconnection from the transducer?
Is the IV tubing into which the vasopressors are running connected appropriately?
Are the vasopressor infusion pumps working?
Are the vasopressors mixed adequately and in the correct dose?
Patient assessment
Do mentation and clinical appearance match the degree of hypotension?
Is the patient adequately volume resuscitated?
Does the patient have a pneumothorax after placement of central venous access?
Has the patient been adequately assessed for an occult penetrating injury (a bullet hole or stab wound)?
Is there hidden bleeding from a ruptured spleen, large-vessel aneurysm, or ectopic pregnancy?
Does the patient have adrenal insufficiency? The incidence of adrenal dysfunction can be as high as 30% in this subset of patients.
Is the patient allergic to the medication just given or taken before arrival?
Is there cardiac tamponade in the dialysis patient or cancer patient?
Is there associated acute myocardial infarction, aortic dissection, or pulmonary embolus?

ringer's solution.[24,39-41] Resuscitation with **crystalloids** requires two to four times more volume than colloids.[24,38,39] The outcome advantage between crystalloid and colloids continues to remain unresolved in sepsis, despite multiple studies.[24,38-41] Due to the equivalency and the higher cost of colloids, crystalloids would seem to be a better choice for resuscitation in the ED.

BICARBONATE USE IN SHOCK

Bicarbonate administration shifts the oxygen-hemoglobin dissociation curve to the left, impairs tissue unloading of hemoglobin-bound oxygen, and may worsen intracellular acidosis. However, many clinicians remain uncomfortable withholding bicarbonate if the pH is <7.00. Animal studies of profound acidosis demonstrate decreased ventricular contractility and systolic blood pressure.[7] In settings of a low pH and when evidence of decreased contractility (despite ongoing resuscitative efforts) or development of a dysrhythmia, partially correct the metabolic acidosis, either with sodium bicarbonate boluses or a drip. Recognize the risk of paradoxical intracerebral intracellular acidosis in the process. Consider situations, such as end-stage renal disease and renal tubular acidosis, that cannot reclaim bicarbonate through normal renal processes and whether bicarbonate may be indicated.

TABLE 12-9 Fluid Therapy

Crystalloids	
Normal saline (NS)	Slightly hyperosmolar containing 154 mEq/L of both sodium and chloride. Risk of inducing hyperchloremic metabolic acidosis when given in large amounts due to relatively high chloride concentration.
Lactated ringer's (LR)	Lactate can accept a proton and subsequently be metabolized to carbon dioxide and water by the liver, leading to release of carbon dioxide in the lungs and excretion of water by the kidneys. LR results in a buffering of the acidemia that is advantageous over NS. Theoretical risk of inducing hyperkalemia in patients with renal insufficiency or renal failure due to small potassium content (very small amount).
Colloids	
Albumin	Derived from human plasma. Available in varying strengths from 4% to 25%. Multiple studies have shown that there is no outcome difference whether colloids or crystalloids are used. Colloids cost significantly more than crystalloids. One study actually showed an increase in mortality in trauma patients complicated by head injury.
Hydroxyethyl starch	Synthetic colloid derived from hydrolyzed amylopectin. Hydroxyethyl starch should be avoided in sepsis. Many harmful effects: renal impairment at recommended doses and impairing long-term survival at high doses, coagulopathy and bleeding complications from reduced factor VIII and von Willebrand factor levels, impaired platelet function.

DISPOSITION AND TRANSITION TO THE INTENSIVE CARE UNIT

Early recognition, treatment, and subsequent transfer of critically ill patients to the intensive care unit improves patient outcomes and improves ED throughput.[15,36] Communicate and document all ED resuscitative efforts to the critical care team. Even when resuscitation is systematic and thoughtful, miscommunication can undo the benefits of initial ED treatment. Ideally, before transfer, verbally communicate and document a system-oriented problem list with an assessment and plan, including all procedures and complications. For prolonged or "boarded" ED stays, constantly reassess the critically ill patient and ensure that care plans are continuing. Often, this will entail ordering tests that are not commonly performed on ED patients or ordering subsequent doses of medicines, particularly antibiotics.

PROGNOSIS

Some clinical variables are associated with poor outcome, such as severity of shock, temporal duration, underlying cause, preexisting vital organ dysfunction, and reversibility. Early recognition, intervention, source control, and smooth transitions of care help ensure the most ideal outcomes. While associated morbidity and mortality remain high for patients with shock, integration of protocol-based care pathways, with ongoing refinement in response to new information, may lead to continued reductions over time.[15,20,25,36] Additional outcome predictions related to physiologic scoring systems, ED-based shock interventions, and the balance between invasive and noninvasive or minimally invasive strategies are still being studied.[15,44,45]

CHAPTER 13

Fluid and Blood Resuscitation in Traumatic Shock

David M. Somand
Kevin R. Ward

INTRODUCTION

Circulatory shock has a high mortality. Severe hemorrhage after injury carries a mortality rate of 30% to 40% and is responsible for almost 50% of deaths occurring within 24 hours of injury.[1,2] Septic shock has a mortality of up to 50%.[3] Resuscitation, starting in the prehospital setting and continuing throughout the victim's care in the ED and on into the hospital, has the goal of restoring the necessary level of tissue perfusion and oxygenation for survival while simultaneously limiting further volume loss.

Intravascular volume depletion is a common feature of circulatory shock; crystalloids, colloids, and blood products (packed red blood cells

TABLE 13-1 Adult Fluid Spaces

Fluid Compartment	% Body Weight*	% Body Water*	Volume* (70 kg)
Total body water	60	100	42 L
Intracellular	40	67	28 L
Extracellular	20	33	14 L
Interstitial	15	25	10 L
Intravascular	~7–8	~11–13	~5.0–5.5 L
Plasma	~4.0–4.5	~7	~3.0–3.5 L
Red blood cells†	~3.0–3.5	~5	~2.0–2.5 L

*Approximate percentage and amount.

†Percentages do not add up to 100% because fluid contained within intravascular red blood cells is included within the intracellular fluid compartment.

and plasma) are the primary volume expanders to reverse intravascular volume depletion. This chapter focuses on the issues related to fluid and blood resuscitation in traumatic shock, with an emphasis on hemorrhagic shock. Processes that cause loss of plasma fluid and electrolytes (e.g., dehydration, burns, sepsis), often requiring aggressive fluid therapy, are discussed in other chapters (see chapters 150, "Toxic Shock Syndromes," 151, "Sepsis," and 216, "Thermal Burns").

The principal objectives of fluid and blood resuscitation in traumatic shock are: (1) to restore intravascular volume sufficient to maintain oxygen-carrying capacity and tissue perfusion for adequate cellular oxygen delivery, and (2) to prevent or correct derangements in coagulation.

PATHOPHYSIOLOGY

Circulatory shock is a state of impaired oxidative metabolism and homeostasis due to inadequate oxygen delivery to meet metabolic demand, and hypoperfusion leading to inadequate cellular waste removal. Acute shock triggers a complex range of physiologic responses that compensate for intravascular volume loss and maintain perfusion to the most important vascular beds. Shock also produces a global insult to the vascular endothelium that activates the coagulation and inflammatory systems (**Figure 13-1**). When uncorrected, coagulopathy, additional inflammation, and organ system damage result.

While moderate transient hypoperfusion may be well tolerated, prolonged or severe hypoperfusion leads to accumulation of oxygen debt and progressive cellular and organ dysfunction. If rapid and severe, sudden cardiovascular collapse and death may occur.

Coagulopathy observed in trauma victims, termed *trauma-induced coagulopathy*, is ascribed to a combination of factors beginning with loss of coagulation factors from hemorrhage, followed by hemodilution from crystalloid resuscitation, and then exacerbated by acidosis (evidenced by a base deficit) and hypothermia that occur during the course of ongoing hemorrhage and resuscitation.[4] These same principles also apply to other causes of shock.[5] However, acidosis does not, by itself, have a significant effect on coagulation until the pH decreases below 7.0.[6]

The lethal triad of hypothermia, hemodilution, and acidosis can be viewed a partially iatrogenic based on the type of resuscitation provided. The normal total circulating volume of an adult is approximately 7% of ideal body weight or about 5 L for an average 70-kg adult patient divided into about 3 L of plasma and 2 L of red blood cell volume (**Table 13-1**). Understanding this distribution explains how trauma-induced coagulopathy can be iatrogenically produced.

Factors exacerbating trauma-induced coagulopathy, including hyperfibrinolysis and clotting factor and platelet consumption or dysfunction, are related to the degree of injury and hemorrhage.[7] Early trauma-induced coagulopathy is characterized by anticoagulation and hyperfibrinolysis, likely modulated through the protein C pathway. Endothelial damage associated with trauma or sepsis stimulates an increase in thrombomodulin expression on the endothelium that complexes with thrombin and in turn activates protein C (**Figure 13-2**). Complexed thrombin is now no longer available for its usual hemostatic role of cleaving fibrinogen to form fibrin. Subsequent consumption of plasminogen activator inhibitor-1 by activated protein C contributes to hyperfibrinolysis (Figure 13-2).[8]

Thrombomodulin normally found in the endothelium may be viewed as protective because it is able to sequester thrombin and thus allow for generation of adequate levels of protein C to prevent thrombosis caused by low-flow states. However, on a mass systemic level, this appropriate local response may become pathologic, resulting in clotting inhibition.

CLINICAL FEATURES

The clinical appearance of acute traumatic shock is variable and depends on the cause, rate, volume, and duration of volume loss or bleeding; the presence of other acute disorders; the effects of current medications; and the patient's baseline physiologic status.

The hemodynamic response to acute severe hemorrhage-induced hypovolemia traditionally includes tachycardia, hypotension, and signs of poor peripheral perfusion (cool, pale, clammy extremities with weak peripheral pulses and prolonged capillary refill). Arterial and venous vasoconstriction leads to a narrowing of the pulse pressure. Cerebral hypoperfusion causes alterations in mental status. With increasing blood loss, signs and symptoms become more pronounced. Classification of hemorrhage severity as a percentage of blood volume loss based on vital signs is not accurate and should not be used to guide ED resuscitation.[9]

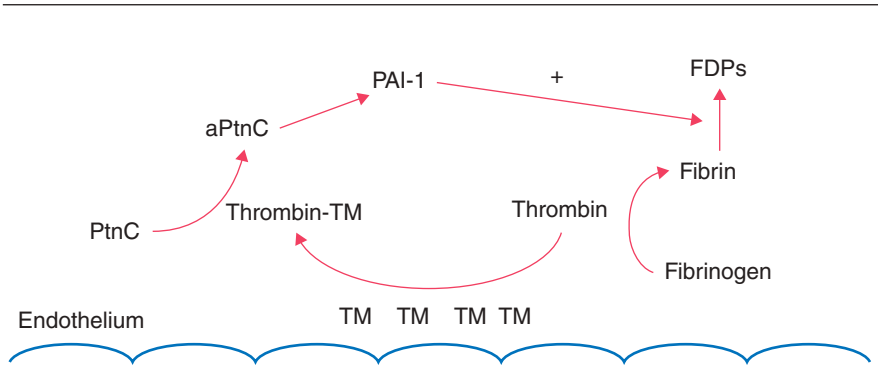

FIGURE 13-2. Endothelial damage results in increased thrombomodulin (TM) expression. TM can complex with thrombin (thrombin-TM complex), leading to activation of the protein C (PtnC to aPntcC) pathway. Modulated through a multistep pathway leading to plasminogen activator inhibitor-1 (PAI-1), fibrinolysis is encouraged, resulting in increased fibrin degradation products (FDPs). In addition, the complexed thrombin is no longer able to perform its usual role in cleaving fibrinogen to fibrin to form clots.

Patients with excellent baseline physiologic status (e.g., young athletes) may have such a robust compensatory response to hemorrhage that they appear stable and do not manifest tachycardia or hypotension, even with large blood volume loss. Signs of peripheral hypoperfusion and subtle mental status alterations may be the only clues that the severity of hemorrhage is greater than predicted based on hemodynamic parameters. Elderly patients may not develop tachycardia due to underlying heart disease or medications such as β-adrenergic blockers. Bradycardia or lack of tachycardia may occur in about 30% of patients with intra-abdominal hemorrhage from increased vagal tone in response to hemoperitoneum. In a pregnant trauma patient, compression of the inferior vena cava by the gravid uterus can decrease central venous return and worsen hypotension and tachycardia in the setting of less severe hemorrhage.

DIAGNOSIS

Vital signs offer little value unless they are in extreme low ranges. Arterial blood pressure does not adequately reflect cardiac output or regional perfusion. Clinical evidence of peripheral hypoperfusion is useful but is not a quantitative measurement. Metabolic information (discussed below), assessment of mechanisms of injury and illness, and appropriate imaging studies offer the best chance for early recognition of severe hemorrhage and for guiding an appropriate response to treatment.

There is a biphasic relationship between oxygen consumption and oxygen delivery (**Figure 13-3**). While this relationship exists for the body as a whole, it also exists for each individual organ system and is largely mediated by the microcirculation. Oxygen debt develops in tissues or organs when oxygen delivery does not meet the metabolic demands and represents the amount of extra oxygen that is needed to metabolize the accumulated products of anaerobic metabolism once perfusion is restored. Oxygen debt is the accumulation of multiple oxygen deficits over time and is a measure of whole-body ischemia. Oxygen debt is the only physiologic measure that has clearly been linked to both mortality and even morbidity in the form of multiple organ failure after shock. The degree of oxygen debt incurred after injury has also been clearly linked to inflammation.[10]

Measurements of lactate and base deficit are in fairly ubiquitous use in trauma centers and EDs and are now even being used as point-of-care testing in the prehospital setting as a triage tool. Using lactate and/or base deficit as a resuscitation trigger and its clearance/normalization as an endpoint is prudent and is associated with improvements in survival. However, elevated lactate and base deficit is a late finding, which is first preceded by increases in oxygen extraction as indicated by a decrease in indicators of oxygen consumption such as mixed or central venous hemoglobin oxygen saturation (Figure 13-2). Furthermore, improvements in oxygen delivery resulting in lactate clearance do not indicate that oxygen extraction is normal.

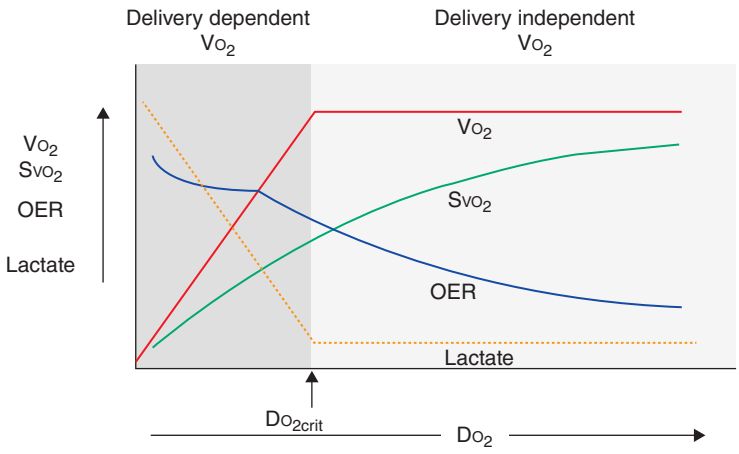

FIGURE 13-3. The biphasic relationship of oxygen delivery (Do_2) and oxygen consumption (Vo_2). As Do_2 decreases, Vo_2 may remain constant due to an increase in the ratio of extracted oxygen (OER) at the tissue level. This is mirrored by a decrease in venous hemoglobin oxygen saturation (Svo_2). However, at some point, OER will not meet the Vo_2 demands of the tissues, resulting in a state of Do_2 dependent Vo_2 whereby aerobic Vo_2 transitions to anaerobic Vo_2. At this point of critical Do_2, oxygen debt begins to accumulate along with metabolic byproducts of anaerobiosis such as lactate. While this relationship exists for the body as a whole, it also exists for each individual organ system and is largely mediated by the microcirculation. [©Kevin R. Ward, MD.]

Although lactate is also a measure of oxygen debt, its resolution during resuscitation does not ensure the important repayment and resolution of oxygen debt. Lactate also suffers from the intermittent and time-dependent nature of its measure and change. To counter these, continuous measures of oxygen consumption surrogates are available in the form of invasive oximetric catheters measuring central venous oxygen saturation ($Scvo_2$) and tissue oxygen saturation (Sto_2) noninvasively from target tissues such as skeletal muscle using near-infrared spectroscopy. Sto_2 measurements with infrared spectroscopy are based on the fact that tissue blood volume is 70% to 80% venous blood with the remaining 10% to 20% a combination of arterial and capillary blood. Thus aggregate measures of hemoglobin oxygenation in the tissue are heavily dominated by the venous blood and thus the postextraction compartment. Although not an exact mirror of $Scvo_2$, ensuring Sto_2 values above 50% appears to be reasonable from both a diagnostic and treatment standpoint to begin and sustain hemostatic resuscitation. A target Sto_2 or $Scvo_2$ between 60% and 70% should be maintained to help ensure resolution of tissue hypoxia.

TREATMENT

Resuscitation begins in the prehospital setting and continues in the ED. The priority for prehospital care is treatment of life-threatening conditions and rapid transport to an appropriate facility. For the hemorrhaging patient, this entails assuring adequate ventilation and oxygenation (including securing an airway if necessary), controlling external bleeding (if present), and protecting the spinal cord (if potentially vulnerable).

In the ED, **restore intravascular volume** to reverse or limit systemic and regional hypoperfusion, **maintain oxygen-carrying capacity** so that tissue oxygen delivery meets demand, and **limit ongoing blood loss** and **prevent the development of coagulopathy**. From the moment resuscitation begins, prevent the development of **hypothermia** by keeping the patient warm and administering warmed IV fluids and blood products.[11] Endogenous hypothermia occurs when heat production from cellular respiration is decreased by hypoperfusion and inadequate tissue oxygen delivery. Major causes of exogenous hypothermia are exposure and the use of below-body-temperature fluid and blood resuscitation. Apply external warming devices early to prevent external heat escape. Warming devices that allow for the rapid warming of infused fluid and blood should be used for all patients in whom large-volume resuscitation is undertaken.[11]

AIRWAY CONTROL, VENTILATION, AND OXYGENATION

If spontaneous ventilation is not adequate, intubate and ventilate to achieve an arterial hemoglobin oxygen saturation of ≥94%. Identify and treat potential respiratory conditions such as pneumothorax, tension pneumothorax, hemothroax, or upper airway obstruction.

VASCULAR ACCESS AND MONITORING

Establish adequate IV access concurrent with airway management. Large-bore (14- to 16-gauge in adults) peripheral lines may be adequate if two or more can be secured. Central venous access may be necessary. Intraosseous lines are suitable for resuscitation.

Institute continuous ECG heart rate monitoring, continuous pulse oximetry, and, if possible, continuous end-tidal carbon dioxide monitoring. Monitor arterial blood pressure, mental status, and peripheral perfusion frequently. Bedside US is useful to identify

intraperitoneal bleeding, assess cardiac function and volume status, and assist in central venous cannulation.[12,13]

HEMOSTATIC-HYPOTENSIVE RESUSCITATION

Hemostatic resuscitation begins in the field. In traumatic shock, the goal is deliberate hypotensive resuscitation, so that intravascular volume expansion is limited and blood pressure is not normalized. Blood pressure goals are systolic blood pressures of 80 to 90 mm Hg (10.7 to 12.0 kPa) in trauma and 90 to 95 mm Hg (12.0 to 12.7 kPa) in head injury. Normalization of blood pressure and the raising of hydrostatic pressure can increase hemorrhage. This is particularly evident in noncompressible hemorrhage where raising blood pressure could potentially "pop the clot" and reestablish active hemorrhage.

Hypotensive resuscitation targets fluid resuscitation only when systolic blood pressure falls below 70 to 80 mm Hg (9.3 to 10.7 kPa) and/or there is evidence of decreasing mental status and, thus cerebral hypoperfusion. This practice has been widely adopted in combat casualty care (see chapter 302, "Military Medicine") and is partially supported by civilian studies.[14] Preliminary results of traumatic injury comparing low versus traditional mean arterial pressure guided resuscitation indicate that a lower mean arterial pressure group sustains less blood loss, requires fewer transfusions, and has improved early and 30-day survival.[15]

Hypotensive resuscitation is problematic for a number of reasons, including the inability to obtain frequent and accurate blood pressures and, in the civilian world, its application to the elderly and those with hypertension or cerebral vascular disease. Hypotensive resuscitation should not be used in patients with myocardial disease, cerebral ischemia, or traumatic brain injury. Obviously there is not an unlimited time span that patients can tolerate hypotensive resuscitation. From a cellular standpoint, patients will at some time incur irreversible damage from prolonged tissue hypoxia if adequate tissue oxygenation is not restored.

ISOTONIC CRYSTALLOID SOLUTIONS

Isotonic crystalloids, normal saline, and lactated Ringer's solution are the most commonly used resuscitation fluids in the United States. Concerns about each fluid are: (1) infusion of large volumes of either normal saline or lactated Ringer's solution can cause increased neutrophil activation, (2) lactated Ringer's solution can increase cytokine release and may increase lactic acidosis when given in large volumes, and (3) normal saline can exacerbate intracellular potassium depletion and cause hyperchloremic acidosis.[16]

Crystalloid solutions are isotonic but hypo-oncotic, because they lack the large protein molecules present in the plasma. Low oncotic pressure results in substantial shifts of crystalloid to the extravascular space corresponding to the relative size of the intravascular and interstitial fluid compartments (**Table 13-2**). This was the physiologic basis for the 3:1 ratio for crystalloid to blood. For every amount of blood lost, three times that amount of isotonic crystalloid is required to restore intravascular volume because, at best, about 30% of the infused fluid stays intravascular. Based on this rule, a loss of 1 L of blood (about 15% to 20% of total circulating blood volume) would require about 3 L of isotonic crystalloid to restore normovolemia, assuming no ongoing blood loss. Bearing this in mind, the recommendations for initial fluid resuscitation have been to administer 2 to 3 L of crystalloid solution in acute hemorrhage and assess the response before initiating blood transfusion. In light of the new data reflecting improved outcomes with plasma-based resuscitation in traumatic hemorrhage, no more than 2 L of crystalloid solution should be administered before giving serious consideration to using blood products, especially if ongoing hemorrhage is expected.

TABLE 13-3 Isotonic Fluid Composition*

Fluid	Na^+ (mmol/L)	K^+ (mmol/L)	Ca^{++} (mmol/L)	Mg^{++} (mmol/L)	CL^- (mmol/L)	Buffer (mmol/L)	Osm (mOsm/L)
Normal saline	154	0	0	0	154	None	308
Ringer's lactate	130	4	1.4	0	109	28 lactate	273
Ringer's acetate	130	5	1	1	112	27 acetate	276
Hartmann's	131	5	2	0	111	29 lactate	278
Plasma-Lyte A	140	5	0	1.5	98	27 acetate 23 gluconate	294

*Minor variations may exist between different commercial manufacturers.

Common modifications of isotonic fluids include use of acetate instead of lactate in Ringer's solution, Hartmann's solution, and Plasma-Lyte (**Table 13-3**). Plasma-Lyte is the shared name for a family of isotonic crystalloid solutions available worldwide, marketed with variation in composition according to regional preferences. Solutions containing lactate or acetate are considered *balanced crystalloids* because they are buffered and have a lower chloride concentration compared to normal saline. There is evidence of low confidence that balanced crystalloids are associated with reduced mortality compared with normal saline when used for fluid resuscitation in sepsis.[17]

COLLOID SOLUTIONS

Colloid solutions contain larger molecular weight particles that have oncotic pressures similar to normal plasma proteins. Therefore, colloids theoretically have several advantages during resuscitation. They would be expected to remain in the intravascular space, replacing plasma proteins lost due to hemorrhage, and more effectively restore circulating blood volume than crystalloid solutions. An argument favoring the use of colloids has been the concern that extravascular shift, or third-spacing, of infused crystalloid solutions has potential adverse effects, including pulmonary interstitial edema with impaired oxygen diffusion and intra-abdominal edema with diminished bowel perfusion. However, pathologic conditions, such as hemorrhagic shock and sepsis, lead to increased vascular permeability that can allow for eventual extravascular leakage of these larger colloid molecules.[18]

The colloids used as resuscitation fluids are a heterogeneous group of agents with widely varying characteristics and effects. These agents have no proven consistent benefit, and there is evidence of harm in some patients with critical illness.[19,20]

Hetastarch is a high-molecular-weight polysaccharide that has no proven benefit in critically ill patients.[21] Currently, for logistical reasons of weight and size, hetastarch is the recommended fluid of choice for the far forward resuscitation of battlefield casualties.[22] It is used as a part of a hypotensive resuscitation strategy with no more than 1000 mL to be given. The administration of 1000 mL of hetastarch is theoretically equal to the administration of 3 L of isotonic crystalloid.

TABLE 13-2 Theoretical Volemic Effect of 1 L of Fluid Administration on Fluid Compartments

	Intracellular (mL)	Interstitial (mL)	Plasma (mL)
5% dextrose in water	660	255	85
Normal saline or Ringer's lactate	−100	825	275
7.5% saline	−2950	2960	990
5% albumin	0	500	500
Whole blood	0	0	1000

HYPERTONIC SOLUTIONS

Hypertonic saline (7.5% saline) has been proposed as a potential crystalloid alternative that would limit the tissue edema effects that are often of concern with isotonic crystalloid solutions. Hypertonic saline has anti-inflammatory and immunomodulatory effects, with demonstrable decrease in lung and intestinal injury in animal models of hemorrhagic shock.[18] The intravascular shift of fluid from the extravascular space may be potentially beneficial in head trauma patients by limiting

cerebral edema, lowering intracranial pressure, and improving cerebral perfusion. The addition of dextran to hypertonic saline was aimed at sustaining the hemodynamic effect of the hypertonic saline. The volume of hypertonic saline solution that can be given during resuscitation is limited due to the potential for hypernatremia. Similar to hetastarch, an approach using smaller volumes (250 mL) of hypertonic saline (7.5%) has also been advocated. Randomized controlled trials have not demonstrated a clinically significant difference in outcome when hypertonic saline was compared with conventional isotonic fluid.[23] However, these studies did not generally incorporate hypotensive resuscitation as a part of the overall strategy, and in the prehospital trail, transport times to trauma centers were short.[24]

PACKED RED BLOOD CELLS

Packed red blood cells (PRBCs) are the most commonly transfused blood product (see chapter 238). Using only PRBCs in the patient with traumatic shock and ongoing bleeding (without plasma and platelets) will do little to promote hemostasis and may not restore tissue oxygenation. If hemorrhage is definitively controlled, do not transfuse if the hemoglobin concentration is > 10 g/dL (> 100 g/L). Consensus recommendations for transfusion are a hemoglobin concentration between 6 and 7 g/dL (60 to 70 g/L) for those without cardiopulmonary, cerebral, or peripheral vascular disease.[25] For a hemoglobin between 6 and 10 g/dL (60 to 100 g/L), use clinical judgement for transfusion.

When possible, typed and cross-matched blood is preferable. However, if time and the patient's clinical status do not permit full cross-matching, type-specific blood is the next option, followed by low-titer O-negative blood. In U.S. blood banks, whole blood is not stocked, and only PRBCs are available (see the chapter 302 for further discussion of whole-blood transfusion).

PRBC transfusion obviously restores lost hemoglobin. Using current preservatives, PRBCs can be stored for up to 45 days, and the average age of a unit of blood administered in the United States is about 21 days. Stored red blood cells can lose deformability, limiting their ability to pass normally through capillary beds or even resulting in capillary plugging. The oxygen dissociation curve is altered by loss of 2,3-diphosphoglycerate in the erythrocytes of stored PRBCs, impeding the off-loading of oxygen at the tissue level.[26] Despite these changes, no consistent harm has been identified with use of "older" stored blood.[27,28]

FRESH FROZEN PLASMA

Fresh frozen plasma (FFP) is plasma obtained after the separation of whole blood from red blood cells and platelets and then frozen within 8 hours. A unit of FFP has a volume of 200 to 250 mL and contains all the coagulation factors present in fresh blood. Kept frozen, FFP can be stored for up to a year after the unit was collected. It takes between 15 and 20 minutes to thaw a unit of FFP in a 37°C water bath, which can limit availability in a massive transfusion situation. However, some major trauma centers and their respective blood banks keep thawed FFP (kept at 1°C to 6°C) available for immediate use. FFP may be kept thawed at this temperature for up to 5 days with little degradation of plasma proteins. FFP ABO compatibility is required, but because there are no red cells in FFP, Rh compatibility is less important, and universal donor FFP is typically AB+ (see chapter 238, "Transfusion Therapy").

PLATELETS

Platelets are collected from whole-blood donations or from single donors using apheresis techniques and can only be stored for up to 5 days. Six units of pooled random-donor platelet concentrate or one apheresis-collected single-donor platelet concentrate in an adult will increase platelet count up to 50,000/mm^3 (50 × 10^9/L).

MASSIVE TRANSFUSION PROTOCOLS

Massive transfusion is generally defined as the requirement for >10 units of PRBCs within the first 24 hours of injury. Massive transfusion is not a substitute for definitive surgical hemostasis but enhances the ability to achieve surgical hemostasis and to limit complications.[29,30] Draw sufficient specimens from the patient early in anticipated massive transfusion because once the patient has received close to one blood volume of transfused products, new blood specimens will contain so much donor blood that cross-matching of subsequent units is difficult. Initially use isotonic solutions to begin resuscitation in predetermined aliquots (250 to 500 mL) while assessing the likelihood of ongoing active hemorrhage and the need for, type, and timing of hemostasis and for hypotensive resuscitation.[31,32] Variables predictive of need for massive transfusion include penetrating mechanism of injury, positive FAST examination, blood pressure <90 mm Hg (< 12.0 kPa), and pulse rate >120 beats/min.[33,34] If hemorrhage is clinically significant and immediate hemostasis is not achievable, transition from crystalloid-based resuscitation to a plasma-based massive transfusion protocol.

An estimated 10% of military trauma patients and 3% to 5% of civilian trauma patients receive massive transfusion.[1] Soldiers receiving high ratios of plasma to PRBC (a plasma:PRBC ratio of about 1:1.4) have significantly improved survival rates than those receiving lower ratios (between 1:1.8 and 1:2.5). Additional evidence supporting this also comes from combat casualty care data suggesting that early administration of fresh whole blood (something not currently practical in civilian trauma) offers survival advantages.[18,35] These survival observations using high plasma-to-PRBC ratios were confirmed by civilian studies, which also appear to indicate less incidence of trauma-induced coagulopathy.[33,36]

High plasma-to-PRBC ratio resuscitation appears to also offer survival benefit independent of coagulopathy, and plasma may enhance cell survival by endothelial repair and reducing vascular permeability. It may also be that plasma is simply a superior fluid for perfusion and tissue oxygenation restoration. In addition, many trauma centers now include early platelet administration in predetermined ratios to plasma and PRBC in their resuscitation protocols based on findings that platelet function can rapidly decrease soon after trauma.[1,34]

Studies routinely using FFP and platelets with PRBCs during massive transfusion have yielded mixed results on reducing mortality.[34,37] The best ratio of PRBCs to platelets to FFP during massive transfusion is controversial.[38] Some experts advocate a 1:1:1 ratio, although lower ratios of platelets and FFP have been used without evidence of inferiority.[39] Likewise, the benefits with adjunctive agents such as calcium chloride, prothrombin complex concentrates, and fibrinogen concentrate included in some protocols are unknown. Tranexamic acid (an antifibrinolytic) is advocated early in the resuscitation process of major trauma victims based on the early fibrinolytic phase of trauma-induced coagulopathy and on clinical studies suggesting improved survival.[40] An institution-specific massive transfusion protocol is recommended to guide the clinician when ordering blood components and to facilitate release from the blood bank (**Figure 13-4**). Tranexamic acid, an antifibrinolytic agent, is not currently a component of massive transfusion protocols in the United States. Its use is discussed in the chapters 254, "Trauma in Adults" and 302, "Military Medicine." If given, it must be administered as soon as possible and within 3 hours of injury. The dose is 1 gram IV bolus in 100 mL normal saline.

Calcium PRBCs and FFP contain citrate that can complex calcium, producing life-threatening hypocalcemia.[41] Most massive transfusion protocols include the administration of calcium and monitoring of ionized calcium. Calcium chloride is preferred over calcium gluconate because a well-perfused liver is required to liberate more free calcium from calcium gluconate. Maintain ionized calcium levels at or above 0.9 mmol/L.[42]

Thromboelastography and Thromboelastometry The blood coagulation system consists of nearly 80 very tightly coupled biochemical reactions. Conventional coagulation testing such as the prothrombin time and activated partial thromboplastin time do not take into account the cellular components of the clot such as red cells and platelets. Because the blood clot itself consists of a complex three-dimensional network of cross-linked fibers made of fibrin, platelets, and red cells entrapped within this mesh, newer viscoelastic tests such as thromboelastography or thromboelastometry are being developed

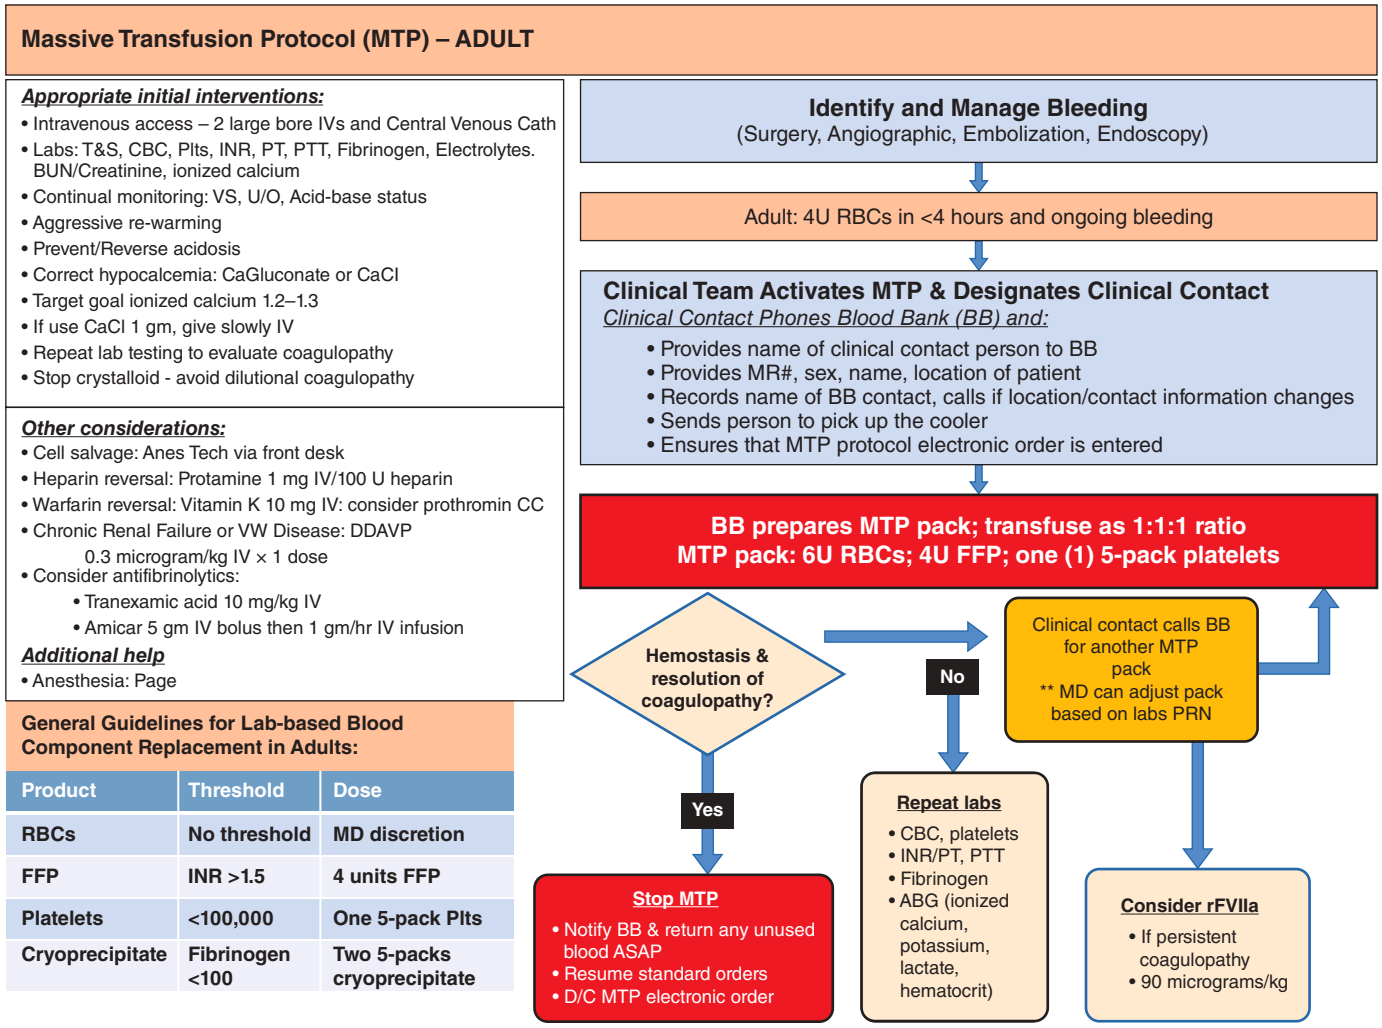

FIGURE 13-4. Massive transfusion protocol (MTP) from the University of Michigan's Level I Trauma Center.

to measure the physical and dynamic characteristics of clotting. Thromboelastography and thromboelastometry can detect trauma-induced coagulopathy and can be used to guide massive transfusion protocols better than traditional prothrombin time and activated partial thromboplastin time assays.[43] However, impact on clinical care is uncertain at this time.[43]

COMPLICATIONS

TRANSFUSION-RELATED ACUTE LUNG INJURY

Acute lung injury is the leading cause of transfusion-related fatalities. It develops within 6 hours of blood transfusion and is felt to be related to an inflammatory reaction.[44] Care is supportive.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

Circulatory overload occurs when the recipient's circulatory system is overwhelmed by the rate of transfusion or the volume of products transfused.[45] Clinically, it is characterized by the acute onset of dyspnea, hypertension, tachypnea and tachycardia, and marked elevation in brain natriuretic peptide levels. Care often involves rapid diuresis.

CHAPTER 14

Anaphylaxis, Allergies, and Angioedema

Brian H. Rowe
Theodore J. Gaeta

INTRODUCTION

Anaphylaxis is a serious allergic reaction, with a rapid onset; it may cause death and requires emergent diagnosis and treatment. Consensus clinical criteria have been developed to provide consistency for diagnosis (**Table 14-1**).[1-3]

The terms *anaphylactic* and *anaphylactoid* were previously applied to immunoglobulin E (IgE)-dependent and IgE-independent events, respectively. Because the final pathway in both events is identical, *anaphylaxis* is the term now used to refer to both.[4] Hypersensitivity is an inappropriate immune response to generally harmless antigens, manifesting a continuum from minor to severe manifestations. Anaphylaxis represents the most dramatic and severe form of immediate hypersensitivity.

Foods, medications, insect stings, and allergen immunotherapy injections are the most common provoking factors for anaphylaxis, but any agent capable of producing a sudden degranulation of mast cells or basophils can induce anaphylaxis (**Table 14-2**).[5,6] Latex hypersensitivity is increasing in prevalence in the general population, with a resultant risk for anaphylaxis. In addition, a significant number of anaphylaxis cases

TABLE 14-1 Clinical Criteria for Anaphylaxis

1. Urticaria, generalized itching or flushing, or edema of lips, tongue, uvula, or skin developing over minutes to hours and associated with at least one of the following:
   Respiratory distress or hypoxia
   or
   Hypotension or cardiovascular collapse
   or
   Associated symptoms of organ dysfunction (e.g., hypotonia, syncope, incontinence)
2. Two or more signs or symptoms that occur minutes to hours after allergen exposure:
   Skin and/or mucosal involvement
   Respiratory compromise
   Hypotension or associated symptoms
   Persistent GI cramps or vomiting
3. Consider anaphylaxis when patients are exposed to a known allergen and develop hypotension

have no identified cause, termed idiopathic anaphylaxis.[7] The lifetime individual risk of anaphylaxis is estimated to be 1% to 3%, but the prevalence of anaphylaxis may be increasing.[8] Although allergic reactions are a common cause for ED visits,[9] anaphylaxis is likely underdiagnosed.[10,11]

PATHOPHYSIOLOGY

Anaphylaxis, for the most part, arises from the activation of mast cells and basophils through a mechanism involving crosslinking of IgE and aggregation of the high-affinity receptors for IgE.[6] Upon activation, mast cells and/or basophils quickly release preformed mediators from secretory granules that include histamine, tryptase, carboxypeptidase A, and proteoglycans. Downstream activation of phospholipase A_2, followed by cyclooxygenases and lipoxygenases, produces arachidonic acid metabolites, including prostaglandins, leukotrienes, and platelet-activating factor. The inflammatory cytokine, tumor necrosis factor-α, is released as a preformed mediator and also as a late-phase mediator with other cytokines and chemokines. These mediators are responsible for the pathophysiology of anaphylaxis. Histamine stimulates vasodilation and increases vascular permeability, heart rate, cardiac contraction, and glandular secretion. Prostaglandin D_2 is a bronchoconstrictor, pulmonary and coronary vasoconstrictor, and peripheral vasodilator. Leukotrienes produce bronchoconstriction, increase vascular permeability, and promote airway remodeling. Platelet-activating factor is also a potent bronchoconstrictor and increases vascular permeability. Tumor necrosis factor-α activates neutrophils, recruits other effector cells, and enhances chemokine synthesis. These overlapping and synergistic physiologic effects contribute to the overall pathophysiology of anaphylaxis.[6]

TABLE 14-2 Common Causes for Anaphylaxis, Anaphylactoid, and Allergic Reactions

Drugs	Foods and Additives
β-Lactam antibiotics	Shellfish
Acetylsalicylic acid (ASA)	Soybeans
Trimethoprim-sulfamethoxazole	Nuts (peanuts and tree nuts)
Vancomycin	Wheat
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Milk
Virtually any drug	Eggs
Others	Salicylates
Hymenoptera stings	Seeds
Insect parts	Sulfites
Molds	
Radiographic contrast material	
Vaccines	
Latex	
Blood products	

CLINICAL FEATURES

The classic presentation of anaphylaxis begins with pruritus, cutaneous flushing, and urticaria. These symptoms are followed by a sense of fullness in the throat, anxiety, a sensation of chest tightness, shortness of breath, and lightheadedness. A complaint of a "lump in the throat" and hoarseness heralds life-threatening laryngeal edema in a patient with symptoms of anaphylaxis. These major symptoms may be accompanied by abdominal pain or cramping, nausea, vomiting, diarrhea, bronchospasm, rhinorrhea, conjunctivitis, and/or hypotension. As the cascade progresses, respiratory distress, decreased level of consciousness, and circulatory collapse may ensue. In severe cases, loss of consciousness and cardiorespiratory arrest may result.

Signs and symptoms begin suddenly, often within 60 minutes of exposure, in most patients. In general, the faster the onset of symptoms, the more severe is the reaction—**one half of anaphylactic fatalities occur within the first hour**. After the initial signs and symptoms abate, patients are at a small risk for a recurrence of symptoms caused by a second phase of mediator release, peaking 8 to 11 hours after the initial exposure and manifesting symptoms and signs 3 to 4 hours after the initial clinical manifestations have cleared. The late-phase allergic reaction is primarily mediated by the release of newly generated cysteinyl leukotrienes, the former slow-reacting substance of anaphylaxis. The incidence of this biphasic phenomenon has been reported to vary widely up to 20%, but prospective studies specifically searching for clinically important biphasic events report an incidence of 4% to 5%.[12,13]

DIAGNOSIS

The diagnosis of anaphylaxis is clinical. Consider anaphylaxis when involvement of any two or more body systems is observed, with or without hypotension or airway compromise (**Table 14-3**).[1,14] The diagnosis is easily made if there is a clear history of exposure, such as a bee sting, shortly followed by the multisystem signs and symptoms described above. Unfortunately, diagnosis is not always easy or clear, because symptom onset may be delayed, symptoms may mimic other presentations (e.g., syncope, gastroenteritis, anxiety), or anaphylaxis may be a component of other diseases (e.g., asthma).

The differential diagnosis of anaphylactic reactions is extensive, including vasovagal reactions, myocardial ischemia, arrhythmias, severe acute asthma, seizure, epiglottitis, hereditary angioedema, foreign body airway obstruction, carcinoid, mastocytosis, vocal cord dysfunction, and non–IgE-mediated drug reactions. The most common anaphylaxis imitator is a vasovagal reaction, which is characterized by hypotension, pallor, bradycardia, diaphoresis, and weakness, and sometimes by loss of consciousness.

Laboratory investigations are of minimal utility.[15] Serum histamine levels, elevated for 5 to 30 minutes after reaction, are unhelpful because they are typically normal upon ED presentation. Tryptase is a neutral protease of unknown function in anaphylaxis that is found only in mast

TABLE 14-3 Clinical Manifestations of Anaphylaxis

System	Signs and Symptoms (approximate incidence)
Respiratory	Shortness of breath and/or wheezing (45%–50%)
	Pharyngeal or laryngeal edema (50%–60%)
	Rhinitis (30%–35%)
Cardiovascular	Hypotension (30%–35%)
	Chest pain (4%–5%)
Skin	Urticaria and/or angioedema (60%–90%)
	Flushing (45%–55%)
	Pruritus only (2%–5%)
GI	Nausea, emesis, cramps, or diarrhea (25%–30%)
Neurologic	Headache (5%–8%)
	Seizure (1%–2%)

cell granules and is released with degranulation. Serum tryptase levels are elevated for several hours and have been proposed for later confirmation of a suspected anaphylactic episode, but this test has poor sensitivity; about one third of patients with an acute anaphylaxis episode have a normal serum tryptase level upon ED arrival,[16] and some patients experience severe anaphylaxis without elevated tryptase levels.[17]

TREATMENT

Triage all acute allergic reactions at the highest level of urgency because of the possibility of sudden deterioration.[10] Current treatment recommendations are derived from the clinical experience of experts as professed in consensus statements and guidelines.[15,18-20]

FIRST-LINE THERAPY

Emergency management starts with airway, breathing, and circulation. Assess vital signs and pulse oximetry. Initiate IV access, oxygen administration, and cardiac rhythm monitoring in patients with severe symptoms. The first-line therapies for anaphylaxis (airway protection, oxygen, decontamination, epinephrine, IV crystalloids) have immediate effect during the acute stage.[19-22]

Airway and Oxygenation **In severe anaphylaxis, securing the airway is the first priority.** Examine the mouth, pharynx, and neck for signs and symptoms of angioedema: uvula edema or hydrops, audible stridor, respiratory distress, or hypoxia. If angioedema is producing respiratory distress, intubate early, because delay may result in complete airway obstruction secondary to progression of angioedema. Provide sufficient oxygen to maintain arterial oxygen saturation >90%.

Decontamination If the causative agent can be identified, termination of exposure should be attempted. Gastric lavage is **not recommended** for foodborne allergens and may be associated with complications (i.e., aspiration) and delays in the administration of more effective treatments (e.g., epinephrine). In insect stings, remove any remaining stinging remnants because the stinger continues to inject venom even if it is detached from the insect (see chapter 211, "Bites and Stings").

Epinephrine Epinephrine is a mixed α_1- and β-receptor agent. The α_1-receptor activation reduces mucosal edema and treats hypotension, β1-receptor stimulation increases heart rate and myocardial contractility, and β_2-receptor stimulation provides bronchodilation and limits further mediator release.[15] **Epinephrine is the treatment of choice for anaphylaxis.[15,18,23,24] However, observational studies indicate that it is underused, often dosed suboptimally, and underprescribed upon discharge for potential future self-administration.[9,11]** Most of the reasons proposed to withhold epinephrine are flawed, and the therapeutic benefits of epinephrine exceed the risk when given in appropriate routes and doses.[23]

In patients without signs of cardiovascular compromise or collapse, administer epinephrine IM (**Table 14-4**).[25] Repeat every 5 to 10 minutes

TABLE 14-4 Drug Treatment of Anaphylaxis and Allergic Reactions

Drug	Adult Dose	Pediatric Dose
First-Line Therapy		
Epinephrine	IM: 0.3–0.5 milligram (0.3–0.5 mL of 1:1000 dilution); *or* EpiPen® 0.3 milligram epinephrine (or equivalent preformulated product)	IM: 0.01 milligram/kg (0.01 mL/kg of 1:1000 dilution) *or* EpiPen Junior® 0.15 milligram of epinephrine (or equivalent preformulated product)
	IV bolus: 100 micrograms over 5–10 min; mix 0.1 milligram (0.1 mL of 1:1000 dilution) in 10 mL NS and infuse over 5–10 min	
	IV infusion: start at 1 microgram/min; mix 1 milligram (1 mL of 1:1000 dilution) in 500 mL NS and infuse at 0.5 mL/min; titrate dose as needed	IV infusion: 0.1–0.3 microgram/kg per min; titrate dose as needed; maximum, 1.5 micrograms/kg per min
Oxygen	Titrate to Sa_{O_2} ≥90%	Titrate to Sa_{O_2} ≥90%
IV fluids: NS or LR	1–2 L bolus	10–20 mL/kg bolus
Second-Line Therapy		
H_1 Blockers		
Diphenhydramine	25–50 milligrams every 6 h IV, IM, or PO	1 milligram/kg every 6 h IV, IM, or PO
H_2 Blockers		
Ranitidine	50 milligrams IV over 5 min	0.5 milligram/kg IV over 5 min
Cimetidine	300 milligrams IV	4–8 milligrams/kg IV
Corticosteroids		
Hydrocortisone	250–500 milligrams IV	5–10 milligrams/kg IV (maximum, 500 milligrams)
Methylprednisolone	80–125 milligrams IV	1–2 milligrams/kg IV (maximum, 125 milligrams)
Prednisone	40–60 milligrams/d PO divided twice a day or daily	1–2 milligrams/d PO divided twice a day or daily
	To be used after initial IV dose (for outpatients: 3–5 d; tapering not required)	To be used after initial IV dose (for outpatients: 3–5 d; tapering not required)
Treatment of Bronchospasm, Add:		
Albuterol	Single treatment: 2.5–5.0 milligrams nebulized (0.5–1.0 mL of 0.5% solution)	Single treatment: 1.25–2.5 milligrams nebulized (0.25–0.5 mL of 0.5% solution)
	4–6 puffs from MDI with holding chamber	4–6 puffs from MDI with holding chamber
	Both repeated every 20 min as needed	Both repeated every 20 min as needed
	Continuous nebulization: 5–10 milligrams/h	Continuous nebulization: 3–5 milligrams/h
Ipratropium bromide	Single treatment: 250–500 micrograms nebulized	Single treatment: 125–250 micrograms nebulized
	4–6 puffs from MDI with holding chamber	4–6 puffs from MDI with holding chamber
	Both repeated every 20 min as needed	Both repeated every 20 min as needed
Magnesium sulfate	2 grams IV over 20 min	25–50 milligrams/kg IV over 20 min
Treatment for Patients on β-Blockers with Refractory Hypotension, Add:		
Glucagon	1 milligram IV every 5 min until hypotension resolves, followed by 5–15 micrograms/min infusion	50 micrograms/kg IV every 5 min

Abbreviations: H_1 = histamine-1; H_2 = histamine-2; LR = lactated Ringer's; MDI = metered dose inhaler; NS = normal saline; Sa_{O_2} = arterial oxygen saturation.

according to response or if relapse occurs. Injections into the thigh are more effective at achieving peak blood levels than injections into the deltoid area.[25] IM dosing is recommended because it provides higher, more consistent, and more rapid peak blood epinephrine levels than SC administration.[25,26] For convenience and accurate dosing, many EDs have adopted the use of EpiPen® (0.3 milligram epinephrine for adults; Dey, L.P., Napa, CA) and EpiPen Junior® (0.15 milligram epinephrine for children <30 kg; Dey, L.P.).

Most patients with anaphylaxis need only a single epinephrine dose. Check blood pressure in patients taking β-blockers, because epinephrine use may result in severe hypertension secondary to unopposed α-adrenergic stimulation. Age is not a barrier to epinephrine IM injections in patients with anaphylaxis.

If the patient is refractory to treatment despite repeated doses of epinephrine IM or has signs of cardiovascular compromise or collapse, then institute an epinephrine IV bolus and/or infusion. The initial epinephrine IV bolus is a dilute solution of 100 micrograms (0.1 milligram) IV, given over 5 to 10 minutes.

If the patient is refractory to the initial bolus, institute an epinephrine IV infusion, starting at 1 microgram/min and titrating to effect. There is a higher risk of cardiovascular complications when IV epinephrine is used to treat anaphylaxis.[27] It should be stressed that the initial IV bolus dose is very dilute, is given over 5 to 10 minutes, and should be stopped immediately if arrhythmias or chest pain occur.

IV Crystalloids Hypotension is generally the result of distributive shock and responds to fluid resuscitation.[15] Administer an isotonic crystalloid solution bolus of 1 to 2 L (10 to 20 mL/kg in children) concurrently with epinephrine. There is no evidence that albumin or hypertonic saline should replace crystalloids.[28]

SECOND-LINE THERAPY

The second-line anaphylaxis treatments include corticosteroids, antihistamines, inhaled bronchodilators, vasopressors, and glucagon.[15,18-20] These drugs are used to treat anaphylaxis refractory to the first-line treatments or associated with complications, and also to prevent recurrences.[22]

Corticosteroids Patients with anaphylaxis often receive corticosteroids to prevent protracted and biphasic reactions, although evidence for clinical benefit is scant and primarily derived from acute asthma studies.[18-20,22,29-31] Methylprednisolone, 80 to 125 milligrams IV (2 milligrams/kg in children; up to 125 milligrams), and hydrocortisone, 250 to 500 milligrams IV (5 to 10 milligrams/kg in children; up to 500 milligrams), are equally appropriate. Mineralocorticoid effects of steroids are ranked in declining order. Hydrocortisone and cortisone have the strongest effects, followed by prednisone. Methylprednisolone and dexamethasone have the lowest mineralocorticoid effect and produce less fluid retention than hydrocortisone and cortisone and thus are preferred for the elderly and for those in whom fluid retention would be problematic.

Antihistamines Most patients with anaphylaxis should receive an H_1-antihistamine, such as diphenhydramine, 25 to 50 milligrams IV by slow infusion or via IM injection,[15,18-20,22] although clinical benefit is unproven.[32] In severe cases, especially with circulatory shock, H_2-antihistamines, such as ranitidine or cimetidine, are recommended,[18-20,22] although evidence for benefit is lacking.[33] Cimetidine should not be used for patients who are elderly (side effects), have multiple comorbidities (interference with metabolism of many drugs), have renal or hepatic impairment, or whose anaphylaxis is complicated by β-blocker use (cimetidine prolongs metabolism of β-blockers and may prolong anaphylactic state). After the initial IV dose of steroids and antihistamines, the patient may be switched to oral medication (**Table 14-4**).

Vasopressors In patients with anaphylaxis and shock resistant to initial treatment, including repeated doses of IM epinephrine, oxygen, and intravenous crystalloids, initiate IV epinephrine infusion. If dangerous dysrhythmias or tachycardia result from epinephrine, other agents (e.g., dopamine, dobutamine, epinephrine, norepinephrine, phenylephrine, or vasopressin) may be effective, and superiority from a specific agent has not been demonstrated.[15,18-20] Clinicians should use the agent they feel most comfortable with and titrate according to the clinical response.

AGENTS FOR ALLERGIC BRONCHOSPASM

A β_2 bronchodilator, such as intermittent or continuous nebulized albuterol/salbutamol, should be instituted if wheezing is present. Asthmatics are often more refractory to the treatment of allergic bronchospasm. For severe bronchospasm refractory to inhaled albuterol/salbutamol, inhaled anticholinergics and IV magnesium sulfate can be added (**Table 14-4**).[29,34] Bronchodilators should be used with caution (lower dose and slower rate) in elderly patients. IV aminophylline is not recommended. Leukotriene receptor antagonists are not effective for the treatment of anaphylaxis.

GLUCAGON

Concurrent use of β-blockers is a risk factor for severe prolonged anaphylaxis. For patients taking β-blockers with hypotension refractory to fluids and epinephrine, IV glucagon should be used every 5 minutes until hypotension resolves, followed by an infusion (**Table 14-4**).[15,18-20] The side effects of glucagon include nausea, vomiting, hypokalemia, dizziness, and hyperglycemia.

DISPOSITION AND FOLLOW-UP

With appropriate initial treatment, admission to hospital is rare, only required in about 1% to 4% of acute allergic reactions treated in the ED.[9,13] All unstable patients with anaphylaxis refractory to treatment or in whom airway interventions were required should be admitted to the intensive care unit. Patients who receive epinephrine should be observed in the ED, but the duration of observation necessary is not well established.[12,13] Otherwise healthy patients who remain symptom-free after appropriate treatment following 4 hours of observation can be safely discharged home.

Consider prolonged observation in patients with a past history of severe reaction and those using β-blockers. Although the risk of important biphasic reactions after ED discharge is low,[13] patients who live alone, reside long distances from medical care, have significant comorbidity (including but not limited to asthma), or are elderly should be observed longer before discharge.

Patients with severe allergic reactions or anaphylaxis are usually discharged with prescriptions for antihistamines and corticosteroids for 3 to 5 days. Although prolonged corticosteroid treatment should not be required for most patients, an aggressive longer-term approach (1 to 2 weeks or until symptoms are controlled) appears to reduce the frequency of relapses in patients with idiopathic anaphylaxis.[7]

Discharge instructions should provide recommendations to prevent future episodes (**Table 14-5**).[35] For all allergic reactions, instruct the patient on how to avoid future exposure to the causative agent (if the agent is known). Prescribe an epinephrine autoinjector to patients with serious allergic reactions or anaphylaxis with clear instructions on the use of the autoinjector. If delay in filling a prescription is anticipated, patients can be discharged from the ED with an epinephrine autoinjector (EpiPen®). Reinforce this prescription with documentation in the ED discharge instructions. Because allergic occurrences are unpredictable, prescriptions should include sufficient samples for multiple locations (e.g., home, vehicle, work), and patients should be advised to carry epinephrine with them at all times.

Refer patients with severe or frequent allergic reactions to an allergist for in-depth preventive management and attempts at allergen identification.[36] Offer patients information about this syndrome (e.g., from Web sites), advice on advocacy groups, and education regarding food contamination for food allergies, and encourage wearing of personal identification alerts about this condition (e.g., MedicAlert® bracelets). Because of the potential for severe and prolonged future reactions, patients with anaphylaxis on a β-blocker should be switched to an agent from a different therapeutic class.

ALLERGIES AND ANGIOEDEMA

URTICARIA

Urticaria, or hives, is a cutaneous reaction marked by acute onset of pruritic, erythemic wheals of varying size that generally are described as

TABLE 14-5 Discharge Planning for Patients with Anaphylaxis

Education
Identification of inciting allergen, if possible
Instructions on use of medications and epinephrine autoinjector
Advice about personal identification/allergy alert tag
Prescriptions for current reaction
Antihistamines: Diphenhydramine, 25–50 milligrams PO every 6–8 h for 3–5 d
Corticosteroids: Prednisone, 40–60 milligrams PO daily for 3–5 d
Prevention
Instructions on avoiding future exposure
Prescription for future reactions
Epinephrine autoinjector (at least 2)
Referral to allergist

"fleeting." Erythema multiforme is a more pronounced variation of urticaria, characterized by typical "target" skin lesions. Although these manifestations may accompany many allergic reactions, they also may be nonallergic; many acute urticarial reactions are due to viruses, especially in children, or present as hives persisting or recurring for more than 24 hours. Obtain a detailed history; if an etiologic agent can be identified, future reactions may be avoided, although many acute urticarial reactions are viral in nature.

Treatment of urticarial reactions is generally supportive and symptomatic, with attempts to identify and remove the offending agent. H_1-antihistamines, with or without corticosteroids, are usually sufficient, although epinephrine can be considered in severe or refractory cases. The addition of an H_2-antihistamine, such as ranitidine, may also be useful in more severe, chronic, or unresponsive cases. Cold compresses may be soothing to affected areas. Referral to an allergy specialist is indicated in severe, recurrent, or refractory cases.

ANGIOEDEMA

Angioedema is a similar reaction as urticaria, but with deeper involvement characterized by edema formation in the dermis, generally involving the face and neck, and distal extremities. Angioedema of the tongue, lips, and face has the potential for airway obstruction.[37] Angioedema is caused by a variety of agents, but an angiotensin-converting enzyme inhibitor (ACEI) is a common trigger, with angioedema occurring in 0.1 to 0.7% of patients taking ACEIs.[38,39] The pathophysiology of **ACEI-induced angioedema** is complex, involving both bradykinin and substance P.[38,39]

Management of ACEI-induced angioedema is supportive, with special attention to the airway, which can become occluded rapidly and unpredictably. Allergic reaction drugs, such as epinephrine, antihistamines and corticosteroids, are not beneficial because ACEI-induced angioedema is not mediated by IgE.[38,39] Icartibant, a bradykinin-2 antagonist, is effective agent to reduce swelling and shorten time to complete resolution (**Table 14-6**).[40] C1 esterase inhibitor [human] at a dose of 1000 units IV also appears effective based on a case-series compared to historical controls.[41] Ecallantide, a kallikrein inhibitor, is not effective in ACEI-induced angioedema.[42]

Immediate withdrawal from the ACE inhibitor is indicated, and another antihypertensive should be prescribed, with the important exception that angiotensin II receptor–blocking agents should not be used. Most cases resolve in a few hours to days, so patients with mild swelling and no evidence of airway obstruction should be observed for 12 to 24 hours, and discharged if swelling diminishes. Rebound or recurrent swelling will not occur unless the patient takes an ACE inhibitor again.

Hereditary angioedema is a rare autosomal dominant disorder due to deficiency in C1 esterase inhibitor; either low levels (Type I) or a dysfunctional enzyme (Type II).[43,44] About 25% of cases are due to new mutations.[45] The disorder is characterized by acute edematous reactions involving the upper respiratory, soft tissue of extremities or trunk, or GI tract. Attacks can last from a few hours to 1 to 2 days. Minor trauma often precipitates an acute episode. Typical treatments for allergic reactions, such as epinephrine, corticosteroids, and antihistamines, are ineffective. The best screening test is the C4 level. A C4 level < 30% of normal suggests hereditary angioedema.

Acute attacks can be shortened by a C1 esterase inhibitor (either human plasma derived or recombinant), by the bradykinin-2 receptor antagonist icatibant, or the kallikrein inhibitor ecallantide (**Table 14-6**).[46,47] Fresh frozen plasma may be used if C1 esterase inhibitor is not available, although the dosing is not standardized, with 2 to 3 units described in most case reports.[48] Prophylaxis of acute attacks is possible with attenuated androgens, such as stanozolol 2 milligrams/d or danazol 200 milligrams/d. Treatment of patients is complex and best done in coordination with the appropriate specialist.

FOOD ALLERGY REACTIONS

Hypersensitivity reactions to ingested foods are generally caused by IgE-coated mast cells lining the GI tract reacting to ingested food proteins

TABLE 14-6 Pharmacologic Treatment of Angioedema in Adults

Agent*	Recommended Adult Dose	Comments
C1 esterase inhibitor [human] (Berinert®)	20 U/kg IV for HAE 1000 U IV for ACEI-induced angioedema	Effective in HAE and ACEI-induced angioedema† Adverse side effects include headache, abdominal pain, nausea, diarrhea, and vomiting
C1 esterase inhibitor [recombinant] (Ruconest®)	50 U/kg IV (max dose 4200 U)	Effective in HAE, but not FDA approved for HAE patients with laryngeal attacks No data for ACEI-induced angioedema Adverse side effects include headache and vertigo
Icatibant (Firazyr®)	30 milligrams SC	Effective in HAE and ACEI-induced angioedema† Bradykin-2 receptor antagonist Single dose highly effective: about 10% require second dose 90% experience mild local reactions: pain ,swelling, erythema
Ecallantide (Kalbitor®)	30 milligrams SC (in three separate 10 milligrams or 1 mL injections)	Effective in HAE, but not ACEI-induced angioedema Kallikrein inhibitor Risk of anaphylaxis in up to 4% May repeat 30 milligram dose within 24 hours if reaction persists Adverse side effects include headache, nausea, fatigue, diarrhea, nasopharyngitis, injection site reactions, and vomiting

Abbreviations: ACEI = angiotensin converting enzyme inhibitor; HAE = hereditary angioedema

*Proprietary names provided to aid in recognition

†Not FDA approved for ACEI-induced angioedema

and, rarely, to additives. Their frequency is rising for unknown reasons and varies based on age (more common in children), country of origin, and definitions and confirmatory tests used.[44] Dairy products, eggs, nuts, and shellfish are the most commonly implicated foods.[49,50]

A detailed dietary history within the 24 hours of allergic symptoms may provide the best clues to food allergy, with particular attention to other allergic history and prior reactions. Diagnosis is often difficult, however, and it may require multiple episodes before an offending agent is identified.[50] Symptoms of food allergy include swelling and itching of the lips, mouth, and pharynx; nausea; abdominal cramps; vomiting; and diarrhea. Cutaneous manifestations, such as angioedema and urticaria, as well as anaphylaxis, can occur. Treatment for mild reactions is supportive, with the administration of antihistamines to lessen symptoms. More severe reactions or anaphylaxis are managed as described above.

ALLERGIC DRUG REACTIONS

Adverse reactions to drugs are a common clinical problem, but true hypersensitivity reactions probably account for less than 10% of these occurrences, with the majority of anaphylaxis from IgE-mediated drug reactions.[51] Most drugs are small organic molecules, generally unable to stimulate an immune response alone. However, when a drug or metabolite becomes protein-bound, either in serum or on cell surfaces, the drug–protein complex can become an allergen and stimulate immune system responses. Thus, the ability of a drug or its metabolites to sensitize the immune system depends on the ability to bind to tissue proteins. Many different drugs and treatments can cause allergic reactions and anaphylaxis.

Penicillin is the drug most commonly implicated in eliciting true allergic reactions and accounts for approximately 90% of all reported allergic drug reactions and about 75% of fatal anaphylactic drug reactions.[52] **Fatal reactions can occur without a prior allergic history; less than 25% of patients who die of penicillin-induced anaphylaxis exhibited allergic reactions during previous treatment with the drug.** Parenteral penicillin administration is more than twice as likely to produce fatal allergic reactions as is oral administration. The cross-reactivity of penicillin allergy with cephalosporins is about 10%, so patients with a previous life-threatening or anaphylactic reaction to penicillin should not be given cephalosporins.

The clinical manifestations of drug allergy vary widely. A generalized reaction similar to immune-complex or serum sickness reactions is very common, especially with trimethoprim-sulfamethoxazole and certain cephalosporins (cefaclor being the most frequent). Sulfa moieties are contained in many drugs, but sulfa allergic reactions upon exposure to the nonantibiotic sulfas are uncommon. See chapter 206, "Antimicrobials" for more discussion of drug allergies.

Serum sickness usually begins in the first or second week after initiation of the drug and can take many weeks to subside after drug withdrawal. Generalized malaise, arthralgias, arthritis, pruritus, urticarial eruptions, fever, adenopathy, and hepatosplenomegaly are common signs and symptoms. Drug fever may occur without other associated clinical findings and may also occur without an immunologic basis. Circulating immune complexes are probably responsible for the lupus-like reactions caused by some drugs.

Other reactions are possible. Cytotoxic reactions include penicillin-induced hemolytic anemia. Skin eruptions include erythema, pruritus, urticaria, angioedema, erythema multiforme, and photosensitivity. Severe reactions, such as those seen in Stevens-Johnson syndrome and toxic epidermal necrolysis, may also occur. Delayed hypersensitivity reactions may manifest as contact dermatitis from drugs applied topically.

Diagnosis is determined by a careful history. Treatment is supportive, with oral or parenteral antihistamines and corticosteroids. Drug cessation is important, but reactions can continue. Referral to an allergy specialist is indicated for severe reactions.

CHAPTER 15

Acid-Base Disorders

Gabor D. Kelen
David D. Nicolaou
David M. Cline

INTRODUCTION

Controversy has existed concerning acid-base physiology and the ideal method to assess acid-base disorders for 130 years.[1] The two most common methods advocated to analyze acid-base disorders are the traditional bicarbonate-centered method[2,3] and the Stewart, or strong ion, method.[4,5] The traditional approach teaches that acid-base homeostasis is maintained by respiratory control of the partial pressure of carbon dioxide (Pco_2) through changes in alveolar ventilation and control of HCO_3^- reabsorption and H^+ excretion by the kidneys. Peter Stewart proposed that acid-base physiology involves the dynamic interaction of body fluids and multiple chemical species including strong ions (primarily Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cl^-) and weak acids, as well as Pco_2 control by the lungs.

Each of these methods has limitations. The traditional bicarbonate-centered model continues to be the most commonly used at the bedside[3] but is criticized for failing to identify acid-base abnormalities that are due to alterations in plasma free water or in complex cases of mixed acid-base disorders.[6,7] The Stewart method is praised for its accuracy in identifying acid-base disorders but is criticized for the difficulty of application at the bedside.[7-11] This chapter does not detail the Stewart method, but we acknowledge its importance and its contribution to underscoring the limitations of the traditional method, which has led to modifications that improve the performance of the traditional method at the bedside.[8] For example, using a correction factor for the albumin level (detailed in this chapter), the traditional method performs as well as the Stewart method for identifying complex acid-base abnormalities in critically ill patients.[8-12]

Many diseases, including those that present an imminent threat to life, produce acid and base (acid-base) disturbances that provide important clues concerning the nature of the underlying illness and suggest immediate therapeutic interventions. Further, ED treatments such as rapid resuscitation of critically ill patients may create unintended acid-base disorders. This chapter describes a practical approach to the clinical evaluation and treatment of acid-base disorders.

PATHOPHYSIOLOGY

MEASUREMENT OF PLASMA ACIDITY

Plasma hydrogen ion concentration ($[H^+]$)* is normally 40 nmol/L, corresponding to a pH of 7.4. Because pH is a logarithmic transformation of $[H^+]$, the relation of $[H^+]$ to pH is not linear for all pH values (**Table 15-1**).

TABLE 15-1 pH and Hydrogen Ion Concentrations

pH	$[H^+]$, nmol/L
6.8	158
6.9	126
7.0	100
7.1	79
7.2	63
7.3	50
7.4	40
7.5	32
7.6	25
7.7	20

*Standard nomenclature is used in this chapter. The presence of brackets, [ ], surrounding an element or molecule implies the term concentration. Without the brackets, the chemical expressions simply refer to the element or molecule.

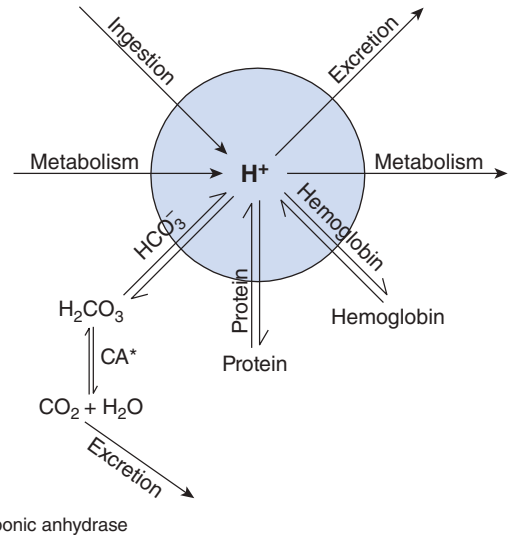

FIGURE 15- 1. Schematic representation of hydrogen ion homeostasis.

However, for pH values from 7.20 to 7.50, the relation between $[H^+]$ and pH is nearly linear; pH changes of 0.01 correspond to approximately 1 nmol/L change in $[H^+]$. This linear relation allows for rapid bedside interpretation of blood gas and electrolyte results.

PLASMA ACID-BASE HOMEOSTASIS

Plasma $[H^+]$ is influenced by the rate of endogenous production, the rate of excretion, exogenous addition (e.g., acetylsalicylic acid ingestion), and the buffering capacity of the body. Buffers mitigate the impact of large changes in available hydrogen ion on plasma pH.

Buffer systems that are effective at physiologic pH include hemoglobin, phosphate, proteins, and bicarbonate (**Figure 15-1**). One can consider the $[H^+]$ to be the result of all physiologic buffers acting on the common pool of hydrogen ions.

The familiar Henderson-Hasselbalch equation, shown in Eq. (1),

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]} \qquad (1)$$

specifies the relationship between carbonic acid, bicarbonate, and pH; any two of these determine the value of the third. The clinical use of the Henderson-Hasselbalch equation is limited. However, if all constants are inserted into the Henderson-Hasselbalch equation and the antilogarithm of all its terms is taken, the result is the Kassirer-Bleich equation [Eq. (2)], which is of great clinical utility.

$$[H^+] = 24 \times \frac{P_{CO_2}}{[HCO_3^-]} \qquad (2)$$

The Kassirer-Bleich equation may be used to estimate the concentration of any component of the bicarbonate buffer system provided the concentrations of the other two components are known. Therefore, it allows clinicians to determine, for example, what the pH must be when the P_{CO_2} and $[HCO_3^-]$ are known.[†] Note that when $[HCO_3^-]$ is normal, the Kassirer-Bleich equation demonstrates that $[H^+] = P_{CO_2}$, using their respective units of measure.

[†]The "bicarbonate concentration" measured by the clinical laboratory is actually the total CO_2, which is the sum of bicarbonate, dissolved CO_2, and H_2CO_3. H_2CO_3 is the P_{CO_2} multiplied by the solubility coefficient of CO_2 in blood (α), 0.03. Thus, total $CO_2 = [HCO3^-] + (0.03)(P_{CO_2})$. Most clinicians simply neglect the second term when the P_{CO_2} is normal; when hypercapnia is present, however, the second term measurably contributes to total CO_2.

ACID PRODUCTION AND EXCRETION

The quantity of $[HCO_3^-]$ in relation to carbonic acid buffer in the system is not fixed, but varies according to physiologic need. This flexibility is largely provided by pulmonary exhalation of carbon dioxide (CO_2), which can vary significantly and change rapidly as required by alterations in the underlying acid-base status.

Renal Influence on Acid-Base Balance The kidney regulates HCO_3^- excretion and the formation of new HCO_3^-. The rate of these processes is dependent on the underlying acid-base status. The renal response to pulmonary acid-base disturbances begins within 30 minutes of onset, but requires hours to days to achieve equilibrium.[13] Bicarbonate is filtered into the urine and must be reclaimed to maintain homeostasis. Eighty-five percent of bicarbonate that is filtered is reclaimed by the proximal convoluted tubule in a sodium-dependent process. H^+ is secreted into the tubular lumen, and Na^+ is absorbed from the tubular lumen into the cell. Sodium is then extruded from the tubular cell into the plasma in exchange for K^+ via the Na^+/K^+-ATPase pump. Thus, the H^+ secreted into the tubule combines with the filtered HCO_3^- in the lumen to produce carbonic acid (H_2CO_3), which in turn is converted to CO_2 and H_2O by carbonic anhydrase. The CO_2 diffuses down its concentration gradient into the tubule cell, where cytoplasmic carbonic anhydrase regenerates H_2CO_3, which then dissociates into HCO_3^- and H^+ (creating a supply of H^+ for extrusion). If tubular disease inhibits H^+ extrusion, a proximal renal tubular acidosis results, in which serum $[HCO_3^-]$ decreases to a steady-state level, i.e., reclaimed HCO_3^- effectively equals H^+ extrusion.

The balance (15%) of HCO_3^- reclamation occurs in the distal tubule via a sodium-independent process. Cytoplasmic carbonic anhydrase generates $H_2CO_3^-$, which dissociates. HCO_3^- diffuses into plasma, and H^+ is secreted into the lumen by an H^+-ATPase pump, thereby maintaining cellular electrical neutrality. H^+ is trapped in the lumen by inorganic phosphate or ammonia (NH_4^+). Failure of H^+ secretion is the underlying mechanism of distal renal tubular acidosis.

New HCO_3^- can also be created by the kidney. A sodium-dependent process allows synthesis of HCO_3^- in the distal tubule. Intracellular glutamine generates HCO_3^- and ammonia NH_4^+. The Na^+/K^+ pump moves Na^+ into the lumen, but Na^+ diffuses back across the cell membrane, and NH_4^+ is secreted into the lumen in exchange. The generated HCO_3^- remains in the cell. Formation of HCO_3^- by this process increases during acidosis, but may require 4 to 5 days to reach equilibrium. Drugs that alter uptake or delivery of Na^+ to the distal tubule can significantly alter HCO_3^- synthesis. The process of acid secretion allows the regeneration of HCO_3^- in proportion to the daily production of acid. Urine, especially under conditions of acidosis, can be made almost entirely without HCO_3^-.

FUNDAMENTAL ACID-BASE DISORDERS

Any condition that acts to increase $[H^+]$—whether through endogenous production, decreased buffering capacity, decreased excretion, or exogenous addition—is known as *acidosis*. Similarly, any condition that acts to decrease $[H^+]$ is termed *alkalosis*. The terms *acidemia* and *alkalemia* refer to the net imbalance of $[H^+]$ in the blood. The difference between acidosis and acidemia is not merely semantic, but of great clinical importance. For example, a patient with acidosis and alkalosis of equal magnitude will have a normal pH. A patient with these disturbances thus has neither acidemia nor alkalemia (resulting in the normal pH), but nevertheless has both acidosis and alkalosis. It is important to appreciate that, although acidemia is diagnostic of acidosis and alkalemia of alkalosis, a normal or high pH does not exclude acidosis and a normal or low pH does not exclude alkalosis.

Acid-base disturbances are further classified as respiratory or metabolic. Respiratory acid-base disorders are due to primary changes in P_{CO_2}, and metabolic acid-base disorders reflect primary changes in $[HCO_3^-]$. Compensatory mechanisms are, by definition, not "disorders," but rather normal physiologic responses to acid-base derangements. Terms such as *compensatory respiratory alkalosis* are therefore misleading. The clinician is nonetheless concerned with the adequacy of compensation, because failure of appropriate compensatory response implies the presence of another primary acid-base disturbance.

It is important to note that compensatory mechanisms return the pH toward normal but do not reach baseline.[‡] The fact that compensatory mechanisms cannot reach completion is evident when one considers that complete compensation would necessarily remove the physiologic stimulus driving the compensation.[2]

The "normal" values of pH, P_{CO_2}, and $[HCO_3^-]$ for given laboratory ranges are intended to include 95% of patients without an acid-base disorder. The normal pH range is 7.35 to 7.45, the normal P_{CO_2} range is 35 to 45 mm Hg, and the normal $[HCO_3^-]$ is usually 21 to 28 mEq/L. However, a patient's values may all fall within the "normal range" and still have significant acid-base disturbances. As detailed further below, a patient with metabolic acidosis and a concomitant metabolic alkalosis of nearly approximate magnitude will have a "normal" pH, P_{CO_2}, and $[HCO_3^-]$. In contrast, abnormal values may be appropriate for a given simple acid-base disturbance. For example, in the presence of a metabolic acidosis where $[HCO_3^-] = 15$ and pH = 7.3, an appropriate respiratory compensation should result in a P_{CO_2} of about 30 mm Hg. This P_{CO_2} value is below the "normal" range, but at the expected level of physiologic respiratory compensation for the degree of metabolic acidosis. In this example, the finding of P_{CO_2} in the normal (35 to 45 mm Hg) range actually implies the presence of a respiratory acidosis, because the expected physiologic respiratory response is inadequate.

THE ANION GAP

The principle of electrical neutrality requires that plasma have no net charge. The charge of the predominant plasma cation, Na^+, must therefore be "balanced" by the charge of plasma anions. Although HCO_3^- and Cl^- constitute a significant fraction of plasma anions, the sum of their concentrations does not equal that of sodium. Therefore, there must be other anions present in the serum to maintain electrical neutrality. These anions are primarily serum proteins (albumin, phosphate, sulfate, and organic anions, such as lactate) and the conjugate bases of ketoacids. Because these substances are not commonly measured, they are termed *unmeasured anions*. Unmeasured cations also exist, largely in the form of Ca^{2+} and Mg^{2+}. Because all cations (measured cations [MC] and unmeasured cations [UC]) must equal all anions (measured anions [MA] and unmeasured anions [UA]):

$$MC + UC = MA + UA \quad (3)$$

it follows that:

$$MC - MA = UA - UC = AG \quad (4)$$

Thus, substituting measured ions produces:

$$[Na^+] - ([HCO_3^-] + [Cl^-]) = AG \quad (5)$$

The unmeasured anion concentration is commonly called the *anion gap* (AG), i.e., the difference between the serum $[Na^+]$ and the sum of serum $[Cl^-]$ and $[HCO_3^-]$ equals the concentration of the unmeasured anions. The contribution of $[K^+]$, largely an intracellular ion, is usually neglected (although some hospital laboratories still include the $[K^+]$ as part of the reported AG value). For the purposes of AG determination, correction of serum $[Na^+]$ in the face of hyperglycemia is unnecessary, because this condition similarly dilutes $[Cl^-]$. The normal value of the AG is generally considered to be 12 ± 4 mEq/L, assuming no major deviations in expected concentration of unmeasured anions or cations. Reports have suggested that a normal AG value of 7 ± 4 mEq/L may be more appropriate to electrolyte measurements made with ion-specific electrodes.[14] However, normal range values used by the clinician should reflect institutional practice. As with other acid-base concepts, the accepted "normal" range for the AG is less important than whether it has changed in relation to the patient's steady-state baseline value. Thus, a relative change in the AG, referred to as the *delta gap*, may be more important than the actual AG value. Virtually all AG values above 15 mEq/L can be considered abnormal, even when there are no previous comparison values available.

The AG may change even in the absence of acid-base disturbances. It may rise when (unmeasured) cations decrease, as in severe states of hypomagnesemia, hypokalemia, and hypocalcemia. A reduced, narrow, or even negative AG may result from an increase in the concentration of unmeasured cations, such as lithium; unmeasured positively charged proteins resulting from myeloma and polyclonal gammopathies; or a significant decrease in unmeasured anions, such as albumin and γ-globulin. Albumin is a major component of the AG. Critically ill patients are frequently hypoalbuminemic, which may decrease the AG into the normal range, effectively masking the presence of a wide AG acidosis.[15] The AG should be corrected $[AG\text{-}Corr_{(albumin)}]$[6,8] for an abnormal albumin level to improve the sensitivity of using the AG to identify a metabolic acidosis:[#]

$$AG\text{-}Corr_{(albumin)} = AG + 0.25 \times ([albumin]_{Reference} - [albumin]_{measured}) \quad (6)^{f}$$

A factitiously narrow or even negative AG may result from a number of conditions including measurement artifact. Bromide toxicity yields false elevations of chloride, unless Cl^- specific electrodes are used for detection;[**] triglyceride levels greater than 600 mg/dL falsely elevate chloride levels and lower sodium levels, resulting in an apparently narrow or even negative AG.[16] If these can be excluded, a narrow AG may imply an excess of unmeasured cations such as may occur with hypergammaglobulinemias and myeloma proteins.

Although increases in the AG are traditionally considered in the context of metabolic acidosis, elevation of the AG may be seen with other acid-base disturbances. Metabolic and respiratory alkalosis, for example, may elevate the AG by 2 to 3 mEq/L, due to elevations in lactate (an unmeasured anion) produced by enhancement of glycolysis.[††] Penicillin and carbenicillin, as unmeasured anions, produce elevations in the AG and may be accompanied by a hypokalemic alkalosis.

Elevations of the AG are usually clinically importance in the emergency setting and most commonly associated with metabolic acidosis (**Table 15-2**). Traditional mnemonics for the differential diagnosis of an elevated AG acidosis (MUDPILES, CAT MUDPILES, GOLDMARK, KARMEL, KUPIN, ACE GIFTs) can help the clinician recall elements of the differential diagnosis for this condition. However, these mnemonics leave the dangerous impression that lactic acidosis is a diagnostic endpoint for elevated AG acidosis. It is not. For example, propylene glycol, iron, seizures from isoniazid, carbon monoxide poisoning, and aspirin ingestions, as well as alcoholic ketoacidosis, may produce significant lactic acidosis. We suggest that the differential diagnosis of metabolic acidosis with an elevated AG should emphasize distinctions between endogenous and exogenous unmeasured anion sources and avoid mixing the etiology of lactic acidosis with that of other increased unmeasured anions. Some authors suggest correcting for lactate in patients known to have lactate elevations at baseline;[17,18] if lactate correction is calculated, the delta lactate should be used.

Clinical use of AG values requires an appreciation of their limitations. Although an AG greater than 30 mEq/L is usually caused by lactic acidosis or diabetic ketoacidosis, these conditions may exist even when the AG is normal.[19] Thus, a "normal" AG does not exclude the possibility of the presence of increased concentrations of unmeasured cations. An AG

[‡]The sole exception is in chronic respiratory alkalosis, where bicarbonate levels may decline to a level that nearly normalizes the pH, such that differentiating the actual pH from normal falls within the range of laboratory error.

[#]This correction is generally not of clinical importance in emergency medicine because even a large decrease in albumin will have negligible effect on the anion gap and the delta gap, particularly in patients with severe acidosis.

[f]For SI units (g/L); if the lab reports g/dL, the factor is increased 10-fold, i.e., 2.5 × Δ albumin.

[**]Other techniques cause reactions where bromide is falsely read as chloride.

[††]This form of lactate is not associated with acid production as occurs with states resulting in anaerobic metabolism.

TABLE 15-2 Unmeasured Anions Associated with an Elevated Anion Gap and Metabolic Acidosis

Diagnostic Category	Anion Species	Origin	Diagnostic Adjuncts
Renal failure (uremia)	$[PO_4^{2-}]$, $[SO_4^{2-}]$	Protein metabolism	BUN/creatinine
Ketoacidosis	Ketoacids, lactate	Fatty acid metabolism	Serum/urine ketones
Diabetic	β-Hydroxybutyrate, lactate	Fatty acid metabolism	Specific test now available (older nitroprusside test yields false-negative result for β-hydroxybutyrate)
Alcoholic	Acetoacetate, lactate	Fatty acid metabolism	
Starvation			Consider coexistent dehydration
Lactic acidosis*	Lactate	Metabolism	Lactate level for subtypes
Sepsis	Lactate	Hypoperfusion, anaerobic metabolism	Culture/organism-specific tests
Cardiac arrest	Lactate	Hypoperfusion/reperfusion injury	Consider other acidosis
Liver failure	Lactate	Decreased lactate clearance	Liver function tests
Iron	Lactate	Disruption of cellular metabolism,	Serum iron level
Metformin	Lactate	Inhibition of gluconeogenesis	
Cyanide	Lactate	Mitochondrial dysfunction, histotoxic hypoxia	
Carbon monoxide	Lactate	Hypoxia, anaerobic metabolism	Carbon monoxide level
Thiamine deficiency	Lactate	Aerobic metabolism interrupted, lactate accumulates	Assess peripheral sensory and motor function for neuropathy
Exogenous poisoning*			
Methanol	Formate	Methanol metabolism	Osmolal gap
Ethylene glycol (EG)	Oxalate and organic anions	EG metabolism favors pyruvate conversion to lactate	Osmolal gap Oxalate crystals (urine)
Salicylate	Salicylate	Salicylate, lactate, ketoacids	Concomitant respiratory alkalosis and metabolic acidosis
Isoniazid	Lactate	Anaerobic metabolism, lactate accumulation	

*This is not an exhaustive list; several other causes exist.

increased from baseline but still within the "normal" range may be a clue (delta gap). Direct measurements of lactate, formate (parent of formic acid), ketoacids, methanol, ethylene glycol (parent of oxalic acid and numerous other organic acids), and salicylate should be ordered when the presence of any of these substances is suspected, but the AG is "normal," (when a delta gap exists, or the AG is in the upper range of normal). Measurement of serum osmolarity and subsequent comparison to calculated serum osmolarity are necessary to detect small unmeasured molecules (such as toxic alcohols).[20] Finally, it is important to recognize that several concomitant causes of wide AG–type metabolic acidosis may be present.

A common clinical problem is the diagnosis of mixed acid-base disturbances in the presence of an elevated AG. Simple acid-base disturbances that produce elevated AGs are referred to as wide AG metabolic acidoses. If a wide AG metabolic acidosis is the only disturbance, then the change (elevation from baseline) in value of the AG (the delta gap) should exactly equal the net decrease in the $[HCO_3^-]$. This is a one-to-one relationship. This concept is represented mathematically in Eq. (7).

$$\Delta \text{ increase in AG} = \Delta \text{ decrease in } [HCO_3^-] \quad (7)$$

If the $[HCO_3^-]$ is lower than the value predicted by the delta AG, then there must be a concomitant hyperchloremic (i.e., normal AG type) metabolic acidosis (**Figure 15-2A**). Similarly, if the $[HCO_3^-]$ is higher than expected based on the delta AG, there must be a concomitant metabolic alkalosis present. Note that acute respiratory conditions (respiratory acidosis or alkalosis) do not affect these determinations, although chronic respiratory conditions may have substantial metabolic compensatory effects. Potential acid-base disturbances related to respiratory status must be further determined, as discussed below (**Figure 15-2A–C**).

PARAMETERS REQUIRED FOR CLINICAL ACID-BASE EVALUATION

When taking a medical history, one should emphasize events that may result in the gain or loss of acid or base, such as vomiting, diarrhea, medications, or ingestions of toxins, and seek evidence of dysfunction of the organs of acid-base homeostasis—the liver, kidneys, and lungs.

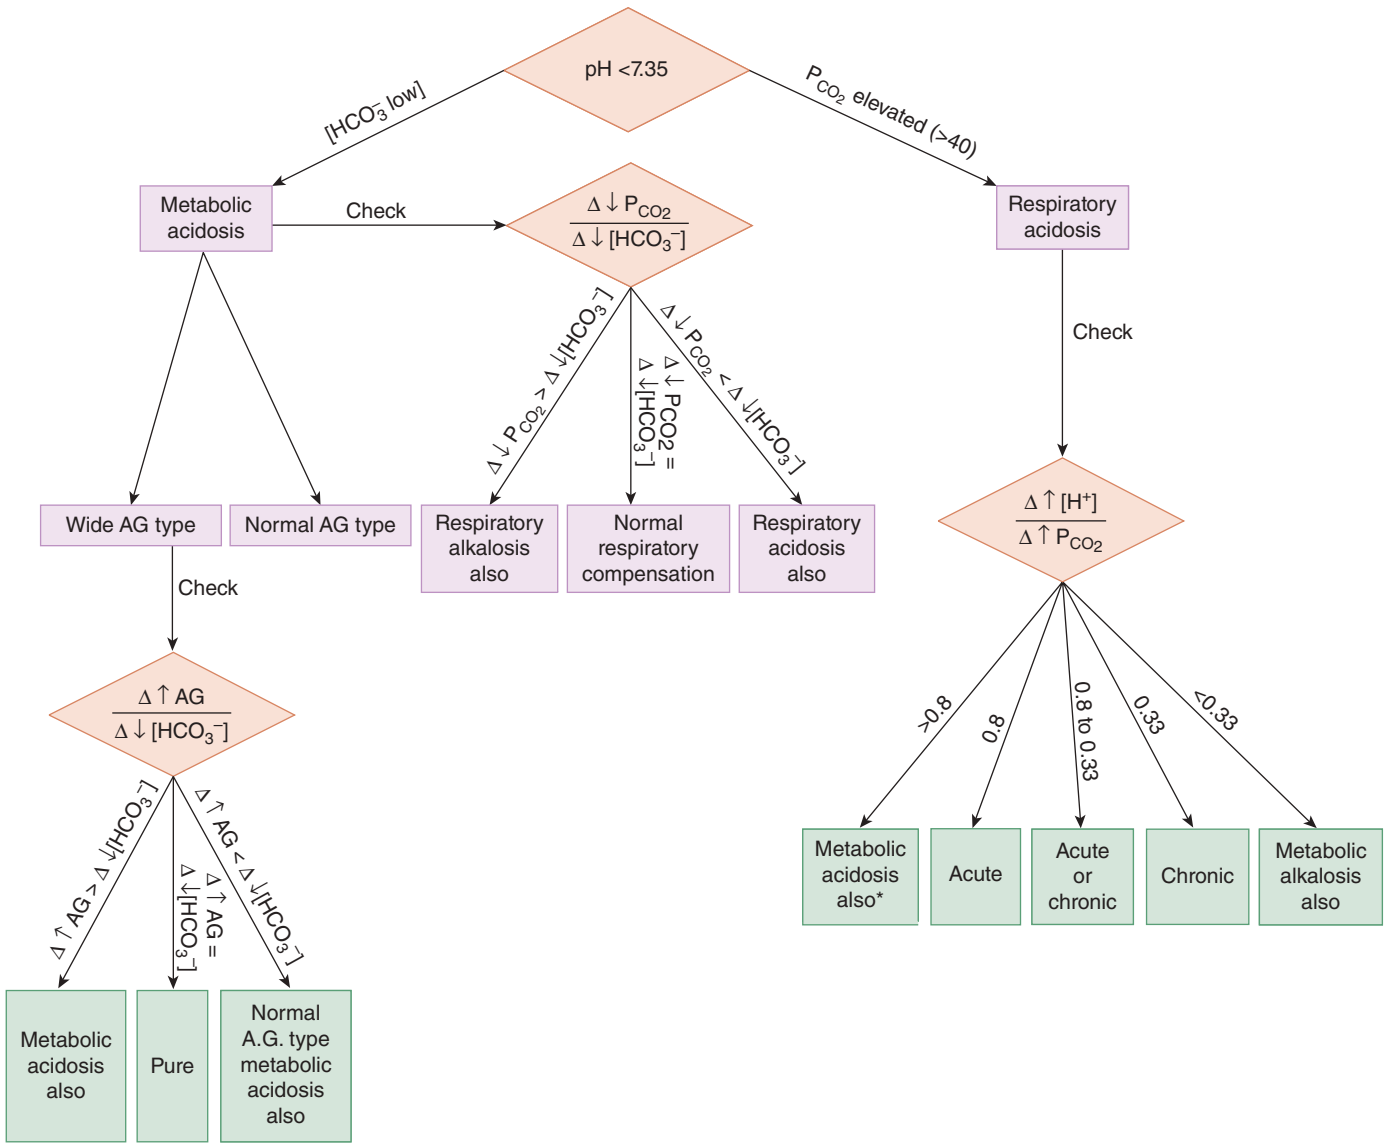
Laboratory evaluation requires blood samples for determination of blood gases (pH, P_{CO_2}, and $[HCO_3^-]$), electrolytes ($[Na^+]$, $[K^+]$, $[Cl^-]$, and $[HCO_3^-]$), and other factors that affect the patient's acid-base status (albumin, lactic acid, creatinine, BUN, drug levels of suspected ingestions such as salicylate). Based on current history and physical and past medical history, consider the need for calcium, magnesium, phosphate, serum ketones and glucose, serum osmolality, and urine electrolytes, osmolality, and glucose. Most clinical laboratories measure two of the parameters reported in blood gas results (most commonly the pH and P_{CO_2}) and use the Henderson-Hasselbalch equation to calculate the third ($[HCO_3^-]$).

Blood samples for acid-base evaluation were historically obtained by arterial puncture, but there is increasing evidence that, in many clinical situations, venous or capillary blood may be used instead.[21] Venous P_{CO_2} may be a sensitive screen for hypercarbia (cutoff 45 mm Hg), but the venous and arterial P_{CO_2} values exhibit wide variation and are not interchangeable.[22] With increasing attention to early goal-directed therapy, point-of-care venous lactate levels are useful to screen for hyperlactatemia.[23] Confirming an elevated venous lactate with an arterial sample[24] is not necessary.[22,23]

Inexperienced clinicians frequently resort to arterial blood gas (ABG) determination as a means to determine the pH. However, **the pH per se is often the least important value for diagnosis and management**. When respiratory status is not compromised (which should be presumed only with caution), the pH can be calculated with the aid of the Kassirer-Bleich equation [see Eq. (2)] from the venous $[HCO_3^-]$ alone, as described below.

METABOLIC ACIDOSIS

Metabolic acidosis may result from HCO_3^- loss, administration or ingestion of acid, or endogenous production and accumulation of acid. Loss of HCO_3^- occurs by externalization of intestinal contents (e.g., vomiting, enterocutaneous fistulae) and renal wasting of bicarbonate (e.g., renal tubular acidosis, carbonic anhydrase inhibitor therapy). Administration of acid, unlikely to be seen in the ED, occurs primarily

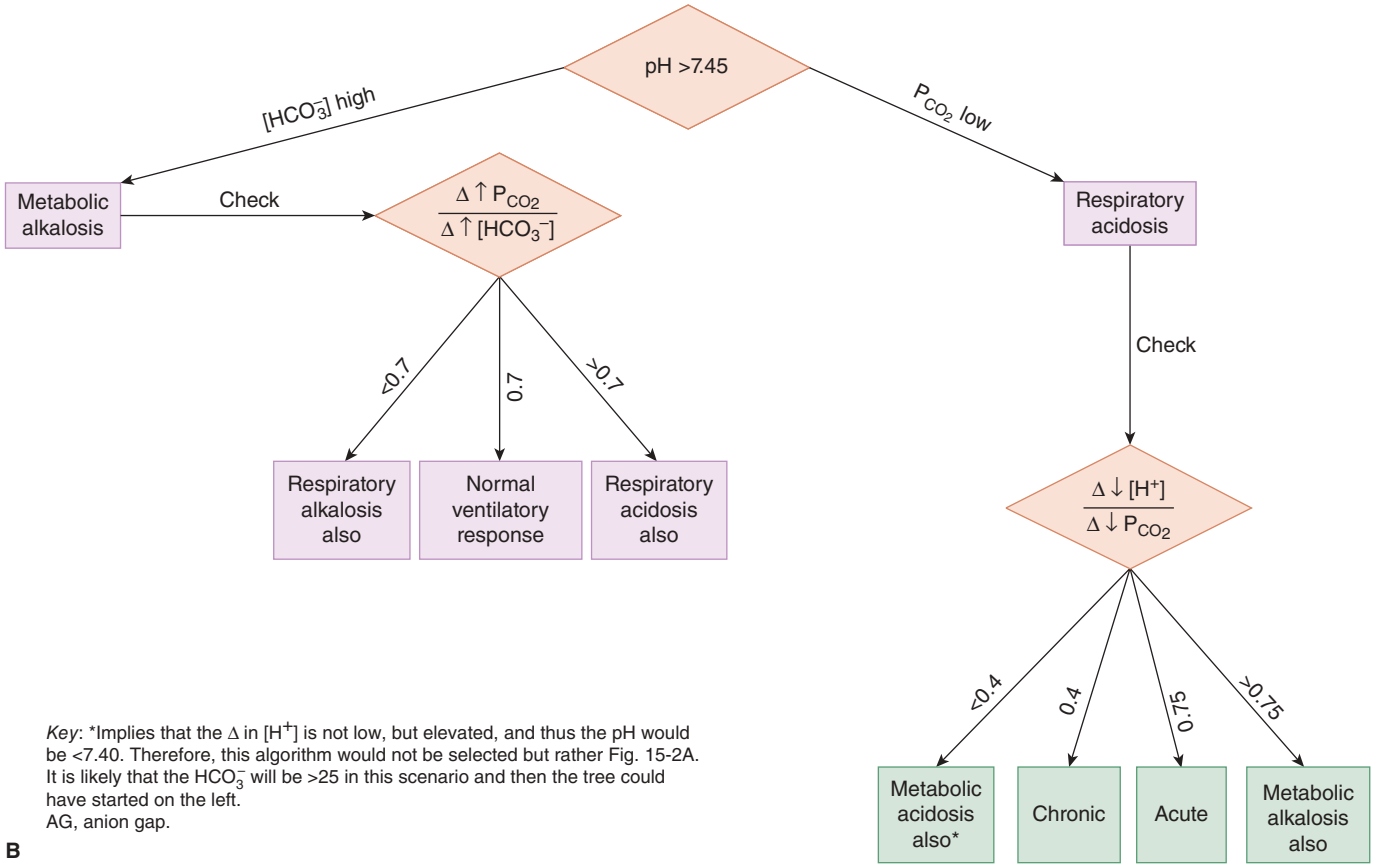


with total parenteral nutrition, whereby patients receive hydrochloric salts of basic amino acids. Endogenous acids accumulate in renal tubular acidosis, ketoacidosis, and lactic acidosis. Acidosis from rapid infusion of normal saline, called dilutional acidosis, has been shown to involve endogenous accumulation from CO_2 hydration.[25]

Unopposed metabolic acidosis results in a decreased serum $[HCO_3^-]$ and an increase in serum $[H^+]$. The increased $[H^+]$ stimulates the respiratory center, resulting in increased minute ventilation. The physiologically based "respiratory compensation" is an attempt to lower the $[H^+]$ by a reduction in P_{CO_2} through increased ventilation. The steady-state relationship between the P_{CO_2} and the $[HCO_3^-]$ is shown in Eq. (8).[12‡‡]

$$P_{CO_2} = (1.5 \times [HCO_3^-] + 8) \pm 2 \quad (8)$$

‡‡The constants in this equation ($P_{CO_2} = 1.54 \times [HCO_3^-] + 8.36 \pm 2$) have been rounded for ease of use.



While equation (8) expresses the steady-state values after 24 hour of metabolic acidosis, the respiratory response is almost immediate. When $[HCO_3^-]$ is greater than ~8 mEq/L, the relationship between P_{CO_2} and $[HCO_3^-]$ is simpler. With normal respiratory compensation, P_{CO_2} decreases by 1 mm Hg for every 1 mEq/L net decrease in $[HCO_3^-]$. Using these relationships allows the clinician to calculate the expected P_{CO_2} from the measured $[HCO_3^-]$, assuming respiratory compensation is normal. If the expected P_{CO_2} value differs from the measured value in steady-state metabolic acidosis, then respiratory compensation is compromised, and a primary respiratory disorder exists in conjunction with the metabolic acidosis. As an example, if the $[HCO_3^-]$ is 15 mEq/L, the expected P_{CO_2} is ~30 mm Hg. If the actual measured value is higher than expected (e.g., 35 mm Hg), then by definition there is a concomitant respiratory acidosis (Figure 15-2A). If the measured value is lower than expected (e.g., 25 mm Hg), then there is a concomitant respiratory alkalosis. This latter case is not an example of overcompensation, but rather a second, simultaneous primary acid-base disturbance. These are important concepts. The body cannot tolerate metabolic and respiratory mechanisms for acidosis simultaneously, as one cannot buffer or compensate for the other.

Key: * It is likely that $[HCO_3^-]$ is <25 in this scenario and the tree could have been started on the left.
AG, anion gap.

FIGURE 15- 2. (*Continued*)

Physiologic studies of otherwise healthy persons with acute metabolic acidosis caused by diarrhea found that the completeness of the respiratory response to metabolic acidosis depends on the duration of the acidosis, the time course of its development, and its severity. When $[HCO_3^-]$ is held constant, steady-state P_{CO_2} is reached in 11 to 24 hours. When acidosis develops slowly, there is no lag in respiratory compensation. If acidosis develops more quickly, the P_{CO_2} is often higher than values observed in steady state; the more rapid and severe the acidosis, the larger is the difference between the observed P_{CO_2} and the predicted steady-state CO_2. The delay in full compensation again indicates the presence of concomitant respiratory acidosis, and the clinician must recognize the contribution of inadequate ventilation to the level of acidosis (e.g., $[H^+]$). Thus, in the ED setting, the delay in reaching steady state is of passing interest as the labs results signify the reality of the moment. Unfortunately, the ED patient's illness can rarely be assumed to be in steady state.

There are limits to the adequacy of respiratory compensation during metabolic acidosis. Respiratory minute volume actually declines when pH decreases below 7.10. This finding has led clinicians to initiate bicarbonate therapy when pH falls below 7.10. It is particularly important to appreciate any contribution to the acidosis from inadequate respiratory response. Administration of HCO_3^- in the presence of hypoventilation may exacerbate the respiratory acidosis, because the HCO_3^- converts to CO_2 and H_2O.

The development of metabolic acidosis that drives the pH below 7.10 is likely associated with a very high risk of inadequate ventilation response, since there is a limit to respiratory compensation. The lowest P_{CO_2} level achievable is ~12 mm Hg. This lower limit in obtainable P_{CO_2} is due to resistance in airflow and increased CO_2 generated by the exertion required for rapid ventilation, both offsetting the ventilator exhalation of CO_2. The superimposition of respiratory acidosis on a patient in such a condition will result in a rapid decline of pH to levels at which organ function drops and pharmacotherapy will fail. Mechanical ventilation usually should be instituted in such situations to ensure the ventilatory rate and volume are sufficient to prevent an increase in P_{CO_2} at this critical time.

The serum $[K^+]$ level is affected by metabolic acidosis. The movement of H^+ into cells is associated with extrusion of K^+. Changes in $[K^+]$ are more substantial during inorganic acidosis, although elevated serum $[K^+]$ is typically seen in diabetic ketoacidosis. In general, for each 0.10 change in the pH, serum $[K^+]$ will change by approximately 0.5 mEq/L, in an inverse relationship. Whatever the mechanism of the acidosis, it is important to remember that normal values as well as low serum $[K^+]$ likely reflect severe intracellular K^+ depletion. As the acidosis is corrected, serum $[K^+]$ should fall, possibly to levels that may produce clinical symptoms, dysrhythmias, and other adverse outcomes.

CLINICAL FEATURES AND PHYSIOLOGIC CONSEQUENCES OF ACIDOSIS

Symptoms of the primary disorder causing metabolic acidosis dominate the clinical presentation; however, several symptoms are common to various etiologies. Patients may complain of abdominal pain, headache, nausea with or without vomiting, and generalized weakness, and because acidosis stimulates the respiratory center, the patient may complain of dyspnea.

Acidemia has numerous negative physiologic consequences that impair the function of enzymes as well as many different organs through mechanisms not yet well understood. Cardiac contractile function is reduced, likely due to impaired oxidative phosphorylation, intracellular acidosis, and alterations in intracellular calcium concentrations. The threshold for ventricular fibrillation falls as the defibrillation threshold rises. Hepatic and renal perfusion and systemic blood pressure decline, and pulmonary vascular resistance increases. The physiologic effects of catecholamines are attenuated, and when acidosis is sufficiently severe, vascular collapse may result. A catabolic state develops, including a generalized increase in metabolism, resistance to insulin, and inhibition of anaerobic glycolysis. The effect of hypoxia on all organs is aggravated.[26]

CAUSES OF METABOLIC ACIDOSIS

The causes of elevated AG metabolic acidosis are listed in Table 15-2. A comparison with the patient's steady-state AG should be made whenever possible. Measurement and detection of specific anions may be indicated.

Differential Diagnosis of Wide AG Acidosis The differential diagnoses to be considered in emergency practice fall into four broad categories: renal failure (uremia), ketoacidosis (diabetic ketoacidosis, alcoholic ketoacidosis, starvation ketoacidosis), lactic acidosis, and ingestions (methanol, ethylene glycol, salicylates, and many others).

Renal failure should be evident from the serum chemistries. Acidosis seen in initial stages of renal failure may be severe, but tends to be stable, with $[HCO_3^-]$ ~15 mEq/L in cases of chronic renal failure.

Positive serum ketones point to one of the ketoacidoses. In instances of known insulin-dependent diabetes mellitus, diabetic ketoacidosis is likely, although there is usually a component of lactic acidosis. In alcoholics who have recently stopped heavy drinking, alcoholic ketoacidosis should be considered; ketoacids contribute far less to the acidosis in ketoacidosis than lactate. Starvation ketosis will be found in patients with recent oral intake that is inadequate, such as in cases of fasting, dieting, or protracted vomiting, although the magnitude of acid-base disturbance in starvation ketosis should be small. The major ketone present in the serum of a patient with untreated diabetic or alcoholic ketoacidosis may be β-hydroxybutyrate. A specific test is now available. The older nitroprusside test yields a false-negative result for β-hydroxybutyrate. See chapter 223, "Type 1 Diabetes Mellitus for a detailed discussion.

Lactic acidosis occurs whenever lactate production exceeds lactate metabolism and is classified into two types. The first, in which tissue hypoxia is present and lactate production is elevated, is referred to as **type A**. Normal tissue oxygenation and impairment of lactate metabolism define the second, called **type B**. Severe acidosis that is resistant to treatment is seen in various type B lactic acidoses and ingestions. **Lactic acidosis is not a diagnosis, but a syndrome with its own differential diagnosis.** Causes of lactic acidosis include renal failure, shock, sepsis, cardiac arrest, trauma, seizures, tissue ischemia, diabetic ketoacidosis, thiamine deficiency, malignancy (e.g., leukemia), liver dysfunction, genetic disorders (e.g., metabolic diseases), toxins (e.g., methanol), and medications (e.g., metformin, salicylates, iron, isoniazid) (Table 15-2).

Lactate levels should be measured and accounted for in an adjustment of the AG. Ethanol is frequently cited as a cause of wide AG acidosis, but **ethanol should never be considered the etiologic source of any significant metabolic acidosis**; look for other causes. Although ethyl alcohol metabolism may lead indirectly to very mild lactic acidosis, usually due to the same mechanism as alcoholic ketoacidosis, in which lactic acidosis is more substantial, neither the alcohol nor its metabolites directly contribute to the acidosis.

Determination of the osmolal gap will help identify methanol and ethylene glycol from other etiologies. Although methanol is measured in most hospital laboratories, determination of ethylene glycol levels is performed off-site in many institutions. A widened osmolal gap without clear evidence of methanol ingestion may determine the diagnosis long before confirmatory laboratory evidence is available. Calculated adjustments to the osmolal gap may need to be made if ethanol is a co-ingestant (see chapter 185, "Alcohols" for detailed discussion).

Concomitant acid-base disturbance may further assist in determining the etiology. The triple acid-base disturbance of wide AG metabolic acidosis, metabolic alkalosis, and respiratory alkalosis is seen with sepsis (lactic acidosis) and salicylate poisoning. The latter also may be associated with a mild temperature elevation.

The relation of $[HCO_3^-]$ to the AG and the $[HCO_3^-]$ to the expected P_{CO_2} compensation must be examined in every patient with wide AG acidosis to determine whether other acid-base disturbances, metabolic or respiratory, exist (Figure 15-2A).

Differential Diagnosis of Unchanged (Normal) AG Acidosis The non-AG type of acidosis is often referred to as "normal" AG acidosis.[3] Some texts refer to this as **hyperchloremic metabolic acidosis**, but not all cases of normal AG acidosis are associated with hyperchloremia. If the patient has hyponatremia with a normal AG acidosis, the chloride

TABLE 15-3 Causes of Normal Anion Gap Metabolic Acidosis

With a Tendency to Hyperkalemia	With a Tendency to Hypokalemia
Subsiding diabetic ketoacidosis	Renal tubular acidosis, type I (classical distal acidosis)
Early uremic acidosis	Renal tubular acidosis, type II (proximal acidosis)
Early obstructive uropathy	Acetazolamide
Renal tubular acidosis, type IV	Acute diarrhea with losses of HCO_3^- and K^+
Hypoaldosteronism (Addison's disease)	Ureterosigmoidostomy with increased resorption of $[H^+]$ and $[Cl^-]$ and losses of HCO_3^- and K^+
Infusion or ingestion of HCl, NH_4Cl, lysine-HCl, or arginine-HCl	Obstruction of artificial ileal bladder
Potassium-sparing diuretics	Dilution acidosis (may occur with 0.9% NaCl infusion)

TABLE 15-4 Potential Indications for Bicarbonate Therapy in Metabolic Acidosis

Indication	Rationale
Severe hypobicarbonatemia (<4 mEq/L)	Insufficient buffer concentrations may lead to extreme increases in acidemia with small increases in acidosis.
Severe acidemia (pH <7.00 to 7.15)* in cases of wide anion gap acidosis, with signs of shock or myocardial irritability that has not responded to supportive measures including adequate ventilation and fluid resuscitation as indicated by the patient's clinical characteristics	Therapy for the underlying cause of acidosis depends on adequate organ perfusion.
Severe hyperchloremic acidemia†	Lost bicarbonate must be regenerated by kidneys and liver, which may require days.

*Presented as a range because recommendations differ among authors; data do not support a specific threshold for treatment.

†No specific threshold indication by pH exists. The presence of serious hemodynamic insufficiency despite supportive care should guide the use of bicarbonate therapy for this indication.

may be in the normal range. Abnormal chloride levels alone usually signify a more serious underlying metabolic disorder, such as metabolic acidosis (elevated chloride) or metabolic alkalosis (low chloride).[27]

Normal AG acidosis results from loss of HCO_3^-, failure to sufficiently excrete H^+, or administration of H^+. Bicarbonate may be lost from the urine or GI tract and is usually accompanied by K^+ loss. However, potassium-sparing diuretics, hypoaldosteronism, urinary tract obstruction, and type IV renal tubular acidosis result in loss of HCO_3^- with retention of K^+ (**Table 15-3**). Acetazolamide exerts its effect through carbonic anhydrase inhibition, inducing a functional renal tubular acidosis.

One should be wary of traditional classification based on $[K^+]$, because serum $[K^+]$ itself is dependent on the actual pH. Thus, in severe acidosis, a normal range $[K^+]$ value may be falsely reassuring. As the acidosis is corrected and acidemia resolves, the $[K^+]$ will concordantly fall.

Because all diuretics may cause a contraction alkalosis, the metabolic acidosis that occurs simultaneously with potassium-sparing diuretics may not be evident, as the two may simply cancel each other out (Figure 15-2C). Because the AG is unchanged, there is no indication that two distinct opposing processes may be occurring. As with wide AG–type acidosis, **the expected P_{CO_2} compensation must be examined in every patient with normal AG acidosis** to determine whether other respiratory acid-base disturbances exist (Figure 15-2A).

TREATMENT

The treatment of acidosis reflects that of the underlying disorder but particularly emphasizes restoration of normal tissue perfusion and oxygenation. The most important step is to determine whether there is a respiratory component to the acidosis (i.e., a primary respiratory acidosis), because the treatment approach differs. If there is inadequate respiratory compensation, the most appropriate treatment will be to first correct the respiratory problem. Address electrolyte disturbances, administer antidotes for toxins as appropriate, and initiate treatment for underlying causes such as sepsis (see chapter 150, "Toxic Shock Syndromes") or diabetic ketoacidosis (see chapter 225, "Diabetic Ketoacidosis").

Buffer Therapy in Acidosis Slow replacement of sodium bicarbonate in patients with sodium bicarbonate loss due to diarrhea or proximal renal tubular acidosis is useful.[28] The adverse effects of acidemia make the concept of buffer therapy teleologically appealing, but its role in instances of cardiac arrest and severe metabolic acidosis is unclear. A small 2013, single-center, randomized controlled trial showed mortality benefit in the treatment of sepsis patients; this study needs confirmation.[29] The traditional therapeutic buffer, sodium bicarbonate, may have negative effects in the treatment of acidosis. Bicarbonate therapy results in the generation of significant quantities of CO_2, which diffuses readily into cells, in particular those of the CNS, which may cause paradoxical worsening of intracellular acidosis. An abrupt CO_2 increase may exceed the ventilatory capacity of a patient already at maximum minute ventilation, thereby producing abrupt and worsening respiratory acidosis. After successful treatment with bicarbonate, "overshoot" alkalosis may result. Bicarbonate therapy imposes an osmotic and sodium load (1000 mEq/L of typical 1 N solution). These concerns suggest that bicarbonate therapy should not be used in the ED treatment of mild to moderate metabolic acidosis.

Concerning use of buffer therapy for cardiac arrest, diabetic ketoacidosis, and lactic acidosis, several studies of HCO_3^- use in adult and pediatric cases, including patients with severe acidosis, failed to show any improvement in speed of recovery or decrease in complication rates with buffer therapy.[26,28,30-33] There has been some suggestion of harmful effects, particularly an increased rate of development of cerebral edema in pediatric patients with diabetic ketoacidosis who were treated with bicarbonate. However, it remains unclear whether certain subgroups of patients (for example, those with cardiac or other disease) may benefit from bicarbonate therapy and dialysis.

The goal of bicarbonate and dialysis therapy in lactic acidosis may be to "bridge" the patient physiologically to definitive treatment of the etiology of the acidosis. Bicarbonate therapy may be appropriate for limited indications (**Table 15-4**).[26,28, 30-34]

When given, HCO_3^- can be dosed 0.5 mEq/kg for each milliequivalent per liter rise in $[HCO_3^-]$ desired.[26] The goal is to restore adequate buffer capacity ($[HCO_3^-]$ >8 mEq/L) or to achieve clinical improvement in shock or dysrhythmias. Bicarbonate should be given as slowly as the clinical situation permits. Seventy-five milliliters of 8.4% sodium bicarbonate in 500 mL of dextrose 5% in water produces a nearly isotonic solution for infusion. Adequate time should be allowed for the desired effect to be achieved, and close monitoring of acid-base balance, especially in patients with organic acidosis, is critical. Other buffers appeared promising in the treatment of metabolic acidosis during early studies but have failed to provide improvement in clinical outcomes, including carbicarb, and tris-hydroxymethyl amino-methane.

METABOLIC ALKALOSIS

Metabolic alkalosis is typically classified as chloride-sensitive and chloride-insensitive, thus indicating the treatment approach. Metabolic alkalosis results from gain of bicarbonate or loss of acid. The relation of metabolic alkalosis to chloride balance defines pathophysiologic features of the disease and its therapy.

CLINICAL FEATURES AND PHYSIOLOGIC CONSEQUENCES OF ALKALOSIS

Symptoms of the primary disorder causing metabolic alkalosis dominate the clinical presentation; however, several symptoms are common to various etiologies. Patients may complain of generalized weakness,

dizziness, myalgia, palpitations, nausea with or without vomiting, paresthesias, and possibly muscle spasm or twitching.

The physiologic effects of alkalemia are substantial. Neurologic abnormalities, especially tetany, neuromuscular instability, and seizures, are common. Reduction in $[H^+]$ results in reductions in ionized calcium, potassium, magnesium, and phosphate levels. Serum proteins, largely polyanionic, buffer H^+; with rapid acid loss, such as that which occurs in respiratory alkalosis, the newly available buffer capacity of those proteins binds calcium and other cations instead. Constriction of arterioles occurs, resulting in reduced coronary and cerebral blood flow. Refractory dysrhythmias may develop.[26] Alkalemia may be of particular concern in patients with chronic obstructive pulmonary disease, because of the shift of the oxygen-hemoglobin dissociation curve to the left, which makes O_2 less available to the tissues. Many patients with chronic obstructive pulmonary disease take diuretics, which lead to a contraction alkalosis. Additionally, the alkalemic environment tends to further depress ventilatory drive.

CAUSES OF METABOLIC ALKALOSIS

Bicarbonate and chloride represent the major serum anions whose concentrations may be readily altered, and their homeostasis is therefore closely intertwined. Conditions that result in chloride loss, such as vomiting (which also causes acid loss), diarrhea, diuretic therapy, and chloride-wasting diseases (e.g., cystic fibrosis and chloride-wasting enteropathy), tend to reduce serum chloride concentration and extracellular volume. The reduction in extracellular volume increases mineralocorticoid activity, which enhances sodium reabsorption and potassium and hydrogen ion secretion in the distal tubule, which in turn enhance bicarbonate generation. The resulting increase in serum $[HCO_3^-]$ eventually exceeds the tubule's maximum ability to reabsorb filtered bicarbonate. The resulting urine is alkaline, and because its anionic content is mostly bicarbonate, it is largely free of chloride (<10 mEq/L). (Nevertheless, the urine chloride may be normal when diuretics are administered.) The result is hypokalemic, hypochloremic alkalosis that responds to normal saline (chloride-responsive alkalosis).

Other diseases that cause metabolic alkalosis are usually associated with normovolemia or hypervolemia and often include hypertension. These diseases usually cause excess mineralocorticoid activity, resulting in the same pathophysiologic cascade described above. However, the excess mineralocorticoid activity is not associated with hypovolemia, so the urine chloride is generally normal or elevated (>10 mEq/L) and the alkalosis cannot be reversed with normal saline. Conditions producing "chloride-unresponsive alkalosis" and hypertension include renal artery stenosis, renin-secreting tumors, adrenal hyperplasia, hyperaldosteronism, Cushing's syndrome, Liddle's syndrome, and exogenous mineralocorticoids (e.g., licorice, fludrocortisone). Chloride-unresponsive alkalosis caused by Bartter's and Gitelman's syndromes is usually associated with normotension.

The compensation for metabolic alkalosis involves reduction in alveolar ventilation, but the exact relation between P_{CO_2} and $[H^+]$ is not well established. Most studies to date have been conducted in dialysis patients or patients with conditions that predispose to alveolar hyperventilation (e.g., sepsis, pneumonia). As a guideline, P_{CO_2} in patients with significant metabolic alkalosis should rise by 0.7 mm Hg for each milliequivalent increase in $[HCO_3^-]$. The P_{CO_2} also rarely rises above 55 mm Hg in compensation for metabolic alkalosis.

TREATMENT

As with all acid-base disorders, therapy of alkalemia emphasizes treatment of the underlying cause with careful supportive care. In the emergency setting, metabolic alkalosis rarely requires active management. Acetazolamide produces significant bicarbonaturia and is effective in the treatment of metabolic alkalosis, but its use requires very careful monitoring of potassium, magnesium, and phosphate concentrations. If alkalosis is severe ($[HCO_3^-]$ >45 mmol/L) and associated with serious signs or symptoms not responsive to supportive care, the use of intravenous hydrochloric acid should be considered. A 0.1 normal solution (100 mmol/L) should be used, infused ideally at 0.1 mmol/kg/h but at no more than 0.2 mmol/kg/h through a central venous catheter. Higher concentrations may degrade the catheter material. An infusion rate of 100 mL/h of 0.1 N solution provides about 10 mmol/h. The dose is calculated using ideal body weight as shown in Eq. (9), with the result in mmol H^+ required.

$$\text{Dose} = (\Delta[HCO_3^-]) * 0.5 \text{ weight, in kg}) \quad (9)$$

RESPIRATORY ACIDOSIS

Respiratory acidosis is defined by alveolar hypoventilation and is diagnosed when the P_{CO_2} is greater than the expected value. Acute respiratory acidosis may have origins in other conditions, such as increased CO_2 production (high-glucose diet) and abnormal gas exchange (e.g., pneumonia). However, the final common path is inadequate ventilation.

Inadequate minute ventilation most frequently results from head trauma, chest trauma, lung disease, or excess sedation. The chronic hypoventilation seen in extremely obese patients is often referred to as the **pickwickian syndrome**. Patients with severe chronic obstructive pulmonary disease have increased dead space and frequently also have decreased minute ventilation.

In general, a rise in the P_{CO_2} stimulates the respiratory center to increase respiratory rate and minute ventilation. However, if the arterial P_{CO_2} chronically exceeds 60 to 70 mm Hg, as may occur in 5% to 10% of patients with severe emphysema, the respiratory acidosis may depress the respiratory center. Under such circumstances, the stimulus for ventilation is provided primarily by hypoxemia acting on chemoreceptors in the carotid and aortic bodies. Giving oxygen could remove the main stimulus to breathe, causing the P_{CO_2} to rise abruptly to extremely dangerous levels. Consequently, when administering oxygen to patients with COPD, careful monitoring for the development of apnea or hypoventilation is required; however, do not withhold oxygen from a patient with severe dyspnea for fear of worsening hypercarbia. Evaluation of ventilation requires attention to several important clinical issues. First, the ventilation that would be expected based on assessment of the respiratory rate and depth should be compared with the actual ventilation of the patient (i.e., P_{CO_2}). A "normal" P_{CO_2} of 40 mm Hg in a tachypneic, dyspneic patient likely reflects significant ventilatory insufficiency. Second, the impact of respiratory acidosis on partial pressure of oxygen in the alveoli (P_{AO_2}) in such a patient may be considerable. The alveolar gas equation suggests that if inspired oxygen concentration and respiratory quotient do not change, increases in P_{CO_2} will result in reductions in P_{AO_2}.

The relation of P_{CO_2} to hydrogen ion concentration in acute respiratory acidosis derived from the Kassirer-Bleich equation shown in Eq. (10):

$$\Delta[H^+] = 0.8\ (\Delta P_{CO_2}) \quad (10)$$

Each 1-mm Hg increase in P_{CO_2} results in a 1-mmol increase in $[H^+]$. Across the linear portion of the pH-hydrogen ion concentration relationship, each 1-mm Hg increase in P_{CO_2} should theoretically produce a 0.01 decrease in pH. The actual relation between changes in P_{CO_2} (up to values of 90 mm Hg) and changes in $[H^+]$ determined in normal humans is about 8 to 10, as shown in Eq. (10). Thus, a 10-mm Hg increment in P_{CO_2} produces an 8-mmol increase in $[H^+]$, with little change in bicarbonate concentration (usually 1 mEq/L) or urinary acid excretion. If the $[H^+]$ is higher or lower than that suggested by the change in the P_{CO_2}, a mixed disorder is present.

The adaptation to chronic respiratory acidosis is complex. Over time, chronic elevation of P_{CO_2} reduces carotid sinus sensitivity to hypercapnia, and ventilatory drive is then controlled by P_{AO_2}. The acidosis results in significant increases in renal HCO_3^- generation and avid reclamation of filtered HCO_3^-. The relation between $[H^+]$ and $[HCO_3^-]$ in chronic respiratory acidosis at steady state, derived from studies in humans, is shown in Eq. (11).

$$\Delta[H^+] = 0.3 * (\Delta P_{CO_2}) \quad (11)$$

TABLE 15-5 Evaluation of Acid-Base Status in Respiratory Acidosis

Ratio = $\Delta[H^+]/\Delta P_{CO_2}$				
Ratio < 0.3	Ratio = 0.3	0.3 < Ratio < 0.8	Ratio = 0.8	Ratio > 0.8
Change in hydrogen ion concentration is less than accounted for by chronic change in P_{CO_2}. Metabolic alkalosis is also present.	Change in hydrogen ion concentration matches chronic change in P_{CO_2}. Chronic respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by chronic change in P_{CO_2}. Chronic respiratory acidosis plus either acute respiratory alkalosis or metabolic acidosis is present; examine pH.	Change in hydrogen ion concentration matches acute change in P_{CO_2}. Acute respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by acute or chronic change in P_{CO_2}. Metabolic acidosis is also present.

Abbreviation: P_{CO_2} = partial pressure of carbon dioxide.

It is frequently uncertain whether a patient has an acute respiratory acidosis, a chronic respiratory acidosis, or a mixed disorder. Evaluation of the acid-base status in such circumstances does not require "baseline" arterial blood gas values. Instead, the change in $[H^+]$ is compared with the change in P_{CO_2}. If this ratio is 0.3, the patient has a chronic respiratory acidosis; if it is 0.8, the patient has an acute respiratory acidosis. Other ratios suggest a mixed acid-base disturbance, as shown in **Table 15-5**.

TREATMENT

Treatment of respiratory acidosis is designed primarily to improve alveolar ventilation. In general, if the minute ventilation is doubled, the P_{CO_2} will be reduced by 50%. In patients with chronic obstructive pulmonary disease, bronchodilators such as β-agonists, anticholinergics, or systemic sympathomimetic agents, with careful administration of small amounts of oxygen, may substantially improve ventilation. However, ventilatory assistance (intubation or noninvasive ventilatory support) may be required in some patients who do not respond adequately to lesser measures, particularly if the pH falls below 7.25.

In patients with a chronic respiratory acidosis, reduction of the P_{CO_2} should generally proceed slowly. The minute ventilation for a 70-kg person is normally about 6 L/min; in chronic obstructive pulmonary disease patients, it may be less than 4 L/min. It is beyond the scope of this chapter to discuss in detail the approach to management of a patient with chronic obstructive pulmonary disease and severe hypercarbia. If treatment is indicated in the ED, it may be wise to start with a minute ventilation of about 5 L/min and then gradually increase it according to the clinical response and changes in P_{CO_2}.

In patients with a chronic respiratory acidosis, the arterial P_{CO_2} should not be reduced by more than 5.0 mm Hg/h. Rapid correction of a chronic respiratory acidosis can cause sudden development of a severe combined metabolic and respiratory alkalosis, with resulting dysrhythmias. A rapid rise in pH can cause an abrupt fall in ionized calcium levels and hypokalemia. Both may cause dangerous dysrhythmias, seizures, and decreased microvascular blood flow.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is defined by alveolar hyperventilation and exists when P_{CO_2} is less than expected. It is caused by conditions that stimulate respiratory centers, including CNS tumors or stroke, infections, pregnancy, hypoxia, and toxins (e.g., salicylates). Anxiety, pain, and iatrogenic overventilation of patients on mechanical ventilators also cause respiratory alkalosis.

Whatever the etiology, the clinical symptoms of acute respiratory alkalosis are predictable from its physiologic effects. Acute reduction in P_{CO_2} produces a reduction in $[H^+]$, resulting in an increase in negative charge on anionic buffers. The now negatively charged proteins instead bind calcium, and if the effect is sufficiently large, the reduction in ionized calcium produces tetany (e.g., carpopedal spasm) and paresthesias.[26] Hypocapnia also produces substantial reductions in cerebral blood flow and results in reduced tissue oxygen delivery due to a leftward shift in the oxygen-hemoglobin dissociation curve (i.e., increased hemoglobin-oxygen binding).

The theoretical relationship of $[H^+]$ and P_{CO_2} predicted by the Kassirer-Bleich equation is that a 1-mmol decrease in $[H^+]$ results from each 1-mm Hg reduction in P_{CO_2}. The actual observed relationship is very close to the predicted values. Each 1-mm Hg reduction in P_{CO_2} results in a 0.75-mmol reduction in $[H^+]$ (Eq. 12).

$$\Delta[H^+] = 0.75 * (\Delta P_{CO_2}) \quad (12)$$

Chronic respiratory alkalosis is unique among the acid-base disorders in that its compensation may be complete. Compensatory events include bicarbonaturia and a reduction in acid excretion, requiring 6 to 72 hours to develop fully and at least 1 week to normalize pH. The steady-state relationship between $[H^+]$ and P_{CO_2} in chronic respiratory alkalosis observed in normal human subjects at high altitude is shown in Eq. (13).

$$\Delta[H^+] = 0.4 * (\Delta P_{CO_2}) \quad (13)$$

TREATMENT

Therapy for acute respiratory alkalosis emphasizes identification and treatment of the underlying cause. The use of "paper-bag" rebreathing in the treatment of respiratory alkalosis should be avoided because it may lead to hypoxia, and patients respond to calm reassurance, which is more effective treatment. Chronic respiratory alkalosis is seen at high altitudes, in particular among mountaineers climbing over 3700 m (12,000 ft), where the partial pressure of O_2 is significantly diminished. Acetazolamide is frequently prescribed to counter the physiologic respiratory effects of such ascents.

CLINICAL APPROACH TO ACID-BASE PROBLEMS AND MIXED ACID-BASE DISTURBANCES

Methodical interpretation of laboratory results followed by correlation with the clinical scenario is necessary to prevent erroneous acid-base evaluation. We present one method that has worked well for the authors; however, the particular method used matters less than the consistency of its application.

1. Look at the pH. If it is decreased, the primary or predominant disturbance is acidosis. If the pH is increased, the predominant disturbance is alkalosis.
2. If the pH indicates acidosis, the primary (or predominant) mechanism can be ascertained by examining the $[HCO_3^-]$ and P_{CO_2} (Figure 15-2A).
   a. If the $[HCO_3^-]$ is low (implying a primary metabolic acidosis), then the AG should be examined and, if possible, compared with a known steady-state value. Correct AG for abnormal albumin level [see Eq. (6), above].
      i. If the AG is increased compared with the known steady-state value or is greater than 15 (or above institutional threshold), then by definition a wide AG metabolic acidosis is present, and the absolute change in the AG should be compared with the

absolute change in the [HCO_3^-] from normal to detect other disturbances.

ii. If the AG is unchanged, then the disturbance is nonwidened or *normal AG* metabolic acidosis, typically with hyperchloremia.

iii. If the change in the AG is equal to the change in the [HCO_3^-] [see Eq. (7) above], then the wide AG acidosis is termed *pure*. If the AG has risen more than the [HCO_3^-] has decreased, then there is also likely to be a concomitant metabolic alkalosis. If the change in the AG is less than the change in the [HCO_3^-], then a normal AG acidosis is also present. (This is a difficult concept, but two separate physiologic mechanisms resulting in increased [H^+] can occur simultaneously.) Next examine whether the ventilatory response is appropriate.

(1) If the decrease in the P_{CO_2} equals the decrease in the [HCO_3^-], there is appropriate respiratory compensation. Note that the pH will not return to normal.

(2) If the decrease in the P_{CO_2} is greater than the decrease in the [HCO_3^-], there is a concomitant respiratory alkalosis. Although there are other formulas for this comparison, this is the simplest, as explained earlier in the text.

(3) If the decrease in the P_{CO_2} is less than the decrease in [HCO_3^-], there is also a concomitant respiratory acidosis.

b. If the P_{CO_2} is elevated (rather than the [HCO_3^-] being decreased), the primary disturbance is respiratory acidosis (Figure 15-2A). The next step is to determine which type it is by examining the ratio of (i.e., the change in) [H^+] to (the upward change in) P_{CO_2}.

i. If the ratio is 0.8, it is considered acute.

ii. If the ratio is 0.33, it is considered chronic.

iii. If the ratio is between 0.8 and 0.33, it is probably an acute exacerbation of the chronic condition.

iv. If the ratio is greater than 0.8, there must be a metabolic explanation for the excess [H^+].

v. If the ratio is less than 0.33, a metabolic alkalosis must also be present.

3. If the pH is greater than 7.45, the primary or predominant disturbance is alkalosis (Figure 15-2B).

a. It is best to look at the [HCO_3^-] first. If it is elevated, there is a primary metabolic alkalosis. There is an expected ventilatory response, although it is quite varied. The ratio of the change upward in P_{CO_2} to the change upward in [HCO_3^-] can be examined. If the ratio is much less than 0.7, there is also a respiratory alkalosis (in addition to the metabolic alkalosis). If the ratio is more or less 0.7, this is likely to be a compensatory ventilatory response. If the ratio is well above 0.7, respiratory acidosis is concomitantly present.

b. If the P_{CO_2} is low, there is a primary respiratory alkalosis, and the ratio of the change in [H^+] to the change in P_{CO_2} should be examined. Acute respiratory alkalosis has a ratio of about 0.75. If the ratio is well above 0.75, there is probably also a concomitant metabolic alkalosis to explain the greater than expected decline in [H^+]. If the ratio is smaller, the condition is chronic or there may also be a metabolic acidosis component.

4. Every arterial blood gas that shows no or minimal pH derangement should still call for examination of the P_{CO_2}, [HCO_3^-], and AG, because there may well be a mixed acid-base disturbance (Figure 15-2C). It is quite possible for the pH, [HCO_3^-], and P_{CO_2} to be normal and yet have significant acid-base disturbances. The only evident abnormality may be the AG. Take the example of an [Na^+] of 145, [Cl^-] of 97, [K^+] of 4.5, and [HCO_3^-] of 25 and a normal arterial blood gas. All the numbers look reasonably normal. However, the AG is 23, so by definition there must be a wide AG metabolic acidosis. The explanation for the normal numbers is a concomitant metabolic alkalosis.

CHAPTER 16

Blood Gases

Casey Glass

Blood gases provide important clinical information for patients with respiratory disorders, compromised circulation, or abnormal metabolism. In recent years, a number of surrogates for blood gas analysis have entered the daily practice of emergency medicine. Leveraging the benefits of blood gases requires an understanding of the underlying physiology, appropriate use of arterial and venous blood gases, and knowledge of the advantages and limitations of noninvasive monitoring methods. This chapter will be limited to evaluation of oxygen and carbon dioxide levels; for information on carbon monoxide, please refer to chapter 222, "Carbon Monoxide."

RESPIRATORY PHYSIOLOGY

Several factors contribute to overall gas exchange in the lungs. Each breath (*tidal volume*) is composed of functional movement of air in and out of the alveolus and nonfunctional movement of air through bronchioles, bronchi, trachea, and nonperfused areas of lung (*physiologic dead space*). The physiologic dead space is approximately 30% of the tidal volume. The air remaining in the chest at the end of exhalation is referred to as the *functional residual capacity*. Dead space and the functional residual capacity do not contribute to gas exchange. The amount of air inhaled and exhaled in a minute is referred to as *minute ventilation* and is the product of the respiratory rate and tidal volume. Relatively small changes in the functional alveolar space demand large increases in the minute ventilation to maintain the same rate of gas exchange. Either raising the fraction of inspired oxygen (F_{IO_2}) or increasing the surface area or functional residual capacity of the lung can increase total alveolar oxygen (O_2) content. Positive-pressure ventilation increases the functional residual capacity through recruitment of collapsed nonventilated alveolar space.

ESTIMATING OXYGEN DELIVERY TO THE ALVEOLAR SPACE

The F_{IO_2} is the fraction or percentage of oxygen in the space being measured. At sea level, room air is 21% oxygen (20% is often used for ease of calculation). As F_{IO_2} increases, the alveolar concentration of oxygen (P_{AO_2}) proportionately increases. Unless the patient is part of a closed system, like a ventilator circuit, the F_{IO_2} is only estimated. Each liter per minute of O_2 flow delivered via nasal cannula increases the F_{IO_2} by about 4%. Flow rates >4 L/min through a nasal cannula are poorly tolerated because of upper airway irritation. A simple O_2 mask provides an F_{IO_2} of 35% to 60% at flows of 10 to 15 L/min. A nonrebreather mask with a reservoir can deliver 95% O_2 at a flow rate of 10 to 12 L/min.

Comparing the measured arterial concentration of oxygen to the expected concentration of oxygen can be useful for determining the nature and severity of respiratory disorders. The approximate arterial oxygen concentration (Pa_{O_2}) values that are expected in normal persons who are inhaling various concentrations of O_2 are listed in **Table 16-1**.

The expected Pa_{O_2} for a patient being given supplemental oxygen can be roughly estimated by multiplying the actual delivered percentage of O_2 by 5, the "**Five Times Rule**." Thus, a patient getting 60% O_2 would be

TABLE 16-1 Expected Pa_{O_2} in Patients Inhaling Various Concentrations of Oxygen (mm Hg)

Fraction of inspired oxygen	0.21 (room air)	0.4	0.6	0.8	1.0
~Pa_{O_2}*	105†	200	300	400	500

Abbreviation: Pa_{O_2} = partial pressure of arterial oxygen.

*Assuming a patient with normal lung function at sea level and a partial pressure of carbon dioxide (P_{CO_2}) of 40 mm Hg.

†Calculation demonstrates slight overestimation using this technique.

expected to have a Pao_2 of about 60 × 5, or 300 mm Hg. For every 1000 ft (305 m) rise in altitude, barometric pressure drops approximately 25 mm Hg, and the atmospheric partial pressure of oxygen (Po_2) drops about 5 mm Hg. The arterial oxygen estimate would therefore be reduced by the fraction of pressure at elevation compared to sea level. The total alveolar oxygen pressure cannot be greater than atmospheric pressure unless the patient is receiving positive-pressure ventilation. Further discussion of O_2 and ventilation at altitude and depth is found in chapters 221, "High-Altitude Disorders" and 214, "Diving Disorders."

ALVEOLAR GAS EXCHANGE AND SYSTEMIC DELIVERY

Once oxygen or carbon dioxide reaches the alveolus, it moves across the interstitial space to either the red blood cell or alveolar space, respectively. The efficiency of diffusion depends on the distance across the alveolar-capillary membrane (interstitial space), the partial pressure of the gas in the alveolar space, and the solubility of the gas. Both oxygen and carbon dioxide are highly soluble, and carbon dioxide is 20 times more soluble than oxygen. As a result, increases in the distance across the interstitial space (as in pulmonary edema, for example) have greater effect on oxygen diffusion than carbon dioxide (CO_2) diffusion. Gas diffusion requires functioning alveolar space, and conditions that damage the alveolus prevent effective oxygen and carbon dioxide transport. Additionally, the alveolar space must be perfused by the pulmonary circulation. When portions of lung are perfused but not ventilated (as in pneumonia), or ventilated but not perfused (as in pulmonary embolism), there is a *ventilation-perfusion mismatch*. Either scenario may lead to hypoxemia, the first as deoxygenated blood passes through the nonfunctional lung and mixes with oxygenated blood in the left atrium, and the second when too little perfused lung is available for adequate oxygen loading.

The effectiveness of alveolar oxygenation can be estimated either by the alveolar-arterial gradient or the Pao_2/Fio_2 ratio. The alveolar-arterial gradient is the difference between the partial pressure of oxygen in the alveolar space (estimated from Fio_2 at atmospheric pressure) and the measured partial pressure of the gas in an arterial blood gas sample. The alveolar-arterial (A-a) gradient can be estimated by the following simplified formula:

$$P(A\text{-}a)O_2 = 147 - (Paco_2 \times 1.25) - Paco_2$$

A normal gradient for young adults is <15 mm Hg. The gradient increases with age at a rate of approximately 4 to 8 mm Hg per decade or can be estimated with the following formula: age/4 + 4. The Pao_2/Fio_2 ratio correlates with the relative venous shunt across the pulmonary circulation and is calculated as the measured Pao_2 divided by the Fio_2 in decimal form. A healthy person on 40% oxygen would be expected to have a ratio of approximately 600, representing a normal physiologic shunt of approximately 5%. As the shunt increases, the ratio decreases. **Table 16-2** illustrates the fall in the Pao_2/Fio_2 ratio with increasing physiologic shunt in hypothetical patients all receiving oxygen with an Fio_2 of 40%.

TABLE 16-2 Interpretation of Pao_2/Fio_2

Pao_2 (mm Hg)	Fio_2 (mm Hg)	Ratio	QS/QT (%)	Impairment of Oxygenation
240	0.4	600	5	None
120	0.4	300	10	Minimal
100	0.4	250	15	Mild
80	0.4	200	20	Moderate
60	0.4	150	30	Severe*
40	0.4	100	40	Very severe*

Abbreviations: Fio_2 = fraction of inspired oxygen; Pao_2 = partial pressure of arterial oxygen; QS/QT = venous-arterial admixture (shunt).

*Ventilatory support and positive end-expiratory pressure to increase functional residual capacity and reduce the QS/QT to 15% should be considered.

The Pao_2/Fio_2 ratio is the most frequently used parameter for evaluating the severity of lung failure and is included in the current definition for acute lung injury/acute respiratory distress syndrome.[1] The amount of oxygen transported to the body is determined to the greatest extent by the total blood hemoglobin content and cardiac output. Relatively little oxygen is dissolved in the plasma itself. The arterial O_2 content of blood (Cao_2) can be calculated with the following formula (hemoglobin [Hb] in grams/dL, Pao_2 in mm Hg, and arterial oxygen saturation [Sao_2] expressed as a fraction of 1.0):

$$Cao_2 = [Hb \times 1.39 \times Sao_2] + (Pao_2 \times 0.0031)$$

As a result, systemic delivery of oxygen can only be practically modified by either increasing the hemoglobin content or oxygen saturation. Although increasing the hemoglobin by transfusion will increase O_2 content, various qualities of transfused blood limit its benefit to patients, and further discussion is beyond the scope of this chapter (see chapters 13, "Fluid and Blood Resuscitation in Traumatic Shock," and 238, "Transfusion Therapy").

Carbon dioxide is transported by the red blood cell as carbamino compounds bound to hemoglobin and other carbamino-containing proteins, as well as in the form of plasma bicarbonate. Most carbon dioxide (60% to 70%) combines with plasma water to form carbonic acid, which dissociates into bicarbonate and hydrogen ions. This reaction is catalyzed by carbonic anhydrase in the erythrocyte such that the reaction is almost instantaneous. The deoxygenated hemoglobin is a willing receptor for released hydrogen ions. As hemoglobin is oxygenated in the lung, hydrogen ions are released, driving the reaction back toward the production of CO_2.

ARTERIAL BLOOD GAS ANALYSIS

The amount of oxygen and carbon dioxide in the blood can be sampled and reported as the partial pressure of the gas. Blood gas analysis also typically includes a direct measurement of the serum pH and estimates of serum bicarbonate derived from the measured partial pressure of carbon dioxide (Pco_2) and pH (see chapter 15, "Acid-Base Disorders"). Current tests often include other useful information such as direct measurement of lactic acid as lactate, total hemoglobin, and serum electrolytes.

An arterial blood sample is the reference standard for pH, oxygen, carbon dioxide, and lactate content providing a description of the oxygen and CO_2 content of the blood after leaving the pulmonary circulation and before any gas exchange in the peripheral tissues has occurred. In scenarios that require precise determination of these variables, an arterial sample is necessary.

Arterial blood gas samples are sometimes used for evaluation of serum hemoglobin and electrolytes. Blood gas analyzers typically have good concordance with the reference venous sample; however, there may be clinically significant variances when the result falls outside the normal range. Arterial electrolytes and hemoglobin results should be interpreted with caution when the results are significantly abnormal.[2-6]

MIXED VENOUS BLOOD GAS ANALYSIS

Mixed venous blood samples provide a source of information regarding the systemic uptake of oxygen and can be used to calculate cardiac output. The ideal sampling site for a systemic venous sample is at the pulmonary artery because blood from all body sites is equally represented. Sampling blood from the pulmonary artery is limited to situations where the patient has a pulmonary artery catheter placed. More commonly, blood is sampled from the superior vena cava or right atrium after placement of a central venous catheter. Blood from the superior vena cava

disproportionally represents cerebral and upper body blood flow but is generally useful for determining systemic oxygen uptake and lactic acid production.

Regular monitoring of the venous O_2 saturation at the superior vena cava ($S_{cv}O_2$) or right atrium ($S_{ra}O_2$) is currently recommended as part of the Surviving Sepsis Campaign.[7,8] Although measurement of the O_2 saturation from a superior vena cava sample is acceptable within the guidelines, this location may not accurately reflect the $S_{ra}O_2$, and neither the $S_{cv}O_2$ nor the $S_{ra}O_2$ may accurately reflect the mixed venous O_2 saturation at the pulmonary artery (S_vO_2) for critically ill patients.[9-13]

PERIPHERAL VENOUS GAS ANALYSIS

Peripheral venous samples are commonly used as the source for gas analysis due to their relative ease of collection and decreased patient discomfort. The substitution of venous blood for an arterial sample is appropriate in particular clinical scenarios as described below.

Peripheral venous blood gases are commonly used to monitor serum pH. When compared to arterial blood gases, the peripheral venous pH correlates very closely such that any differences are not usually clinically significant (+/– 0.05 pH units).[14] Venous Pao_2 values do not correlate with arterial oxygen content and cannot be used for evaluation of oxygenation. Venous CO_2 values trend along with arterial CO_2, although they do vary somewhat (up to +/– 20 mm Hg). Normal venous CO_2 is predictive of normal $Paco_2$; however, the clinical outcomes of substituting venous CO_2 for evaluation of hypercarbia have not been described in the literature.[14-19]

It may be possible to derive a mathematical correction to venous blood gas values that better approximates arterial values. To date, no recognized validated approach has been identified.[20-24]

Peripheral venous estimations of serum lactate production are widely used for patient care; however, most studies describing the clinical utility of serum lactate reference an arterial or mixed venous sample. Peripheral venous lactate measurements correlate with arterial lactate; however, they are not equivalent, and a peripheral venous lactate level may be significantly higher than arterial lactate.[25-27]

NONINVASIVE OXYGEN MONITORING

It is not possible to directly measure the arterial oxygen concentration by noninvasive means. In the clinical context, the arterial oxygen saturation is often as helpful for patient management and treatment decisions. For the last 30 years, the standard bedside tool for estimating arterial oxygen saturation has been the photometric pulse oximeter.

Pulse oximetry measures the relative absorption of oxygenated hemoglobin and deoxygenated hemoglobin and reports the percentage of oxygenated hemoglobin compared to the total. Pulse oximetry is fairly accurate, typically within 2% to 5% of the directly measured value performed at blood gas analysis. Importantly, the discrepancy between peripheral pulse oxygenation results and arterial gas saturation increases with hypoxia and poor circulation. Pulse oxygenation values greater than 92% are highly predictive of arterial saturations greater than 90%.[28] Pulse oxygenation values between 88% and 92% do not necessarily reflect normal arterial saturations and may overestimate arterial oxygen saturation. The pulse oximeter may overestimate saturation when arterial saturations fall below 80% to 90%, and marginally normal values should be interpreted with caution.[29,30] Carbon monoxide also causes hemoglobin to conform to the saturated state and will cause a false elevation in measured saturation (see chapter 222).

Although clinically useful, pulse oximetry does not allow for determination of the partial pressure of oxygen in the arterial blood, which, in combination with total hemoglobin content, is the primary determinant of peripheral oxygen delivery. A basic understanding of the oxygen saturation/dissociation curve is essential for practicing clinicians when using pulse oximetry to guide clinical therapy (**Figure 16-1**). Most notably, arterial oxygen content declines precipitously when the oxygen saturation falls below 92%.

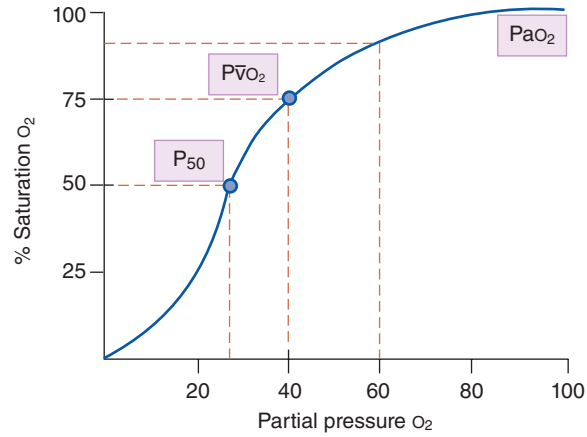

FIGURE 16-1. The oxyhemoglobin dissociation curve. This curve demonstrates the relationship of the partial pressure of oxygen (Po_2) in the plasma to the saturation of hemoglobin molecules with O_2. The P_{50} is the Po_2 at which hemoglobin is 50% saturated and correlates with Po_2 of 27 mm Hg normally. Normal mixed venous blood has an oxygen partial pressure ($Pmvo_2$) of 40 mm Hg and an oxyhemoglobin saturation of 75%. A partial pressure of arterial oxygen (Pao_2) of 60 mm Hg normally results in approximately 90% saturation of hemoglobin.

NONINVASIVE CARBON DIOXIDE MONITORING

The CO_2 content of arterial blood can be estimated by several noninvasive methods including direct transcutaneous measurement, cutaneous photometric measurement, or sampling of expired gases. Of these, only the later method is in common use in the ED.

Expired gases can be directly sampled to determine their CO_2 content. The carbon dioxide content of expired gases at the end of the expiration phase of respiration ($Etco_2$) proportionally approximates the $Paco_2$ content in healthy individuals because CO_2 rapidly diffuses into the alveolar space along its pressure gradient, and arterial levels are typically only about 5 mm Hg higher than alveolar samples when pulmonary ventilation and perfusion are functioning normally. The CO_2 content of the entire volume of expired gas can be photometrically assessed by means of a **mainstream** detector, or a sample of the expired gases can be aspirated from airway via a **side stream** detector. Mainstream detectors are larger and must be inserted into the ventilator loop, either in a ventilator circuit or with the patient breathing through a mask or other tube. Side stream detectors are smaller and have the advantage of ease of use in nonintubated patients. Interpretation of the capnogram is not necessarily intuitive. A summary of typical capnogram waveforms is described in **Figure 16-2**.

End-tidal CO_2 measurements ($PEtco_2$) do not accurately represent $Paco_2$. Mainstream and side stream sampling may each include air that has not been involved in the gas exchange process, either from physiologic dead space or via environmental air that enters the sample. In either case the $PEtco_2$ value will be lower than the arterial value. End-tidal CO_2 measurement is not as useful in obstructive pulmonary disease due to incomplete expiration of gases secondary to air trapping. In a study of ED patients with chronic obstructive pulmonary disease, end-tidal measurements did not significantly vary from presentation to admission and were not clinically different for patients discharged home as compared to those requiring admission.[31] Studies assessing the accuracy of $Etco_2$ measurements compared to arterial sampling are mixed. In one study of patients presenting to the ED with undifferentiated dyspnea, mainstream $PEtco_2$ did correlate closely with $Paco_2$.[32] In a comparison of healthy individuals, neither mainstream nor side stream sampling accurately predicted the arterial Pco_2.[33] A convenience sample of ED patients with an indication for arterial blood gas did not have a close correlation of side stream $Etco_2$ with the $Paco_2$.[34] The precise role

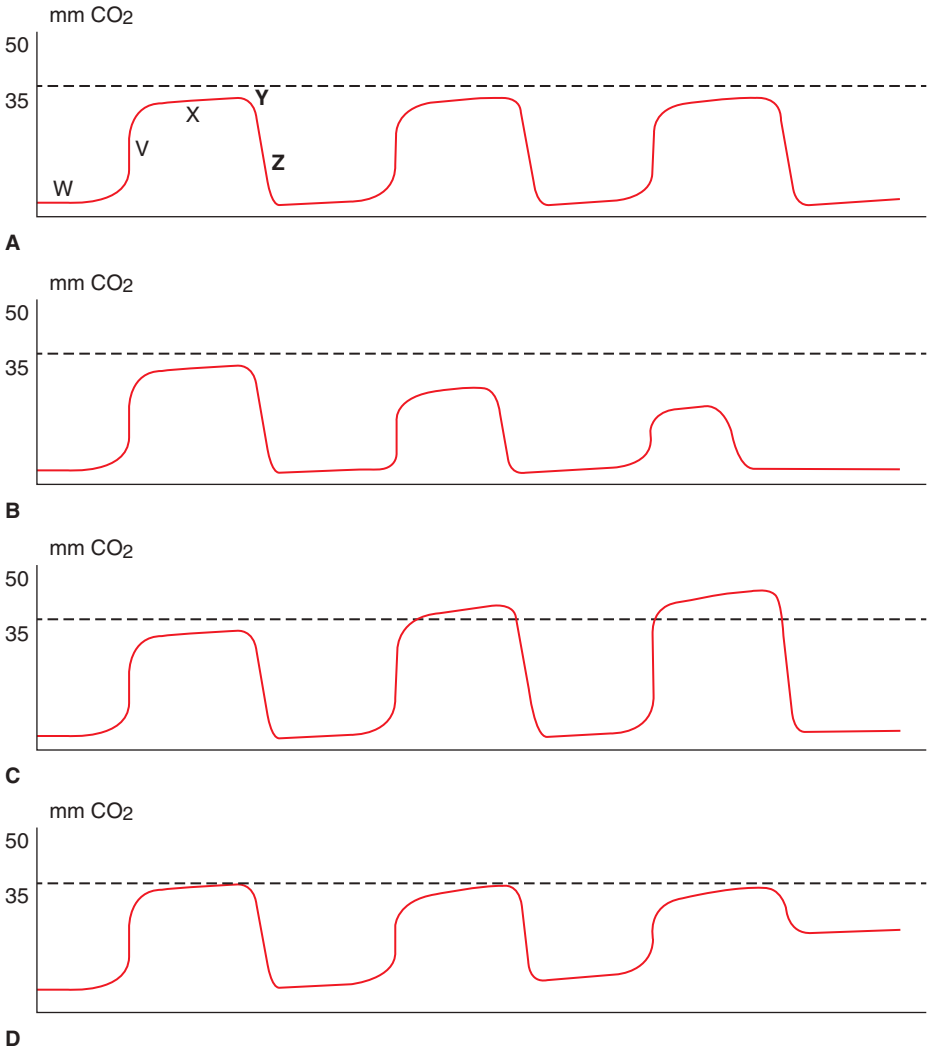

FIGURE 16-2. End-tidal capnogram. Capnogram **A** depicts a normal capnogram with inspiratory baseline (V), expiratory upstroke (W), expiratory plateau (X), end-tidal concentration (Y), and inspiratory downstroke (Z). Capnogram **B** represents apnea, which appears as serially decreasing end-tidal concentrations as little gas is expired. Capnogram **C** represents hypoventilation, which appears as an upward trend in the plateau and end-tidal concentration. Capnogram **D** represents rebreathing or air trapping, which appears as an increase in the baseline phase of the capnogram.

for $Etco_2$ measurements in the management of critically ill patients in the ED or intensive care unit is still to be determined.[35]

CHAPTER 17

Fluids and Electrolytes

Roberta Petrino
Roberta Marino

FLUIDS AND SODIUM

PATHOPHYSIOLOGY

Total body water (TBW), which accounts for approximately 60% of total body weight, can be divided into intracellular fluid (ICF) and extracellular fluid (ECF) compartments. The ECF is comprised of intravascular fluid and extravascular, or interstitial, fluid. Body fluid compartment proportions for an adult are diagrammed in **Figure 17-1**. **Figure 17-2** presents the individual characteristics of each compartment. Three fundamental homeostatic equilibriums govern the behavior of fluids: the osmotic equilibrium, the electric equilibrium, and the acid-base equilibrium.

The key point is that sodium is much more concentrated in the ECF (~140 mEq/L) than in the ICF (~10 mEq/L) but is equal in both compartments of the ECF because the capillary membrane between intravascular fluid and interstitial fluid is permeable to water and electrolytes. In contrast, the cell membrane is permeable to water but not to electrolytes, which are moved through ionic pumps against gradient to keep the intracellular sodium concentration constant around 10 mEq/L and potassium at 150 mEq/L. **Table 17-1** lists the electrolyte concentration of body fluids and the most commonly used therapeutic solutions. **Table 17-2** defines commonly used terms that describe measures or characteristics of electrolytes and/or disorders.

When two solutions are separated by a membrane that is permeable only to water, water crosses into the compartment with the more concentrated solution to equalize the ion concentration in each. The force driving this movement is "osmotic pressure."[1] In human fluids, the substances that contribute the most to osmotic pressure in ECF are Na^+ and the anions HCO_3^- and Cl^-, plus glucose. In physiology, this force is called *effective osmolality* or *tonicity*. This force is not affected by molecules like urea that may enter freely into the cells. The formula to calculate **effective osmolality** or **tonicity** is

$2 \times [Na] + glucose/18$ (normal range, 275–290 mOsm/L)

If values are in SI units, these are already molar (mmol/L, for example), so these do not need to be divided by their molecular weight.

As a function of	TBW	ICF	ECF	IF	IVF
Total weight	60%	40%	20%	15%	5%
TBW		67%	33%	25%	8%
ECF compartment				75%	25%

†Multiply by 0.25 to convert to SI units in mmol/L.
‡Multiply by 0.323 to convert to SI units in mmol/L.

When 1 L of free water is added to the ECF it crosses the cell membrane into the ICF to equalize ECF osmolality. The result is TBW expansion and slight reduction in osmolality (**Figure 17-3**). When 1 L of isotonic saline solution 0.9% is added to the ECF, there is no movement of water into the cells, and the final result is ECF expansion only[2] (Figure 17-3).

In contrast, when there is a fluid loss and a consequent increase in osmolality, the subject feels thirsty and the antidiuretic hormone (ADH) is secreted by the pituitary gland stimulated by baroreceptors and osmoreceptors, with a consequent urine water reabsorption and vasoconstriction.[1-3]

TABLE 17-2 Definition of Terms

Term	Definition	Comments
Mole	6.02×10^{23} molecules of a substance	Unit measure used in International System of Units format.
Equivalent	Mass (in grams) of a mole of a substance divided by charge of substance	Unit of measure used in conventional lab values.
Osmole	Amount of a substance (in moles) that dissociates to form 1 mole of osmotically active particles	
Osmolarity	Measure of solute concentration per unit *volume* of solvent	Osmolarity varies with changing temperature, because water changes its volume according to temperature.
Osmolality	Measure of solute concentration per unit *mass* of solvent	Osmolality is the preferred term because it remains constant with changes in temperature.
Tonicity or effective osmolality	Measure of the osmotic pressure gradient between two solutions, across a semipermeable membrane	Tonicity is affected only by solutes that cannot cross a semipermeable membrane. For example, tonicity is not affected by urea or glucose as they cross semipermeable membranes

A useful index to roughly evaluate Na^+ balance and the ability of the kidney to concentrate or dilute the urine is the **electrolyte free water clearance (CH_2Oe)**.[2] It is expressed with the formula:

$$_CH_2Oe = V_{urine}(1 - U_{Na+} + U_{K+}/P_{Na+})$$

where V_{urine} is urine volume, U_{Na+} is the urine sodium level, U_{K+} is the urine potassium level, and P_{Na+} is the plasma sodium level. When more water is reabsorbed, $_CH_2Oe$ is negative and hyponatremia will develop. When more water is excreted, $_CH_2Oe$ is positive and hypernatremia will be present. The $_CH_2Oe$ is calculated using a 24-hour urine collection, which is not possible in the ED. The spot urine calculation of the ratio, $U_{Na+} + U_{K+}/P_{Na+}$, is a reliable compromise. In hyponatremia, the ratio is >1, and in hypernatremia it is ≤0.5. A ratio between 0.5 and 1 is considered normal.

HYPONATREMIA

The human body tightly maintains serum $[Na^+]$ between 138 and 142 mEq/L despite what may be marked changes in daily intake depending on the person's diet. Hyponatremia is a condition of excess water relative to Na^+ and is defined as a serum $[Na^+]$ <138 mEq/L. However, symptomatic hyponatremia rarely occurs until $[Na^+]$ falls below 135 mEq/L or lower. In the setting of normal water intake, high circulating levels of ADH with subsequent water retention is a prerequisite for the development of hyponatremia.[3] Urine osmolality is always >100 mOsm/L H_2O with the exception of samples from patients with psychogenic polydipsia, which drives down urine osmolality below the typical minimum.

EPIDEMIOLOGY

Mild hyponatremia is common, with an incidence of 15% to 30% in hospitalized patients; only 1% to 4% of patients have sodium levels below 130 mEq/L.[4,5] Approximately 50% of cases are iatrogenic from administration of hypotonic fluids.[4,5]

CLASSIFICATION AND ETIOLOGY

The concentration of Na^+ does not give information regarding volume status. **Therefore, the first step in the evaluation should include a clinical evaluation of ECF volume status plus measured and calculated plasma osmolarities.** In *true* hyponatremia, plasma osmolality is reduced; in *factitious* hyponatremic states, it is normal or increased as shown in **Table 17-3**.[2]

HYPEROSMOLAR HYPONATREMIA (P_{osm} >295 mOsm/kg H_2O)

Hyperosmolar hyponatremia occurs when large quantities of osmotically active solutes accumulate in the ECF space. In this setting, there is a net movement of water from the ICF to the ECF, thereby effectively diluting the ECF $[Na^+]$. **This happens commonly with severe hyperglycemia.** Each 100 milligram/dL increase in plasma glucose above the normal level of 100 milligrams/dL decreases the serum $[Na^+]$ by 1.6 mEq/L.[1-4] Other causes of hypertonic hyponatremia are administration of osmotic agents like mannitol, glycerol, and maltose, causing an osmolar gap and hyponatremia. The osmolar gap is the difference between measured osmolality and calculated osmolality. Normally the difference is around 10 mOsm/L; if it is >15 mOsm/L it means that a nondetectable agent with osmotic activity is present, causing an osmolar gap. A consequent osmotic diuresis will cause $[Na^+]$ deficit with volume depletion that must be treated with saline solution. Other substances like methanol, alcohol, ethylene glycol, and urea, although causing an osmolar gap, do not cause water movement across membranes and therefore do not cause hyponatremia (see chapter 185, "Alcohols" in Toxicology section for more details).[2]

ISO-OSMOLAR HYPONATREMIA (P_{osm} 275 TO 295 mOsm/kg H_2O)

Pseudohyponatremia is a factitiously low value of $[Na^+]$ that may occur in the setting of severe hyperproteinemia or hyperlipidemia. This phenomena is due to displacement of serum water by an elevated concentration of lipids or protein creating laboratory misinterpretation

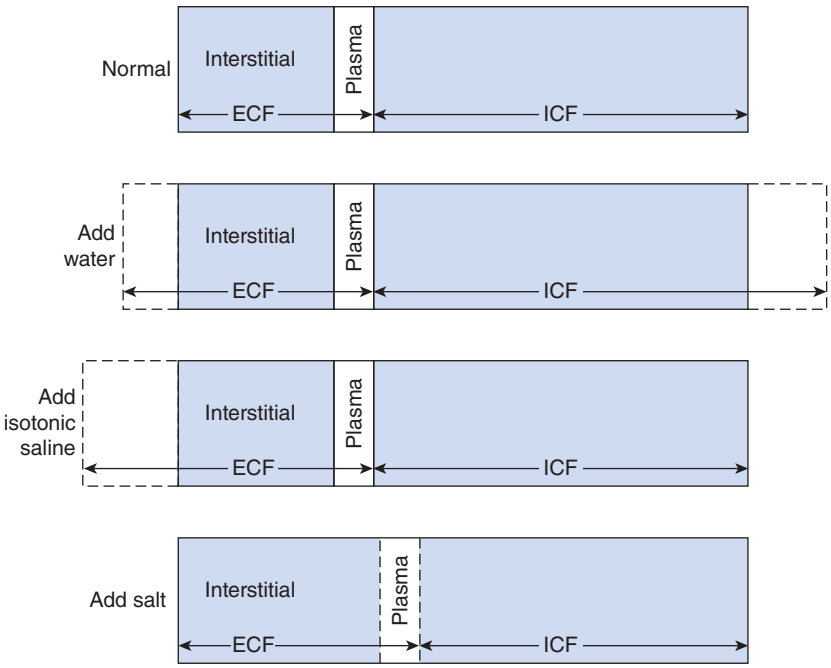

FIGURE 17-3. Distribution of total body water into the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. Addition of water expands both compartments. Addition of isotonic saline expands only the ECF, whereas addition of salt without water expands the ECF at the expense of the ICF. [Reproduced with permission from Eaton DC, Poole JP (eds): *Vander's Renal Physiology*, 8th ed. McGraw-Hill, Inc., 2013. Fig 6-1.]

of normal [Na+]; some laboratories use instruments that avoid this laboratory error; check with your laboratory administrator. Patients are asymptomatic; treatment is not needed.

HYPO-OSMOLAR HYPONATREMIA (P_{osm} <275 mOsm/kg H_2O)

In **Table 17-4**,[6] the different causes of hypo-osmolar (hypotonic) hyponatremia according to volume status are listed.[2,3] Hyponatremia develops due to an increase in ADH secretion and activity, which causes impaired water excretion and increased water reabsorption. In situations like heart failure,[7,8] cirrhosis,[9] and nephrotic syndrome, the effective arterial blood volume is decreased because water is mainly distributed to the interstitial space. Thus Na^+ and water reabsorption are increased, and water excretion is reduced.

Two important hyponatremic disorders are the **syndrome of inappropriate ADH secretion** and the less common **cerebral salt-wasting syndrome.**[1,2] Both conditions are diagnoses of exclusion after dismissing other causes of hyponatremia. The onset of both syndromes is linked to chronic cerebral disease, but syndrome of inappropriate ADH secretion may also be caused by many other diseases and conditions as described in **Table 17-5**. In syndrome of inappropriate ADH secretion, volume status is normal, whereas in cerebral salt-wasting syndrome, there is hypovolemia; therefore, these two disorders are treated differently (see treatment section below).

Methylenedioxymethamphetamine (MDMA or Ecstasy) intoxication is an uncommon but important cause of hyponatremia that may be profound. This "club drug" induces inappropriate secretion of ADH and causes increased gut water absorption[10] (see also chapter 188, "Hallucinogens").

TABLE 17-3 Classification of Hyponatremia According to Serum Osmolality

Serum Osmolality	Clinical Conditions	Mechanisms
Hyperosmolality (Hypertonic hyponatremia)	Hyperglycemia Mannitol administration Glycerol administration Maltose administration	Hyponatremia due to osmotic diuresis
Iso-osmolality (Pseudohyponatremia)	Hyperproteinemia Hyperlipidemia	Displacement of serum water by elevated concentration of lipids or protein creating laboratory misinterpretation of normal [Na^+]
Hypo-osmolality (Hypotonic hyponatremia)	See Table 17-4	Hypervolemic Normovolemic Hypovolemic

CLINICAL FEATURES

The most important symptoms of hyponatremia are due to its effects on the brain; symptoms can be divided into moderately severe and severe, according to a European clinical practice guideline.[3,4] Moderately severe symptoms often start when a plasma [Na] is <130 mEq/L and consist of headache, nausea, disorientation, confusion, agitation, ataxia, and areflexia. When [Na^+] reach levels <120 mEq/L, severe symptoms may develop including intractable vomiting, seizures, coma, and ultimately respiratory arrest due to brainstem herniation. Brain injury may become irreversible. The symptoms of hyponatremia can be due to many other conditions, and clinicians are cautioned to consider other etiologies before making treatment decisions.[4] The presence of hyponatremia-related symptoms is directly related to the rapidity of onset. After a certain period, brain cells begin to adapt to hyponatremia. Initially the hypo-osmolality drives water into the brain cells yielding swelling.[2,3] Due to the rigid skull, intracranial hypertension occurs and the described symptoms begin. After 48 hours, the brain cells start to adapt by extruding Na^+, K^+, Cl^-, and organic osmolytes like glycine and taurine from the cells, reducing cell osmolality and preventing further water uptake. In several clinical or physiologic conditions, this adaptation mechanism is impaired, as in the syndrome of inappropriate ADH secretion, in children, in menstruating women, and in hypoxia. In such cases, symptoms are more severe and persistent.

DIAGNOSIS

The diagnosis of hyponatremia and its subtypes is based on the clinical findings of volume status in association with specific laboratory values including serum [Na^+], serum osmolality, volume status, urinary sodium (U_{Na+}), and urine osmolality (U_{osm}). Acute and chronic hyponatremia are defined by an onset time of less than (acute) or greater than (chronic) 24 to 48 hours. Experts recommend that when duration is unknown, the hyponatremia should be assumed to be chronic and treated as chronic with a longer correction time. If urine osmolality is not readily available from the laboratory, it can be estimated using urinary specific gravity (π). Consider the numerals in the hundredths and thousandths decimal places of the π as whole numbers and multiply them by 35 to obtain U_{osm}. As an example, for a π of 1.0<u>05</u>, $U_{osm} = 05 \times$

TABLE 17-4 Classification, Differential Diagnosis, and Features of Hyponatremia According to Volume Status

	Clinical Conditions	Orthostatic Hypotension	Edema	$U_{(Na^+)}$, mEq/L*	U_{osm}, mOsm/L*
Hypervolemic hypernatremia	CHF Cirrhosis Nephrotic syndrome Acute and chronic kidney disease	Absent	Yes	Compensated: >20 Decompensated: <10	Compensated: <100 Decompensated: >100
Normovolemic hyponatremia	Psychogenic polydipsia Glucocorticoid deficit Hypokalemia Drugs SIADH	Absent	No	>20	>100
Renal hypovolemic hyponatremia	Diuretics Mineralocorticoid deficit Salt-losing nephropathy	Normally present	No	>20	>100
Extrarenal hypovolemic hyponatremia	Vomiting Diarrhea	Normally present	No	<10	>100

Abbreviations: CHF = congestive heart failure; SIADH = syndrome of inappropriate ADH excretion.

35 = 175 mOsm/L.[1] Table 17-4 lists the values of U_{Na^+} and U_{osm} in different classifications of hyponatremia according to volume status and the differential diagnosis for each classification. As a rule, only in patients with edematous syndromes and in patients with vomiting and diarrhea will U_{Na^+} be found to be <10 mEq/L.[6] The diagnostic criteria for syndrome of inappropriate ADH secretion are listed in **Table 17-6**.

Use care when assessing patients with potential exercise-associated hyponatremia. Since the worldwide effort to encourage consuming fluids during endurance exercise beginning in the early 1980s, overhydration with hypotonic fluids is now being seen. If a postexercise athlete presents with bloating, nausea, vomiting, and edema (check wrists and fingers), consider hyponatremia; dehydration presents with excessive thirst, sunken eyes, poor skin turgor, and postural hypotension.

TABLE 17-5 Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion

1. Neurologic and psychiatric disorders
   a. Infections: meningitis, encephalitis, brain abscess
   b. Vascular: thrombosis, subarachnoid or subdural hemorrhage, temporal arteritis, cavernous sinus thrombosis, stroke
   c. Malignancy: primary or metastatic
   d. Traumatic brain injury
   e. Psychosis, delirium tremens
   f. Other: Guillain-Barré syndrome, neurosurgery
2. Drugs
   a. Cyclophosphamide
   b. Carbamazepine
   c. Vinca alkaloids
   d. Thioridazine, other phenothiazines, haloperidol
   e. Selective serotonin reuptake inhibitors and selective serotonin and norepinephrine reuptake inhibitors
   f. Bromocriptine
   g. Narcotics, opiate derivatives
   h. Amiodarone
   i. Desmopressin overtreatment of DI or enuresis
3. Lung diseases
   a. Tuberculosis
   b. Lung abscess, empyema
   c. Acute respiratory failure
4. Non-CNS tumors with ectopic production of vasopressin
   a. Carcinoma of lung (small cell, bronchogenic), duodenum, pancreas, thymus, olfactory neuroblastoma, bladder, prostate, uterus
   b. Lymphoma, leukemia
   c. Sarcoma

Abbreviations: DI = diabetes insipidus.

TREATMENT

Treatment of hyponatremia is guided by four variables: severity of symptoms, rate of onset, volume status, and the current serum $[Na^+]$. **When $[Na^+]$ is <120 mEg/L, the patient presents with severe neurologic symptoms, and hyponatremia is acute, the initial treatment includes infusion of 3% hypertonic saline** as recommended by European guidelines,[4] and U.S. experts[5,11] (**Table 17-7**).

Raising serum sodium by 4 to 6 mEq/L is typically all that is required to see an improvement in severe neurologic symptoms.[4,11,12] The volume of a saline solution required to raise the serum sodium the desired amount can be calculated. First calculate the expected change in serum sodium from the infusion of a liter of saline solution. Second, determine the portion of the liter required to raise the sodium the desired amount. To calculate the expected change in serum sodium after an infusion of 1 L IV saline, use the following formula:

$$\textbf{Expected change in serum } Na^+ \textbf{ (mEq/L)} =$$

$$\textbf{Infusate } Na^+ \textbf{ (mEq/L)} - \textbf{serum } Na^+ \textbf{ (mEq/L)}/(\textbf{TBW} + 1)$$

Estimate TBW based on age, sex, and weight of the patient. For children and adult males <65 years old, TBW is 60% of the weight; for adult females <65 years old and elderly males, TBW is 50% of the weight; for elderly females, TBW is 45% of weight. Three percent hypertonic saline contains 513 mEq/L of sodium. As an example, a clinician desires to

TABLE 17-6 Syndrome of Inappropriate Secretion of Antidiuretic Hormone Diagnostic Criteria

Diagnostic Criteria
Hypotonic hyponatremia with (P_{osm} <275 mOsm/kg H_2O)
Inappropriately elevated urinary osmolality (usually >200 mOsm/kg)
Elevated urinary $[Na^+]$ (typically >20 mEq/L)
Clinical euvolemia
Normal adrenal, renal, cardiac, hepatic, and thyroid functions

TABLE 17-7 Treatment for Hyponatremia Symptomatic with Seizures or Coma

Step 1	Assess for indication for 3% hypertonic saline: severe symptoms of hyponatremia such as seizures or coma with suspected impending brainstem herniation in setting of acute* or chronic† hyponatremia
Step 2	Infuse 100 mL of 3% hypertonic saline IV over 10–15 min‡
Step 3	Measure serum sodium level after each 3% hypertonic saline infusion
Step 4	Stop infusion when symptoms improve, or a target of 5 mEq/L (range 4–6 mEq/L) increase in serum sodium concentration is achieved.
Step 5	May repeat 100 mL of 3% hypertonic saline up to three total doses, or a total of 300 mL IV of 3% hypertonic saline.
Step 6	Keep the IV line open with minimal volume of 0.9% normal saline until cause-specific treatment is started. Limit increase in sodium level to no more than 8 mEq/L during the first 24 h.

*Both European guidelines and U.S. expert panel recommend 3% hypertonic saline infusion for acute life-threatening hyponatremia, which is most commonly due to self-induced water intoxication during endurance exercise, psychiatric illness, in association with methylenedioxymethamphetamine intoxication, or intracranial pathology or increased intracranial pressure.

†European guidelines state that regardless of onset of acute or chronic hyponatremia, presence of seizures or coma is an indication for brief infusion of hypertonic saline to improve symptoms.

‡European guidelines recommend a prompt 150-mL 3% hypertonic saline infusion over 20 minutes, then checking the serum sodium concentration after 20 minutes while repeating an infusion of 150 mL 3% hypertonic saline for the next 20 minutes, repeating this sequence up to twice more, and stopping with clinical improvement or when target sodium level is reached.

raise the sodium level of a 68-year-old male having seizures secondary to a [Na^+] of 108 mEq/L, using 3% hypertonic saline. The man weighs 70 kg; therefore, the calculated TBW would be [$0.5_{\text{correction factor}} \times 70$ kg] = 35 L. Change in [Na^+] expected = (513 – 108)/(35 + 1) = 11.25 mEq rise in serum sodium if the man was given 1000 mL of 3% hypertonic saline. The fraction of the liter of 3% hypertonic saline required to raise serum sodium 5 mEq/L would be 444 mL of 3% hypertonic saline.

After clinical improvement in severe symptoms, the 3% hypertonic saline must be stopped and either continued at a slower rate or with a different [Na^+] in the solution. For patients with acute hyponatremia with mild or moderate symptoms, 3% hypertonic saline infusion at 0.5 to 2 mL/kg/h can be given with frequent [Na^+] checks every 2 hours. Na^+ and K^+ lost in urine should be replaced with the appropriate solution.[1,2]

In chronic hyponatremia, the [Na^+] correction should be slower than for acute hyponatremia. Rapid correction increases risk for the most dangerous complication of treatment, the osmotic demyelination syndrome. For **chronic hyponatremia [Na^+], the correction rate should not exceed 6 mEq/24 h** in high-risk patients and 12 mEq/24 h in low-risk patients (see "Osmotic Demyelination Syndrome" section below for risks).[3,4] Hypertonic (3%) saline can be given at a low infusion rate, 0.5 to 1 mL/kg/h, with frequent [Na^+] checks. Isotonic (0.9%) saline is frequently used (sometimes before the [Na^+] is known), especially for the treatment of mild hyponatremia; however, the additional fluid load must be accounted for in treatment calculations. Loop diuretics (primarily furosemide, starting with a small dose of 20 milligrams IV) may be used in addition to treatment with saline infusions. Urine volume and [Na^+] should be strictly measured. Specific recommendations for hyponatremia treatment are summarized in **Table 17-8**.[2]

COMPLICATIONS OF TREATMENT

Osmotic Demyelination Syndrome Osmotic demyelination syndrome is caused by rapid correction of hyponatremia (>12 mEq/L/24 h) as water moves from cells to ECF yielding intracellular dehydration (**Figure 17-4**). Risk factors for osmotic demyelination syndrome include [Na^+] <120 mEq/L, chronic heart failure, alcoholism, cirrhosis, hypokalemia, malnutrition, and treatment with vasopressin antagonists such as tolvaptan. Main symptoms are dysarthria, dysphagia, lethargy, paraparesis or quadriparesis, seizures, coma, and death. The treatment of [Na^+] overcorrection is rarely done in the ED but consists of giving 5% dextrose in water at 3 mL/kg/h, loop diuretics, and desmopressin.[3,4]

HYPERNATREMIA

Hypernatremia is defined as serum or plasma **[Na^+] >145 mEq/L and hyperosmolality** (serum osmolality >295 mOsm/L).

TABLE 17-8 Cause-Specific Treatment for Hyponatremia

Clinical Condition	Therapy	Cautions/Comments
Chronic heart failure and cirrhosis	Loop diuretics, water restriction. Consider vasopressin antagonists* if the above therapies fail for patients with chronic heart failure.	When vasopressin antagonists* are used serum [Na^+] should be frequently measured to avoid hypernatremia. FDA recommends against vasopressin antagonists in patients with liver disease.
Nephrotic syndrome	Water restriction	
Acute or chronic kidney disease	Water restriction	Frequent assessment of creatinine
Psychogenic polydipsia	Water restriction	Treat the underlying psychiatric disease
Hypothyroidism	Levothyroxine	Several days of therapy are typically required to correct hyponatremia.
Glucocorticoid deficiency	Hydrocortisone. If neurologic symptoms, consider vasopressin antagonists* if resistant to hydrocortisone.	When vasopressin antagonists* are used, [Na^+] should be frequently measured.
SIADH	Water restriction. Enhanced Na^+ and protein intake + furosemide. Vasopressin antagonists* can be used for [Na^+] <125 mEq/L. Demeclocycline. Lithium.	Isotonic (0.9%) NaCl may worsen hyponatremia; when vasopressin antagonists* are used, [Na^+] should be frequently measured.
Diarrhea and vomiting	Isotonic (0.9%) NaCl. Add KCl if hypokalemia is present.	Treat the cause, monitor hemodynamic status
Diuretics (most commonly thiazides)	Stop diuretic. KCl may be sufficient in patients with coexistent potassium depletion and normal dietary sodium intake. NaCl can be given orally.	Slow correction is recommended. Do not overcorrect K^+ deficit.
Mineralocorticoid deficiency	Replace volume deficit. Fludrocortisone therapy is indicated once diagnosis is confirmed.	Mechanism: volume depletion → ↑ ADH → decreases water excretion, ↑ Na loss
Salt losing nephropathies	Isotonic (0.9%) NaCl.	
Cerebral salt wasting	Isotonic (0.9%) NaCl. Fludrocortisone may be considered after the diagnosis is confirmed.	NaCl orally at home

Abbreviations: ADH = antidiuretic hormone; FDA = Food and Drug Administration; SIADH = syndrome of inappropriate antidiuretic hormone secretion.

*Vasopressin antagonists or vaptans are rarely started in the ED; they are not indicated unless [Na^+] <125 mEq/L; starting doses are tolvaptan, 15 milligrams PO daily; and conivaptan, 20 milligrams loading dose IV over 30 minutes, then continuous infusion of 20 milligrams over 24 hours for 2 to 4 days.

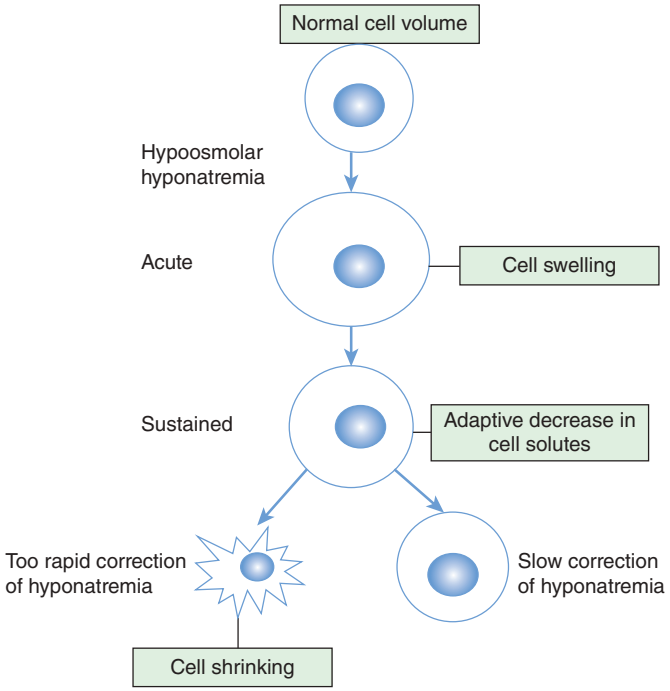

FIGURE 17-4. Adaptation of brain volume to hyponatremia and effect of correction.

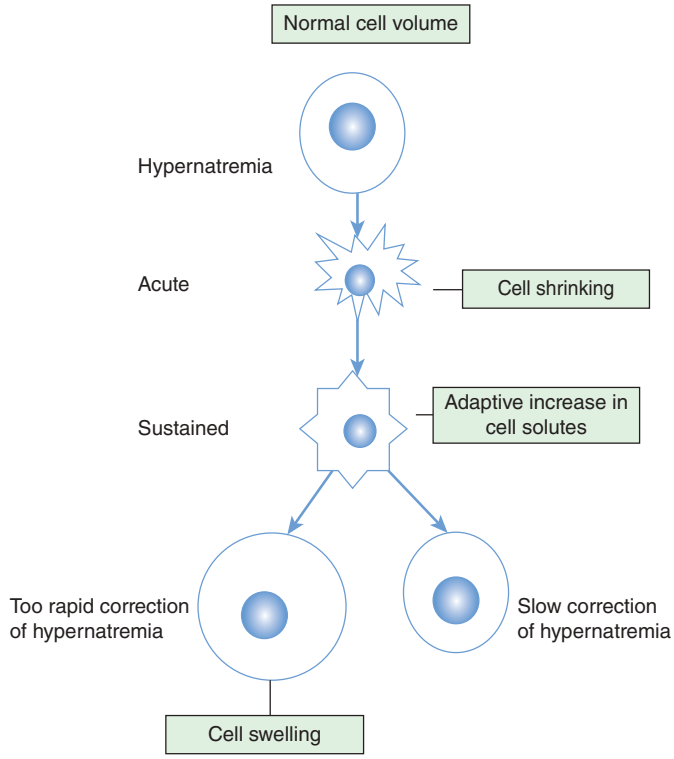

FIGURE 17-5. Adaptation of brain volume to hypernatremia and effect of correction.

PATHOPHYSIOLOGY

Hypernatremia results from a deficit in TBW and/or a net gain of Na^+ (less common). When $[Na^+]$ and osmolality increase, normal subjects become thirsty, drink free water, and the Na^+ level returns toward normal. Any clinical situation that impairs the patient's sense of thirst, limits the availability of water, limits the kidney's ability to concentrate urine, or results in increased salt intake predisposes the patient to hypernatremia. Elderly patients, decompensated diabetics, infants, and hospitalized patients are at particular risk of developing hypernatremia. In addition, hypernatremia may be the result of loss of free water in diarrheal stools or in the urine.[13]

As in hyponatremia, symptoms will be more severe and evident when the onset is rapid; after the first 48 hours, there is an adaptation of brain cells with an increase in electrolytes and organic osmolytes and thus increased intracellular water partly correcting the initial cell shrinking (**Figure 17-5**).

If severe hypernatremia develops in the course of minutes to hours, such as from a massive salt overdose in a suicide attempt, a suddenly shrinking brain may prompt intracranial hemorrhage. While the causes of hypernatremia are many, leading to varied signs and symptoms, the most serious manifestations are related to changes in the brain. If hypernatremia is corrected too rapidly, cerebral edema and potentially central herniation may occur.

CLASSIFICATION AND ETIOLOGY

Based on volume status, hypernatremia may be classified as hypovolemic hypernatremia (decreased TBW and total body Na^+ with a relatively greater decrease in TBW), hypervolemic hypernatremia (increased total body Na^+ with normal or increased TBW), or normovolemic hypernatremia (near normal total body sodium and decreased TBW)[1,2] (**Table 17-9**).

CLINICAL FEATURES

History depends on hypernatremia type and may reveal nausea and vomiting, lethargy, weakness, increased thirst, low water intake, salt intake, polyuria (>3000 mL of urine/24 h), diabetes, hypercalcemia, hypokalemia, medications such as lactulose, loop diuretics, lithium, demeclocycline (may cause nephrogenic diabetes insipidus), or nonsteroidal anti-inflammatory drugs (may cause interstitial nephritis). Physical exam may reveal hypotension, tachycardia, orthostatic blood pressures, sunken eyes, dry mucous membranes (symptoms of hypovolemia) altered mental status (may be present in any the hypernatremia classifications), poor skin turgor, or edema in hypervolemic hypernatremia (Table 17-9). Without intervention, coma, seizures, and shock may occur. Signs of Cushing's syndrome may be present, including moon facies, fatty deposits between the shoulders and upper back, and thinning of the skin.

DIAGNOSIS

The diagnosis of hypernatremia and its classification are based on the clinical evaluation including volume status and specific laboratory tests, including serum electrolytes and osmolality, urine osmolality, urea/creatinine ratio, and free water deficit. A BUN/creatinine ratio >40 is indicative of hyperosmolar dehydration. The free water deficit[1,2] may be calculated with the formula:

$$\textbf{Free water deficit} = \textbf{TBW} \times \textbf{P}_{\textbf{osm}} - 285/\textbf{P}_{\textbf{osm}}$$

where TBW is calculated using age and sex (giving a correction factor for body water) times weight in kilograms (see hyponatremia treatment section for scale), $P_{osm} = 2 \times [Na^+]$ + glucose/18, and 285 is used as normal plasma osmolality. As an example, a 60-kg woman with a $[Na^+]$ of 165 mEq/L and glucose of 130 milligrams/dL has a free water deficit calculated as follows: TBW = 0.5 × 60 = 30; P_{osm} = (2 × 165 = 330) + (130/18 = 7.2) = 337.2 mOsm/kg H_2O; free water deficit = 30 × (337.2 – 285)/337.2 = 4.64 L. Urine osmolality can be used to suggest the type of hypernatremia (**Table 17-10**). If urine osmolality is not readily available, it can be estimated using urine specific gravity (π). Consider the numerals in the hundredths and thousandths decimal places of the π as whole numbers and multiply them by 35 to estimate U_{osm}.

TREATMENT

First, shock, hypoperfusion, or volume deficits should be treated with isotonic (0.9%) saline. Second, treat any existing underlying cause,

TABLE 17-9 Hypernatremia Classification and Features According to Volume Status

	Clinical Conditions	Orthostatic Hypotension	Edema	$U_{[Na^+]}$, mEq/L	U_{osm}, mOsm/kg H_2O
Hypervolemic hypernatremia	Cushing's syndrome Primary hyperaldosteronism Salt water intake Iatrogenic	Absent unless treated with diuretics	Yes	Compensated >20	>100
Normovolemic hypernatremia	DI Central DI Partial DI Gestational DI Nephrogenic DI Hypodipsia	Absent	No	>20	Central DI <300 Partial DI >300 but <800
Renal hypovolemic hypernatremia	Osmotic diuretics Loop diuretics Postobstructive diuresis	Normally present	No	>20	>100
Extrarenal hypovolemic hypernatremia	Vomiting Diarrhea GI fistulas Sweating Burns	Normally present	No	<10	>800

Abbreviation: DI = diabetes insipidus.

such as diabetes insipidus (see "Diabetes Insipidus" section below) vomiting, diarrhea, or fever. Third, correct the patient's free water deficit at a rate reflecting the acuity or duration time of the hypernatremia onset (**Table 17-11**).[11,14,15] In cases of a lethal sodium chloride ingestion/load (0.75 to 3.0 grams/kg) less than 6 hours prior to presentation, FWD may be replaced rapidly with no reported adverse events.[11,14] Management requires evaluating volume status and the free water deficit (see formula above in diagnosis section). When the adaptation of brain cells is incomplete (onset over <48 hours), the correction rate of acute hypernatremia can be performed at a rate of 1 mEq/L/h. In an alert patient capable of safely drinking water, the route of administration should be two-thirds free water orally and one-third IV. If hypernatremia is chronic (onset over >48 hours), the rate of correction should be slower, to avoid the risk of cerebral edema, at no more than 0.5 mEq/L/h or 10 to 12 mEq/24 h.[11,16]

DIABETES INSIPIDUS

Diabetes insipidus is a disease where the ability of the kidney to reabsorb free water is compromised.[2,17] The disorder is characterized by polyuria, polydipsia, and an increased volume of hypo-osmolar urine. Hypernatremia is present only when the thirst center is impaired or water intake is reduced. Diabetes insipidus can be central (also called neurogenic), due to inadequate ADH secretion, or renal (also called nephrogenic), when ADH secretion is normal or increased but the v2R receptors of the kidney's collecting duct cells do not respond appropriately to ADH. Diabetes insipidus may be congenital or acquired. In **Table 17-12**, the main causes of diabetes insipidus are listed. Congenital forms of diabetes insipidus present during infancy. Eventually, recurrent cellular dehydration causes cerebral calcifications that manifest as delayed intellectual advancement.

TABLE 17-10 Urine Osmolality Findings in Selected Hypernatremic States

Urine Osmolality (U_{osm})	Potential Hypernatremic State
U_{osm} <300 mOsm/kg H_2O	Central or nephrogenic diabetes insipidus
U_{osm} >300, <800 mOsm/kg H_2O	Partial diabetes insipidus or osmotic diuresis
U_{osm} >800 mOsm/kg H_2O	Hypertonic dehydration

Central diabetes insipidus is acquired in most cases, associated with various disorders that cause destruction of ADH-secreting neurons. When a diagnosis is not possible, despite imaging and other diagnostic tests, diabetes insipidus will be defined as idiopathic diabetes insipidus.

The most common clinical symptoms and signs are excessive thirst, polydipsia, and polyuria plus several nonspecific symptoms including weakness, lethargy, myalgias, and irritability. In infancy, congenital forms of diabetes insipidus present with fatigue and weakness often manifested by less activity or tiring with feeding, vomiting, polyuria, and sometimes fever. Diagnosis can be suspected in the ED by clinical presentation, but the diagnosis requires a prolonged test, requiring 4 to 18 hours. Urine osmolality is assessed after water deprivation; many cases require another assessment after a dose of desmopressin, the "water deprivation test." A spot check in the ED without water deprivation will typically reveal a U_{osm} of <300 mOsm/L. In central diabetes insipidus, a

TABLE 17-11 Treatment of Hypernatremia

Treatment	Indication and Comments
Isotonic (0.9%) saline	Use for correction of volumn deficits.
Etiology-specific therapy	Treat fever with antipyretics, vomiting with antiemetics, and diabetes insipidus with desmopressin (see "Diabetes Insipidus" section below).
D_5W to replace free water deficit over 2-3 days	In cases of chronic hypernatremia, it is suggested that correcting (lowering) the sodium level should occur at a rate of no more than 0.5 mEq/L/h or 10 to 12 mEq/24 h.
0.45% normal saline at 100 mL/hour	Correct volume deficts first. A commonly used infusion for mild to moderate hypernatremia, but this therapy adds to total body sodium.
D_5W to replace free water deficit over 1-2 hours	Reserved only for those cases where acuity is known to be <6 h and the salt load is known to be lethal (0.75–3.0 grams/kg of body weight).
Hemodialysis	An alternative or as a suppliment to D_5W to replace free water deficit in life-threatenting acute cases of salt ingestion.

Abbreviation: D_5W = 5% dextrose in water.

TABLE 17-12 Classification of Diabetes Insipidus

Class	Acquisition	Pathophysiology
Central or neurogenic diabetes insipidus	Congenital	Structural malformations affecting the hypothalamus or pituitary
		Autosomal dominant (or rarely recessive) mutations in the gene encoding AVP-NPII precursor protein
	Acquired	Primary tumors (craniopharyngioma) or metastases
		Infection (e.g., meningitis, encephalitis)
		Histiocytosis and granulomatous diseases
		Trauma
		Surgery
		Idiopathic
Nephrogenic diabetes insipidus	Congenital	X-linked: inactivating mutations in *AVPR2* gene
		Autosomal: recessive or dominant mutations in *AQP-2* gene
	Acquired	Primary renal disease
		Obstructive uropathy
		Metabolic causes (e.g., hypokalemia, hypercalcemia)
		Sickle cell disease
		Drugs (e.g., lithium, demeclocycline)
Primary polydipsia or dipsogenic diabetes insipidus	Acquired	Psychogenic illness characterized by excessive fluid intake. Treatment is aimed at the psychiatric disease.

cerebral MRI is indicated (on a nonurgent outpatient basis) to evaluate the hypothalamic–pituitary area (**Figure 17-6**).

Central diabetes insipidus is treated with the synthetic hormone desmopressin, as a nasal spray, 10 micrograms (0.1 mL) every 12 hours, or PO, 0.05 milligrams every 12 hours, as starting doses. Therapy of nephrogenic diabetes insipidus includes a low-salt, low-protein diet, adequate hydration, and the careful use of one to three agents that act together to concentrate urine in these patients: a thiazide diuretic, the potassium-sparing diuretic amiloride, and indomethacin. Exogenous ADH, 5 to 10 micrograms subcutaneously, two to four times daily, is also used in noncongenital nephrogenic diabetes insipidus, as these patients have a partial response to ADH. Patients with significant electrolyte abnormalities should be admitted to the hospital, whereas stable patients suspected of having diabetes insipidus should be referred for testing.

POTASSIUM

PATHOPHYSIOLOGY

Potassium (K^+) is the major intracellular cation of the body: 98% of total body potassium in healthy subjects is intracellular, and 70% to 75% of total K^+ is in muscle tissues. The normal intracellular concentration averages 150 mEq/L, and the normal extracellular concentration is 3.5 to 5.0 mEq/L. The total body K^+ store is approximately 55 mEq/kg or 3500 mEq in a healthy 70-kg adult. Daily intake of K^+ ranges from 50 to 150 mEq. Foods rich in potassium include vegetables, fruits, dry fruits, nuts, and meat. Potassium is excreted predominantly by the kidneys (80% to 90%). Potassium is filtered freely through the renal glomerulus and then reabsorbed in the proximal and ascending tubules. It is secreted in the distal tubule in exchange for Na^+. In healthy individuals, the kidneys are able to excrete up to 6 mEq/kg/d. The several mechanisms of potassium handling along the nephron are the targets of diuretic therapy.

Extracellular [K^+] represents about 2% of total body K^+ and is influenced by two important variables: total body K^+ stores and distribution between the ICF and ECF spaces. Being mostly intracellular, an accurate calculation of total body K^+ is difficult, but an estimation of the K^+ deficit can be determined with the following equation: **estimated K^+ deficit in mEq/L = (expected serum [K^+] in mEq/L – measured serum [K^+] in mEq/L) × ICF** (calculated as 40% of total body weight).[1]

However, this equation is only reliable for healthy subjects, because critical patients sustain significant and rapid intracellular to extracellular shifting in response to severe injury (i.e., surgical stress, trauma, or burns), acid-base imbalance, catabolic states, increased extracellular osmolality, or insulin deficiency. So it is possible to have hyperkalemia in patients with a total body K^+ deficit (e.g., diabetic ketoacidosis) and hypokalemia with total body K^+ surplus.[2] These shifts are crucial considering the role of potassium in maintaining the resting membrane potential, as the ratio of intracellular to extracellular K^+ is the most important determinate of neuromuscular and cardiovascular excitability.[18,19]

Acid-base imbalance plays an important role in critically ill patients: there is an inverse proportionality between serum pH and [K^+], with [K^+] rising about 0.6 mEq/L for every 0.1 decrease in pH and vice versa, through an exchange between H^+ and K^+.[1,20]

Also the duration of both hypo- and hyperkalemia influences the clinical response: chronic potassium depletion or surplus allows adaptation through shifts in intra-/extracellular K^+ concentration to maintain the resting membrane potential, thus mitigating neuromuscular and cardiac electrophysiologic effects.

HYPOKALEMIA

PATHOPHYSIOLOGY

Hypokalemia is defined as a serum [K^+] of <3.5 mEq/L. The most frequent causes of hypokalemia are insufficient dietary intake (e.g., fasting, eating disorders, alcoholism), intracellular shifts (e.g., alkalosis, insulin, β_2-agonists, hypokalemic periodic paralysis), and increased losses, mainly GI (vomiting, nasogastric suction, diarrhea) or renal (diuretics,[5] hyperaldosteronism, osmotic diuresis, toxins)[21] (**Table 17-13**).

The clinical manifestations result from abnormalities in membrane polarization and affect almost every body system, but are particularly dangerous in the excitable myocardium. Hypokalemia makes the resting potential more electronegative, thus enhancing depolarization; the reduction in [K^+] conduction delays repolarization, causing prolonged QT_c, flattened T waves, and the appearance of U waves in the ECG (**Figure 17-7**).

CLINICAL FEATURES

Symptoms of hypokalemia (**Table 17-14**) usually start when serum concentrations reach 2.5 mEq/L, although they may appear sooner with rapid decreases in concentration or appear later (i.e., at even lower [K^+]) for chronic depletion.

Particular attention must be paid to cardiac arrhythmias, usually tachyarrhythmias (atrial fibrillation,[22] torsade de pointes, ventricular tachycardia, and ventricular fibrillation), that can be life threatening.

DIAGNOSIS

Diagnosis of hypokalemia is made with serum chemistry measurement; the etiology is investigated with additional testing. An ECG should be obtained from hypokalemic patients in the ED (Figure 17-7). Obtain blood gas analysis when alkalosis is suspected. If the cause of hypokalemia is not apparent from history, spot urinary electrolytes can be obtained before starting K^+ replacement (see **Table 17-15** for interpretation of urine K^+ values[1]); also U_{Na+}, U_{osm}, and P_{osm} should be measured, because a U_{Na+} value <30 mEq/L and a U_{osm} value less than P_{osm} suggest polyuria. Polyuria can increase K^+ excretion even if total body K^+ is depleted; thus U_{K+} may be misleading for diagnosis in the setting of polyuria.[2]

Another useful tool for differential diagnosis is **transtubular K^+ gradient (TTKG) = (U_{K^+} × P_{osm})/(U_{osm} × P_{K^+})** with normal values of 8 to 9 mEq/L. Values lower than 5 mEq/L suggest hyperaldosteronism; if paralysis is present, values lower than 3 mEq/L suggest hypokalemic periodic paralysis. A calcium/phosphate ratio >1.7 on a spot urine is 100% sensitive and 96% specific for thyrotoxic hypokalemic periodic paralysis.[23,24]

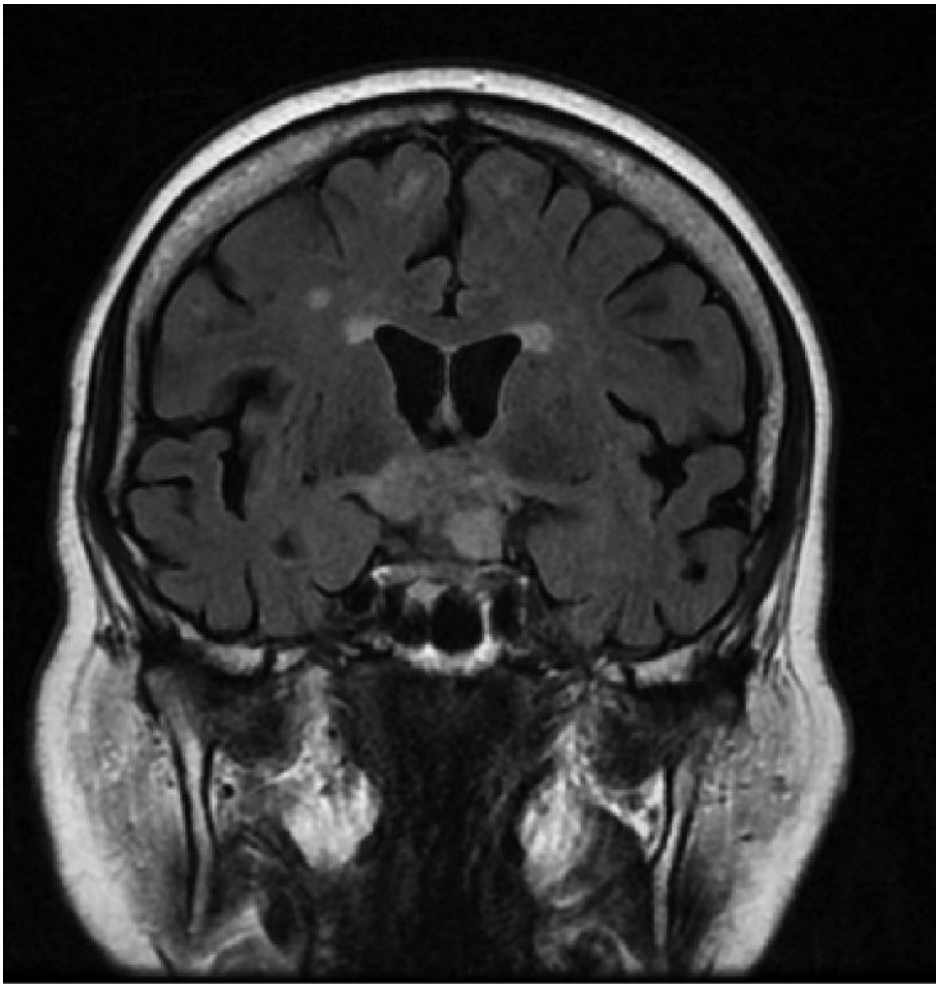

FIGURE 17-6. MRI image of a craniopharyngioma that caused diabetes insipidus in a 46-year-old patient.

TREATMENT

The treatment of hypokalemia is replacement of K^+. This should be done orally in stable patients with mild hypokalemia (>3.0 mEq/L) who are able to tolerate oral intake.[2] Foods rich in K^+ (fruits, dried fruits, vegetables) can be suggested at discharge from ED, as well as salt substitutes or K^+ supplements that should be prescribed with abundant fluids and/or food to prevent gastric irritation. Additional treatment targeted to the underlying cause should be considered. For example, it is possible to treat (and prevent) chronic hypokalemia induced by loop or thiazide diuretics by adding an adequate amount of spironolactone to the patient's chronic therapy[25]; however, the primary care physician should be aware of or guide such a change in medication. Whenever modifying diuretics or other drugs at ED discharge, recommend follow-up within 1 week for repeat assessment of renal function and $[K^+]$. In hypokalemia secondary to respiratory alkalosis (as caused by an acute anxiety disorder), the simple correction of the acid-base imbalance (through reassurance or anxiolytics) can correct $[K^+]$ without administering exogenous potassium.

Intravenous replacement is indicated in patients with severe (<2.5 mEq/L) hypokalemia and in symptomatic patients with moderate (2.5 to 3 mEq/L) hypokalemia. Treat patients with cardiac arrhythmias, prolonged QT_c, or when oral replacement is not tolerated or not feasible (see **Table 17-16** for common medications known to prolong QT_c). Monitor the patient's rhythm when treating with intravenous K^+.

Monitor closely those patients who sustain rapid $[K^+]$ changes due to their illness (e.g., postobstructive polyuria) or intravenous treatment. An example is diabetic ketoacidosis treatment, where rapid hypokalemia (including life-threatening arrhythmias) should be prevented by adequate IV K^+ administration prior to the detection of a rapid fall in serum potassium.

The following are **general principles in hypokalemia correction:**

1. Use KCl and avoid administering K^+ in glucose solutions, to reduce insulin-induced K^+ transfer into cells.
2. Potassium is irritating to the endothelium; adequate dilution is mandatory to prevent pain and phlebitis (maximum recommended $[K^+]$ in 500 mL of a saline solution is 40 mEq, to be infused in 4 to 6 hours in a peripheral line. If a more aggressive correction is needed, an identical solution can be administered in a second peripheral line. Higher concentrations can be administered through a central line, but infusion rates should never exceed 20 mEq/h).
3. Reassessing serum $[K^+]$ should be adjusted to infusion rate and coexisting factors (e.g., concomitant acid-base imbalance, volume depletion, cardiac arrhythmias).
4. ECG monitoring is recommended.
5. In most cases, hypokalemic patients are also hypomagnesemic. So Mg^{2+} (20 to 60 mEq/24 h) may be added to the infusion both to optimize tubular reuptake of potassium and to contrast proarrhythmic effect of hypokalemia.[1]

HYPERKALEMIA

PATHOPHYSIOLOGY

Hyperkalemia is defined as measured serum $[K^+]$ of >5.5 mEq/L. The most common cause is factitious hyperkalemia due to release of intracellular potassium caused by hemolysis during phlebotomy. Other causes are listed in **Table 17-17**.

Clinical manifestations of hyperkalemia result from disordered membrane polarization (**Figure 17-8**). Cardiac manifestations are the most

TABLE 17-13 Causes of Hypokalemia

Transcellular shifts	Alkalosis*
	Increased plasma insulin (treatment of diabetic ketoacidosis)
	β-Adrenergic agonists
	Hypokalemic periodic paralysis (congenital)
	Thyrotoxic hypokalemic periodic paralysis
Decreased intake	Fasting
	Alcoholism (worsened by hypomagnesemia)
	Eating disorders
GI loss	Vomiting*, nasogastric suction
	Diarrhea* (including laxative, enema abuse)
	Malabsorption
	Ureterosigmoidostomy
	Enteric fistula
	Villous adenoma
Renal loss	Diuretics (carbonic anhydrase inhibitors, loop diuretics, and thiazide-like diuretics)*
	Primary hyperaldosteronism
	Secondary hyperaldosteronism
	Licorice ingestion
	Excessive use of chewing tobacco
	Renal tubular acidosis
	Postobstructive diuresis
	Osmotic diuresis
	Bartter's syndrome (mimics loop diuretic use)
	Gitelman's syndrome (mimics thiazide diuretic use)
	Apparent mineralocorticoid excess and related syndromes (Conn's, Liddle's)
	Drugs and toxins (aminoglycosides, echinocandins, carbenicillin, penicillins, amphotericin B, levodopa, lithium, thallium, cesium, barium, toluene, theophylline, chloroquine, steroids, etc.)
Sweat loss	Heavy exercise
	Heat stroke
	Fever
Other	Hypomagnesemia
	Acute leukemia and lymphomas
	IV hyperalimentation
	Recovery from megaloblastic anemia
	Hypothermia (accidental or induced)

*Frequently encountered etiologies in the ED.

serious. In hyperkalemia the resting potential of the excitable myocardium becomes less electronegative, with a consequent partial depolarization that reduces the activation of voltage-dependent sodium channels; this results in a slower and reduced amplitude of action potential. **Table 17-18** summarizes the ECG effects that may lead to arrhythmic complications, such as sinoatrial and atrioventricular blocks and atrial paralysis (Figure 17-8). Calcium administration does not affect potassium levels; rather, calcium antagonizes the effects of hyperkalemia at the level of the cell membrane, raising the threshold potential, thus restoring the membrane potential and myocyte excitability close to normal[1] (**Figure 17-9**).

CLINICAL FEATURES

Cardiac dysrhythmias, such as ventricular fibrillation, sinoatrial and atrioventricular blocks until complete heart block, and asystole, may occur. Death from hyperkalemia is usually the result of diastolic arrest or ventricular fibrillation. Other common symptoms include neuromuscular dysfunctional weakness, paresthesias, areflexia, ascending paralysis, and GI effects (nausea, vomiting, and diarrhea).[26,27]

TREATMENT

A stat ECG is essential in all hyperkalemic patients (Table 17-18); **if ECG changes are present, emergency treatment of hyperkalemia should start immediately.** In addition, if ECG changes are detected in a patient whose electrolyte levels are not yet known (e.g., a dialysis patient), hyperkalemia should be suspected and treated. A symptomatic patient with a relatively small elevation of $[K^+]$ (5.0 to 6.0 mEq/L) requires identification and treatment of the underlying cause. A spot urine potassium may identify the diagnosis. An elevated spot urine potassium (>20 mEq/L) suggests an extrarenal cause (and will more likely be responsive to therapy). A low urine K^+ output (<10 mEq/L) suggests oliguric kidney failure or drug effect, such as angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers.

Emergency treatment includes continuous ECG monitoring and immediate intervention with several therapeutic medications, which based on the action mechanism, can be divided into three modalities: membrane stabilization (crucial for cardiac tissue, must be done immediately), intracellular shift of K^+, and removal/excretion of K^+ from the body. All three modalities should be administered sequentially in rapid succession. Each mode has a different onset time and duration[28] (**Table 17-19**).

A blood gas is essential if acidosis is present; treatment should correct the underlying cause of the acid-base imbalance. If pH is normal or alkaline, the therapeutic measures that act to promote an intra- to extracellular shift of $[K^+]$ will be less effective, and treatment should be aimed to improve renal excretion.

Until recently, sodium polystyrene sulfonate was the only oral agent that lowered potassium levels by enhancing excretion (rather than shifting potassium into cells). This agent has an unpleasant taste and may cause diarrhea. Two new oral agents currently in development, **patiromer** and **sodium zirconium cyclosilicate**, may prove useful to lower potassium levels for patients with mild hyperkalemia if confirmatory studies support the initial randomized controlled trials[29,30]; however, the onset of action for these new drugs is too slow to be of benefit in life-threatening hyperkalemia.

The following are **general principles in treatment of hyperkalemia:**

1. Immediate cessation of further K^+ administration, reduction of dietary intake, and suspension of drugs impairing K^+ renal excretion directly (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, K^+-sparing diuretics) or indirectly through worsening of renal function (e.g., nonsteroidal anti-inflammatory drugs, iodine contrast, antibiotics).
2. Fluid administration enhances K^+ renal excretion through increasing urine output.
3. If a patient is on digitalis,[31] hypercalcemia enhances the toxic cardiac effects of digitalis. However, in severe hyperkalemia secondary to digitalis intoxication with advanced intraventricular conduction impairment (wide, low-voltage QRS complexes), calcium administration must be considered, in association with antidigoxin antibodies.[1,32]
4. ECG continuous monitoring should be used to confirm the effects of therapy, thus reducing the frequency of rechecking $[K^+]$.

MAGNESIUM

The total body content of magnesium (Mg^{2+}) is 24 grams, or 2000 mEq, 50% to 70% of which is fixed in bone and only slowly exchangeable. Most of the remaining Mg^{2+} is found in the ICF space, with a concentration of approximately 40 mEq/L. The distribution of Mg^{2+} is similar to that of K^+, with the major portion being intracellular. It is the second most abundant intracellular cation. Normal serum $[Mg^{2+}]$ ranges between 1.5 and 2.5 mEq/L (0.7 to 1.1 mmol/L or 1.7 to 2.7 milligrams/dL). Circulating Mg^{2+} is 25% to 35% bound to proteins (mainly albumin), 10% to 15% complexed, and 50% to 60% ionized, which is the active portion. The normal dietary intake of Mg^{2+} is approximately 240 to 336 milligrams/d

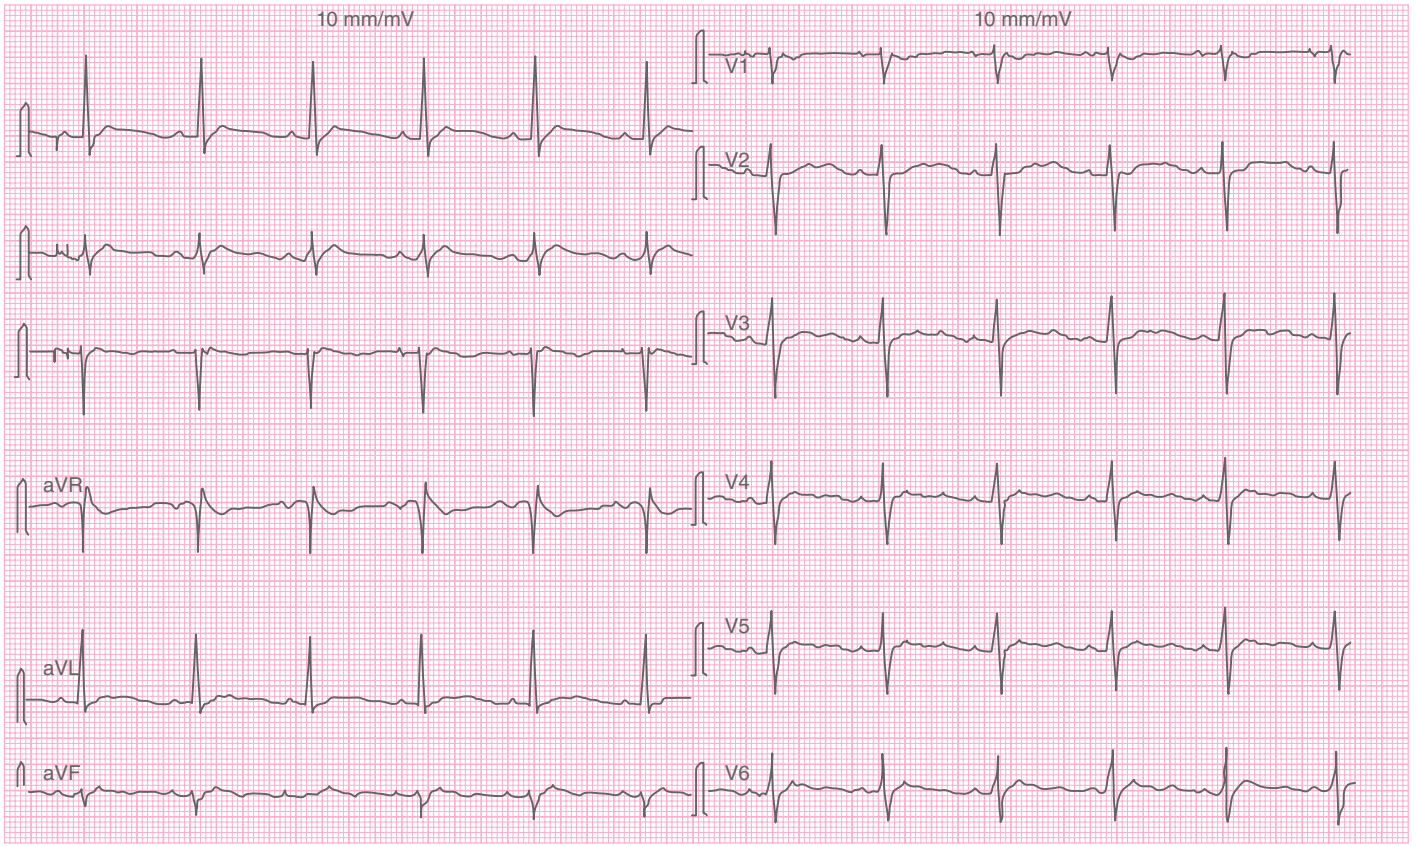

FIGURE 17-7. ECG of a patient with K^+ of 1.4 mEq/L, with leg paralysis and deep fatigue. The patient had been taking a thiazide-like diuretic for hypertension. Notice the prolonged QT_c and a flattened T wave with a U wave visible in V_2-V_5.

and is found in vegetables such as dry beans and leafy greens, meat, and cereals. Sixty percent of excreted Mg^{2+} is through stool, with the remainder via the urine. Renal reabsorption is carried out with sodium and water and is unidirectional; that means that it is impaired by volume overload, osmotic diuresis, and diuretics. About 300 enzymes have their activities regulated by Mg^{2+}; it assists the production of adenosine triphosphate, participates in nucleic acid and protein synthesis, and is involved in coagulation, platelet aggregation, and neuromuscular activity, as well as in cardiac action potential.[1,2,33]

Magnesium homeostasis is very complex and finely regulated by many factors, such as parathyroid hormone, calcitonin, ADH, glucose, insulin, glucagon, catecholamines, sodium, potassium, calcium, and phosphorus levels. Magnesium is effective therapy in severe asthma when added to standard therapy[34] (see chapter 69, "Acute Asthma").

*Frequent or important ED diagnostic considerations.

HYPOMAGNESEMIA

PATHOPHYSIOLOGY

Table 17-20 lists the different causes of hypomagnesemia. The major causes are alcoholism, malnutrition, cirrhosis, pancreatitis, and excessive GI fluid losses.

IV hyperalimentation or treatment of diabetic ketoacidosis without adequate provision of Mg^{2+}, especially in a previously malnourished patient, can cause an abrupt fall in plasma magnesium levels. Acid-base imbalance affects the levels of ionized magnesium; a typical example is respiratory alkalosis that enhances neuromuscular activity (thus provoking tremors and cramps) by rapidly decreasing ionized $[Mg^{2+}]$ and $[Ca^{2+}]$ at the same time.

Among the iatrogenic causes, **proton pump inhibitors** may cause hypomagnesemia,[35,36] especially in association with **diuretic therapy**, probably through the inhibition of intestinal absorption. Concomitant hypomagnesemia and hypokalemia may coexist.

CLINICAL FEATURES

Magnesium is essential to a large number of enzymes, including membrane-bound adenosine triphosphatase. Consequently, hypomagnesemia may result in a wide variety of neuromuscular, GI, and cardiovascular effects (**Table 17-21**).

DIAGNOSIS

Hypomagnesemia is common in acute illness; it has been found in 12% of hospitalized patients and in up to 65% of medical intensive care patients.[37,38] It is likely underdiagnosed because few hospitalized patients have levels drawn.[39]

The diagnosis of hypomagnesemia in the presence of normal serum calcium levels is suggested by increased neuromuscular irritability, shown by hyperreflexia tremor, tetany, or even convulsions. Chvostek sign and Trousseau sign, findings traditionally associated with hypocalcemia, may be elicited in hypomagnesemic patients. Hypomagnesemia should be suspected in patients with alcoholism, cirrhosis, or those requiring IV fluids or hyperalimentation for prolonged periods.

The ECG changes may be similar to those caused by hypokalemia and/or hypocalcemia because they may be due to Mg^{2+} deficiency altering cardiac intracellular potassium content. As for hypokalemia, low $[Mg^{2+}]$ levels enhance digitalis toxicity, so hypomagnesemia should be searched in ECG disturbances associated with digoxin intake, especially when both digoxin and potassium levels are normal.[40]

Low total $[Mg^{2+}]$ can also be secondary to hypoalbuminemia; if it is not possible to measure ionized magnesium, which is unaffected by hypoalbuminemia, the following two formulas can be used to correct magnesemia for albumin level. If reference lab reports $[Mg^{2+}]$ in mmol/L: corrected serum $[Mg^{2+}]$ (mmol/L) = measured total $[Mg^{2+}]$ + [0.005 × (40 – serum albumin in grams/L)]. If reference lab reports $[Mg^{2+}]$ in milligrams/dL, use the following conversion: corrected serum $[Mg^{2+}]$ (mEq/L) = measured total $[Mg^{2+}]$ × 0.42 + 0.05 (4 – serum albumin in grams/dL).

TREATMENT

Hypokalemia, hypocalcemia, and hypophosphatemia are often present with severe hypomagnesemia and must be monitored carefully. Hypocalcemia does not develop until $[Mg^{2+}]$ falls below 1.2 milligrams/dL.

The following are **general principles in treatment of hypomagnesemia:**

1. Treat or stop the cause of hypomagnesemia.
2. For asymptomatic patients (including ECG changes), magnesium supplements should be administered orally, in multiple low doses during the day, to avoid diarrhea. Magnesium lactate, chloride, gluconate, and proteinate are the formulations with minimum effect on intestinal motility.
3. For severe and symptomatic hypomagnesemia, urgent IV replacement is mandatory. The formulation most commonly used is

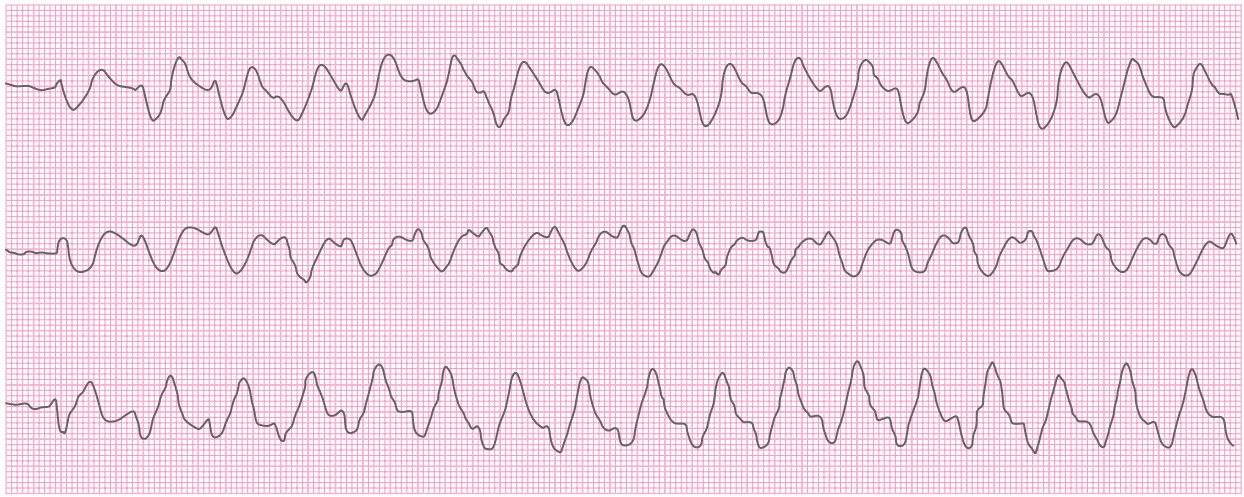

FIGURE 17-8. Monitor strip (V_1–V_3) of a 35-year-old patient in critical condition, who was hypotensive and fatigued and rapidly deteriorated into cardiac arrest. Potassium level was 9.1 mEq/L. She was on spironolactone and steroid therapy.

TABLE 17-18 ECG Changes Associated with Hyperkalemia

$[K^+]$ (mEq/L)	ECG Changes*
6.5–7.5	Prolonged PR interval, tall peaked T waves, short QT interval
7.5–8.0	Flattening of the P wave, QRS widening
10–12	QRS complex degradation into a sinusoidal pattern

*In chronic or slowly developing hyperkalemia, ECG changes may not occur until higher $[K^+]$ levels are reached.

FIGURE 17-9. The same patient as in Figure 17-8 during calcium chloride infusion. She regained a pulse and became conscious. The QRS and T wave narrowed, as compared with Figure 17-8.

TABLE 17-19 Emergency Therapy of Hyperkalemia

Therapy	Dose and Route	Onset of Action	Duration of Effect	Mechanism
Calcium chloride (10%)*	5–10 mL IV	1–3 min	30–50 min	Membrane stabilization
Calcium gluconate (10%)*	10–20 mL IV	1–3 min	30–50 min	Membrane stabilization
$NaHCO_3$	50–150 mEq IV	5–10 min	1–2 h	Shifts $[K^+]$ into cell
Albuterol (nebulized)	10–20 milligrams in 4 mL of normal saline, nebulized over 10 min	15–30 min	2–4 h	Upregulates cyclic adenosine monophosphate, shifts $[K^+]$ into cell
Insulin† and glucose‡	5–10 units regular insulin IV Glucose 25 grams (50% solution) IV	30 min	4–6 h	Shifts $[K^+]$ into cell
Furosemide	40–80 milligrams IV	Varies	Varies	Renal $[K^+]$ excretion
Sodium polystyrene sulfonate	25–50 grams PO or PR	1–2 h	4–6 h	GI $[K^+]$ excretion
Hemodialysis	—	Minutes	Varies	Removes $[K^+]$

*Calcium chloride has three times the elemental calcium when compared to calcium gluconate. 10% calcium chloride = 27.2 milligrams $[Ca^{2+}]$/mL; 10% calcium gluconate = 9 milligrams $[Ca^{2+}]$/mL. Due to its short duration, calcium administration (both chloride and gluconate) can be repeated up to four times per hour.

†Reduce dose of insulin in patients with renal failure.

‡Glucose infusion should be administered after initial bolus to prevent hypoglycemia. Glucose should not be administered in hyperglycemic patients.

magnesium sulfate ($MgSO_4$). In life-threatening conditions (torsade de pointes, eclampsia), 1 to 4 grams or 8 to 32 mEq diluted in at least 100 mL of 5% dextrose or normal saline (0.9%) solution can be administered in 10 to 60 minutes under continuous monitoring: ECG (risk of hypokinetic arrhythmias), noninvasive blood pressure (risk of hypotension), and ventilatory pattern (risk of respiratory depression, usually preceded by areflexia, that can be monitored as an alarm sign). As a minor side effect, flushing due to vasodilatation is common.

4. Patients with chronic Mg^{2+} deficiency may require >50 mEq of oral Mg^{2+} (6 grams of $[MgSO_4]$ per day). In chronic alcoholics with delirium tremens and in patients with severe hypomagnesemia, up to 8 to 12 grams of $MgSO_4$ may be given IM (possible, but very painful) or IV the first day. The first 10 to 15 mEq (1.5 to 2.0 grams) of IV $MgSO_4$ can be given over 1 to 2 hours. This may be followed by up to 4 to 6 grams/d. Approximately half of the administered Mg^{2+} will be lost in the urine.
5. Spironolactone is effective in maintaining $[Mg^{2+}]$ homeostasis as well as in reducing the incidence of arrhythmias in congestive heart failure patients.[41]

HYPERMAGNESEMIA

PATHOPHYSIOLOGY

Hypermagnesemia is rarely encountered in emergency medicine practice, because the kidney can increase the fractional excretion of magnesium up to nearly 100%. A small elevation in serum concentration has little clinical significance. The most common cause for hypermagnesemia can be found in patients with renal insufficiency or renal failure who ingest Mg^{2+}-containing drugs.[42] Hypermagnesemia is more commonly seen in the perinatal setting secondary to the treatment of pre-eclampsia or eclampsia. It has been described as a serious, life-threatening consequence of magnesium-containing laxative abuse in patients with normal renal function.[43,44] Other causes of hypermagnesemia include lithium ingestion, volume depletion, or familial hypocalciuric hypercalcemia (**Table 17-22**).

CLINICAL FEATURES

Hypermagnesemia rarely produces symptoms. Magnesium decreases the transmission of neuromuscular messages and thus acts as a CNS depressant and decreases neuromuscular activity. Signs and symptoms related to $[Mg^{2+}]$ can be found in **Table 17-23**.

DIAGNOSIS

Serum $[Mg^{2+}]$ is usually diagnostic. **The possibility of hypermagnesemia should be considered in patients with hyperkalemia or hypercalcemia.** Hypermagnesemia also should be suspected in patients with renal failure, particularly in those who are taking magnesium-containing antacids or laxatives.

TREATMENT

Immediate cessation of Mg^{2+} administration is required. If renal failure is not evident, dilution by IV fluids followed by furosemide (40 to 80 milligrams IV) may be indicated. Calcium directly antagonizes the cardiac effects of magnesium because it reverts the calcium channel blockade provoked by elevated $[Mg^{2+}]$. Severe symptomatic hypermagnesemia can be treated with 10 mL of 10% $CaCl_2$ IV over 2 to 3 minutes. Further infusion of 40 to 60 mL during the next 24 hours can be administered. Patients with renal failure may benefit from dialysis using a decreased $[Mg^{2+}]$ bath that lowers serum $[Mg^{2+}]$.

TABLE 17-23 Symptoms and Signs of Hypermagnesemia

Level (mEq/L)	Clinical Manifestations
2.0–3.0	Nausea
3.0–4.0	Somnolence
4.0–8.0	Loss of deep tendon reflexes
8.0–12.0	Respiratory depression
12.0–15.0	Hypotension, heart block, cardiac arrest

CALCIUM

PATHOPHYSIOLOGY

Calcium is the most abundant mineral in the body. The total body $[Ca^{2+}]$ is 15 grams/kg of body weight, or about 1 kg in an average-sized adult. Calcium is 99% bound in bone as phosphate and carbonate (mineral apatite), with the remainder in the teeth, soft tissues, plasma, and cells. The normal daily intake of Ca^{2+} is 800 to 3000 milligrams, one third of which is absorbed primarily in the small bowel by active (vitamin D–dependent) and passive (concentration-dependent) absorption. Excretion of Ca^{2+} is primarily via the stool.

The cell content of Ca^{2+} is 10,000 times lower than the plasma content, and this gradient is maintained by Ca-ATPase, Ca^{2+}-specific channels and by Na/Ca exchangers.

Plasma $[Ca^{2+}]$ is between 8.5 and 10.5 milligrams/dL (4.3 to 5.3 mEq/L or 2.2 to 2.7 mmol/L) and is present in three different forms: ionized calcium, 50% of total (4.5 to 5.6 milligrams/dL; 1.1 to 1.4 mmol/L), which is the only active fraction; protein bound calcium, 40% of total, which is inactive and not filtered by glomerulus; and complexed calcium, 10% of total, which is bound to anions like phosphate, carbonate, and citrate.

It is necessary to be aware of **standard units** used by different laboratories to express calcium value: **1 mEq/L = 2 milligrams/dL = 0.5 mmol/L.** The ionized fraction is the only biologically active fraction; a decrease in albumin decreases the total $[Ca^{2+}]$ but does not change the ionized fraction. On average, 0.8 milligram of Ca^{2+} binds to 1 gram of protein. Therefore, total serum $[Ca^{2+}]$ is equal to ionized $[Ca^{2+}]$ plus the product of 0.8 and total protein. Alkalosis produces a decrease in ionized fraction with no change in the total serum $[Ca^{2+}]$. Each 0.1 rise in pH lowers ionized $[Ca^{2+}]$ by about 3% to 8%. The opposite effect is produced by acidosis.

The role of Ca^{2+} is crucial for muscle and cardiac contraction, nerve conduction, cell growth, enzyme activation, and coagulation, and consequently, any hypo- or hypercalcemia leads to severe dysfunctions.

HOMEOSTASIS OF CALCIUM

The organs involved in the homeostasis of calcium are bones, kidneys, and the intestines, whereas the major determinates are three hormones and one receptor.[1,2,44,45]

1. **1,25-Dihydroxycholecalciferol (active vitamin D_3)**[45] is formed in the distal tubule. It promotes Ca^{2+} absorption from intestine, but this activity is modulated by physiologic conditions that may enhance it (pregnancy and growth) or reduce it (oxalates and phytates in food and aging).
2. **Parathyroid hormone (PTH)** is secreted by parathyroid glands when $[Ca^{2+}]$ is low and is regulated by Ca^{2+}-sensing receptor, vitamin D_3, and Mg^{2+} (hypomagnesemia inhibits PTH secretion). PTH stimulates bone demineralization by activating osteoclasts and by increasing the synthesis of vitamin D_3 and increasing Ca^{2+} reabsorption from kidney.
3. **Calcitonin** is a peptide secreted by C-cells of the thyroid gland when $[Ca^{2+}]$ is high. It inhibits the activity of osteoclasts and thus bone resorption.
4. **Ca^{2+}-sensing receptor**[46,47] is mainly present on plasma membranes of parathyroids, kidney, bones, and thyroid. It becomes active in case of hypercalcemia and inhibits the production of PTH. In the kidney, activated Ca^{2+}-sensing receptor provokes hypercalciuria and polyuria preventing nephrocalcinosis. The activation of the receptor also stimulates the secretion of calcitonin and inhibits osteoclast formation.

Urinary secretion of calcium is variable and influenced by many different factors. Hypercalcemia, metabolic acidosis, hypervolemia, and loop diuretics increase urinary secretion of $[Ca^{2+}]$. PTH, vitamin D_3,

TABLE 17-24 Some Causes of Hypocalcemia

Cause	Mechanism
Decreased calcium absorption	
Vitamin D deficiency	
Decreased oral intake	Malnutrition
Decreased intestinal absorption	Intestinal bypass, gastrectomy
Decreased production of $25(OH)D_3$	Liver failure
Decreased synthesis of $1,25(OH2)D_3$	Renal failure, hyperphosphatemia
Malabsorption syndromes	
Increased calcium excretion/reduced bone resorption	
Alcoholism	Hypomagnesemia causing inhibition of PTH secretion, PTH resistance to bone resorption
Hypoparathyroidism	Genetic, autoimmune, surgical, tumoral
Pseudohypoparathyroidism	Resistance to PTH action
Hypomagnesemia	Inhibition of PTH secretion, PTH resistance to bone resorption
Drugs (Table 17-25)	
Miscellaneous	
Sepsis	
Acute pancreatitis	Fatty acids combine with $[Ca^{2+}]$ to form insoluble Ca^{2+} soaps and lead to a reduction of serum $[Ca^{2+}]$
Massive transfusions	
Rhabdomyolysis	

Abbreviations: $25(OH)D_3$ = 25-hydroxyvitamin D_3; $1,25(OH2)D_3$ = 1,25-dihydroxyvitamin D3; PTH = parathyroid hormone.

metabolic alkalosis, hypovolemia, and the chronic use of thiazides reduce secretion.

HYPOCALCEMIA

PATHOPHYSIOLOGY

Hypocalcemia is defined by an ionized $[Ca^{2+}]$ level <2.0 mEq/L (<4 milligrams/dL; or <1.1 mmol/L). Homeostasis is regulated by the maintenance of the gradient between cells and ECF, is controlled by the above described mechanism, and is mediated intracellularly by phosphates, cyclic adenosine monophosphate, and ion pumps.[44] Any process that interferes with cell metabolism, such as shock or sepsis, will tend to reduce ionized $[Ca^{2+}]$ by allowing increased net movement of Ca^{2+} across the cell membrane into the cytoplasm of the poorly functioning cells. As an example, serum $[Ca^{2+}]$ may be low after trauma, especially with the fat embolism syndrome, not only due to cell dysfunction and binding of calcium to free fatty acids but also because of fatty inhibition of cell membrane calcium pumps.

ETIOLOGY

Table 17-24[1,2,47,48] lists the most common causes of hypocalcemia and the primary mechanism of each. **Table 17-25** lists the principal drugs that cause hypocalcemia.[2]

CLINICAL FEATURES

The severity of signs and symptoms depends greatly on the rapidity of the decrease in $[Ca^{2+}]$. **Table 17-26** lists the different signs and symptoms that can be seen in the course of hypocalcemia.[1,2]

Neuromuscular and cardiovascular signs and symptoms predominate. As serum $[Ca^{2+}]$ falls, neuronal membranes become increasingly more permeable to sodium, thereby enhancing excitation, causing smooth and skeletal muscle contractions. Irritability, confusion, dementia, extrapyramidal symptoms, seizures, and hallucination may occur.

TABLE 17-25 Drugs That Can Cause Hypocalcemia

Phosphates (e.g., enemas, laxatives)
Phenytoin, phenobarbital
Gentamicin, tobramycin, dactinomycin, foscarnet
Cisplatin
Citrate
Loop diuretics
Glucocorticoids
Magnesium sulfate
Bisphosphonates, calcitonin, denosumab
Cinacalcet

Decreased ionized $[Ca^{2+}]$ reduces the strength of myocardial contraction primarily by inhibiting relaxation. The most characteristic ECG finding in hypocalcemia is a prolonged QT_c interval.[18,19] The T wave may be of normal width, and it is the ST segment that is actually prolonged. In very severe hypocalcemia, T waves may present abnormalities that may mimic ischemia (**Figure 17-10**). This finding is usually seen with total serum calcium levels <6.0 milligrams/dL.

A positive Chvostek sign (twitch at the corner of the mouth when the examiner taps over the facial nerve just in front of the ear) and Trousseau sign (carpal spasm produced when the examiner applies a blood pressure cuff to the upper arm and maintains a pressure above systolic for 2 to 3 minutes; the fingers are spastically extended at the interphalangeal joints and flexed at the metacarpophalangeal joints with wrist flexion and forearm pronation) are classically associated with hypocalcemia (but also may occur in respiratory alkalosis, which shifts ionized calcium to the protein-bound form). These diagnostic signs have not been subjected to rigorous assessment, and there is no agreement on sensitivity or specificity.[49,50]

DIAGNOSIS

In addition to total serum $[Ca^{2+}]$, a full electrolyte panel, renal function tests, ionized $[Ca^{2+}]$, and magnesium levels aid in the diagnosis. An albumin level should be obtained because hypoalbuminemia may falsify the diagnosis.

In cases where acid-base abnormalities are suspected, a blood gas analysis to evaluate pH should be obtained. Also consider a phosphate

TABLE 17-26 Symptoms and Signs of Hypocalcemia

Muscular	Weakness, fatigue
	Spasms, cramps
Neurologic	Tetany

Miscellaneous	Dental hypoplasia
	Cataracts
	Decreased insulin secretion

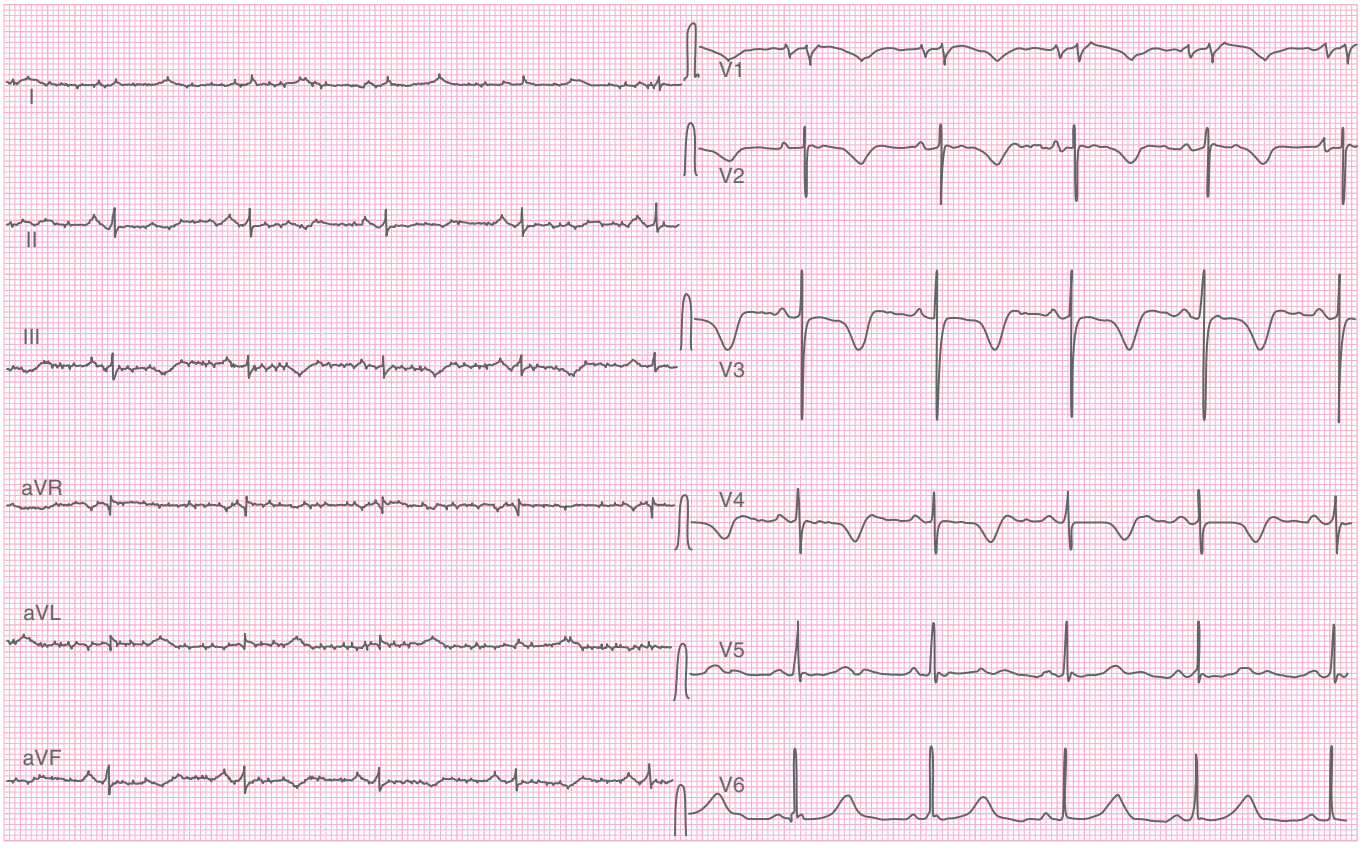

FIGURE 17-10. ECG of a patient with severe hypocalcemia (Ca^{2+} 4.5 milligrams/dL) who was complaining of chest and abdominal pain, pain in the legs, and Trousseau sign. A very long QT_c and T wave abnormalities mimicking ischemia are evident.

level. Blood samples for PTH and vitamin D_3 levels should be drawn (but results are not required) before starting therapy.

TREATMENT

Treatment of hypocalcemia is tailored to the individual patient and directed toward the underlying cause. If a patient is asymptomatic or if the hypocalcemia is not severe or prolonged for >10 to 14 days, oral Ca^{2+} therapy with or without vitamin D may be sufficient. Ca^{2+} lactate, ascorbate, carbonate, and gluconate are available in oral preparations and contain variable percentages of elemental calcium; 1 mEq of elemental calcium is equal to 20 milligrams of elemental calcium. **Regimens can be 500 to 3000 milligrams of elemental calcium by mouth daily, in one dose or up to three divided doses. The dose must be individualized for each patient, according to the cause and severity of hypocalcemia.**

IV calcium is recommended only in cases of symptomatic or severe hypocalcemia[2] (ionized [Ca^{2+}] <1.9 mEq/L or <0.95 mmol/L), because IV Ca^{2+} administration causes vasoconstriction and possible ischemia, especially in patients with low cardiac output who already have significant peripheral vasoconstriction. **IV calcium gluconate is preferred over IV calcium chloride** in nonemergency settings due to the dangers of extravasation with calcium chloride (calcinosis cutis). **With severe acute hypocalcemia, 10 mL of 10% $CaCl_2$ (or 10 to 30 mL of 10% Ca^{2+} gluconate) may be given IV over 10 to 20 minutes and repeated every 60 minutes until symptoms resolve or followed by a continuous IV infusion of 10% $CaCl_2$ at 0.02 to 0.08 mL/kg/h (1.4 to 5.6 mL/h in a 70-kg patient).**[51] The serum [Ca^{2+}] should then be rechecked before continuing parenteral Ca^{2+}. **IV Ca^{2+} should be used with caution in patients taking digitalis, because hypercalcemia can potentiate digitalis toxicity.**[52] Symptomatic patients after thyroid or parathyroid surgery are often treated with parenteral Ca^{2+}.

During massive transfusions, if the blood is being given faster than 1 unit every 5 minutes, 10 mL of 10% $CaCl_2$ can be given after every 4 to 6 units of blood if a patient is in shock or has heart failure despite adequate volume replacement therapy.

Hypocalcemia is difficult to correct if hypomagnesemia is also present because of reduction of PTH and Ca^{2+} releases from bone. Therefore, magnesium should be replaced before, or in conjunction with, Ca^{2+} replacement.[44,45]

HYPERCALCEMIA

Hypercalcemia is relatively common. It is defined as a total [Ca^{2+}] >10.5 milligrams/dL or an ionized [Ca^{2+}] level >2.7 mEq/L.

PATHOPHYSIOLOGY

Because calcium is necessary for cellular functions, every organ and system is affected by hypercalcemia, and clinical manifestations are dependent on the level of [$Ca2^{+}$]: mild hypercalcemia, 10.5 to 11.9 milligrams/dL; moderate, 12 to 13.9 milligrams/dL; severe, >14 milligrams/dL.[2,4,53]

Neuromuscular changes include decreased sensitivity, responsiveness, and strength of muscular contraction and nerve conduction. The conduction of the heart is slowed and automaticity is decreased with a shortening of the refractory period. Increased sensitivity to cardiac glycosides may be seen.

Loss of concentrating ability is the most frequent renal effect of hypercalcemia. This is a reversible tubular defect, which results in polyuria and volume depletion even in the presence of thirst. Potassium wasting resulting in hypokalemia may occur in up to one third of patients. Nephrocalcinosis and nephrolithiasis may result from hypercalcemia and can be exacerbated by volume depletion. As the hypercalcemia persists, increasing microscopic Ca^{2+} deposits in the kidney can lead to progressive renal insufficiency.

TABLE 17-27 Causes of Hypercalcemia

Cause	Mechanism
Hypercalcemia due to increased bone Ca^{2+} resorption	
Primary hyperparathyroidism	↑ PTH
Malignancy	Osteolysis, PTH-related protein (PTHrP) production
Pseudohyperparathyroidism	PTH
Renal failure	Secondary and tertiary hyper-PTH due to chronic hypocalcemia
Addison's disease	↑ Albumin, bone reabsorption
Hyperthyroidism	Osteoclast activation
Immobilization	
Hypercalcemia due to decreased urinary Ca^{2+} excretion	
Familial hypercalcemic hypocalciuria	Mutation of CaSR
Thiazides	Increased kidney Ca^{2+} reabsorption in proximal tubule
Hypercalcemia due to increased GI Ca^{2+} absorption	
Granulomatous diseases (sarcoidosis, tuberculosis, coccidioidomycosis, histoplasmosis)	1α-Hydroxylase activity
Milk (calcium)-alkali syndrome	Vitamin D_3
Vitamin D intoxication	↑Ca^{2+} intake and absorption, ↑renal reabsorption due to nephrogenic diabetes insipidus

Abbreviations: CaSR = Ca^{2+}-sensing receptor; PTH = parathyroid hormone.

TABLE 17-28 Signs and Symptoms of Hypercalcemia

General	*Cardiovascular*
Malaise, weakness	Hypertension
Polydipsia, dehydration	Dysrhythmias
Neurologic	Vascular calcifications
Confusion	ECG abnormalities
Apathy, depression, stupor	QT shortening
Decreased memory	Coving of ST-T wave
Irritability	Widening of T wave
Hallucinations	Digitalis sensitivity
Headache	*Gastrointestinal*
Ataxia	Anorexia, weight loss
Hyporeflexia, hypotonia	Nausea, vomiting
Mental retardation (infants)	Constipation
Metastatic calcification	Abdominal pain
Band keratopathy	Peptic ulcer disease
Conjunctivitis	Pancreatitis
Pruritus	*Urologic*
Skeletal	Polyuria, nocturia
Fractures	Renal insufficiency
Bone pain	Nephrolithiasis
Deformities	

ETIOLOGY

More than 90% of occurrences are associated with hyperparathyroidism[2,54] or malignancy, the latter being the most likely presentation in the ED. A list of potential causes of hypercalcemia and the relative mechanism of onset is provided in **Table 17-27**.[2]

CLINICAL FEATURES

Hypercalcemic patients with plasma total [Ca^{2+}] below 12.0 milligrams/dL are usually asymptomatic, but higher levels can cause a wide variety of symptoms (**Table 17-28**).

Patients with total [Ca^{2+}] >14 to 16 milligrams/dL are usually very weak, lethargic, and confused. Polyuria and polydipsia are due to impaired renal tubular reabsorption of water and result in volume depletion. Total [Ca^{2+}] >15.0 milligrams/dL may cause somnolence, stupor, and even coma. A mnemonic sometimes used for the signs and symptoms of hypercalcemia is *stones* (renal calculi), *bones* (osteolysis), *moans* (psychiatric disorders), and *groans* (peptic ulcer disease, pancreatitis, and constipation).

Hypercalcemia should be investigated in patients with extensive metastatic bone disease, particularly if the primary site involves the breast, lungs, or kidneys, and in individuals with combinations of clinical problems, such as renal calculi, pancreatitis, or ulcer disease.

On ECG, hypercalcemia may be associated with depressed ST segments, widened T waves, and shortened ST segments and QT intervals. Bradyarrhythmias may occur, with bundle-branch patterns that may progress to second-degree block or complete heart block. Levels of [Ca^{2+}] above 20 milligrams/dL may cause cardiac arrest.

DIAGNOSIS

True hypercalcemia must be confirmed by measuring ionized [Ca^{2+}][55]; then electrolytes, CBC, phosphate, magnesium, BUN, creatinine, and alkaline phosphatase will help determine the cause. The acuity of hypercalcemia can be determined or suggested using the medical history together with an ECG, chest x-ray, and laboratory investigation. The need for other studies such as serum or urine protein electrophoresis, PTH and vitamin D levels, thyroid tests, or bone scans should be individualized and will not determine what is done in the ED. Normally, acute, severe hypercalcemia is not caused by hyperparathyroidism. Malignancies, in particular lymphoma, leukemia, and metastatic bone cancer, are common causes of severe, acute hypercalcemia. A corrected calcium level should be calculated if albumin is not in the normal range: Corrected Ca^{2+} (milligrams/dL) = measured total Ca^{2+} (milligrams/dL) + 0.8 (4.0 – serum albumin [grams/dL]), where 4.0 represents the average albumin level in grams/dL. If the reference lab reports values in mmol/L, use the following formula: Corrected Ca^{2+} (mmol/L) = measured total Ca^{2+} (mmol/L) + 0.02 (40 – serum albumin [grams/L]), where 40 represents the average albumin level in grams/L. If the values listed in the corrected calcium formulas for normal albumin do not match your institution's lab, adjust this value accordingly.

TREATMENT

Symptomatic patients or asymptomatic patients with [Ca^{2+}] levels above 14 milligrams/dL should receive treatment starting with volume repletion. Administer **0.9% normal saline at 500 to 1000 mL/h for 2 to 4 hours** as tolerated by the patient. In general, 3 to 4 L should be given over the first 24 hours, then 2 to 3 L per 24 hours until a urine output of 2 L/d is achieved.[56] Furosemide is recommended to promote a diuresis of 150 to 200 mL/h, which increases the calciuric effect,[1,56] with an initial dose of 20 to 40 milligrams. Larger doses may be required. Hypokalemia and/or hypomagnesemia should be assessed and treated, especially if furosemide is being used.

Decreased mobilization of [Ca^{2+}] from bone through reduction of osteoclastic activity can be obtained with **corticosteroids,** such as prednisone, 1 to 2 milligrams/kg PO, or hydrocortisone, 200 to 300 milligrams IV initial dose, in Addison's disease or in steroid-responsive malignancies.

In very severe cases, it will be necessary to receive **hemodialysis** to quickly remove calcium from blood.[53] In the ED, initiating bisphosphonates or calcitonin is not mandatory. However, for hypercalcemia associated with malignancy, intravenous bisphosphonates are now considered first-line therapy;[56] examples are pamidronate or zoledronate (zoledronic acid). Zoledronic acid is recommended;[56] for a corrected [Ca^{2+}] level of 12 milligrams/dL or higher, 4 milligrams as a single dose can be given IV over 15 minutes. Calcitonin works more rapidly than bisphosphonates and can be given at a dose of 4 units/kg SC or IM.

PHOSPHORUS

Phosphorus (PO_4^{3-}) is an essential mineral that exists mainly as hydroxyapatite (85%) or as an intracellular constituent (10% to 15%). Only about 1% is in the ECF, so serum measurements may not accurately reflect total body stores. It is involved in oxidative phosphorylation and mitochondrial respiration, and it is the essential component of adenosine triphosphate, a requirement for cellular energy metabolism.[2,57] Serum [PO_4^{3-}] decreases with age from a range of 4.0 to 7.0 milligrams/dL in newborns to 2.5 to 5.0 milligrams/dL in adults. The total body phosphorus store in a normal man is approximately 700 grams (10 to 15 grams/kg). Metabolism of phosphorus is strictly linked to that of calcium. The only active status of PO_4^{3-} is in biological fluids. Homeostasis of PO_4^{3-} is mainly regulated by gut absorption and urine excretion. Gut absorption is localized in two different sites. The first is the duodenum, which is inhibited by calcitonin and is stimulated by a vitamin D_3 and low phosphate intake. The second is the jejunum and ileum, where absorption is passive and dependent on PO_4^{3-} concentration in the gut.

Excretion is predominantly in the urine by the glomerulus, with the majority reabsorbed in the proximal tubules. Excretion is regulated by PTH, which lowers serum phosphate by increasing renal excretion, and by a hormone secreted by osteoclasts and osteoblasts, the fibroblast growth factor-23, that increases PO_4^{3-} excretion and inhibits intestinal absorption. Proximal tubule absorption increases when serum [PO_4^{3-}] levels drop and with hypoparathyroidism, volume depletion, hypocalcemia, or the presence of growth hormone. Excretion increases in the presence of volume expansion, hypercalcemia, acidosis, hypomagnesemia, hypokalemia, glucocorticoids, diuretics, calcitonin, or PTH.[57]

HYPOPHOSPHATEMIA

PATHOPHYSIOLOGY

Hypophosphatemia is defined as serum [PO_4^{3-}] <2.5 milligrams/dL, but severe symptoms may not occur until the [PO_4^{3-}] level drops to <1 milligram/dL. Because phosphorus is abundant in many foods and readily absorbed, hypophosphatemia is relatively unusual. Mechanisms include a shift of phosphate into cells, increased renal excretion, and decreased GI absorption (**Table 17-29**). Only when depletion is present will clinical manifestations occur and require treatment. It is important to understand pseudohypophosphatemia, which occurs when a patient is treated with mannitol, which binds to molybdate in the serum, causing an artificially low value when [PO_4^{3-}] is measured by the laboratory.

Severe hypophosphatemia can occur in patients with prolonged use of antacids, such as aluminum hydroxide, magnesium hydroxide, or calcium carbonate. Several other drugs may cause hypophosphatemia with different mechanism (**Table 17-30**).

Critically ill patients are particularly at risk for hypophosphatemia, which occurs in up to 30% of those admitted to the intensive care unit with sepsis, trauma, and pulmonary diseases. The mechanism is glucose infusions, starvation, refeeding, shock, acidosis, alkalosis, diuretics, and catecholamine treatment.

CLINICAL FEATURES

Symptoms are due to the depletion of adenosine triphosphate and the reduction of erythrocyte 2,3-diphosphoglycerate. The final outcome will be cellular dysfunction and hypoxia. The main symptoms of hypophosphatemia are listed in **Table 17-31**.[58]

TREATMENT

When symptomatic, hypophosphatemia can be corrected both orally and IV. Possible adverse effects of IV therapy include hypocalcemia with consequent myocardial depression, arrhythmias, acute kidney injury, and calcifications. The suggested doses for PO_4^{3-} replacement are listed in **Table 17-32**, and the commonly used preparations are described in **Table 17-33**.[2,58]

TABLE 17-29 Causes of Hypophosphatemia

Shift from ECF to ICF without depletion of PO_4^{3-}	Glucose Insulin Catecholamines Respiratory alkalosis
Shift from ECF to ICF with depletion of PO_4^{3-}	Hyperalimentation Refeeding syndrome
Decreased intestinal absorption	Low intake Malabsorption Chronic use of calcium acetate or bicarbonate, aluminum hydroxide Vitamin D deficiency
Increased renal loss	Hyperparathyroidism Increased fibroblast growth factor (FGF-23) Genetic hypophosphatemia mutations Tubular acidosis Fanconi's syndrome Hypokalemia Hypomagnesemia Polyuria Acidosis
Miscellaneous causes	Alcoholism (poor intake, vitamin D deficiency) Diabetic ketoacidosis (osmotic diuresis) Toxic shock syndrome
Drugs	See **Table 17-30**

Preparation	PO_4^{3-} Content	Na^+ Content	K^+ Content
Neutral Na/K PO_4 (PO)	8 mmol	7.1 mEq	7.1 mEq
Sodium PO_4^{3-} (IV)	3 mmol/mL	4 mEq/mL	0
Potassium PO_4^{3-} (IV)	3 mmol/mL	0	4.4 mEq/mL

TABLE 17-34 Causes of Hyperphosphatemia

Decrease in renal excretion of PO_4^{3-}	Acute and chronic renal failure* Hypoparathyroidism, pseudohypoparathyroidism
Shift of PO_4^{3-} from ICF to ECF	Hemolysis* Rhabdomyolysis* Tumor lysis syndrome Respiratory acidosis Diabetic ketoacidosis
Addition of PO_4^{3-} exogenous to the ECF	Oral or IV treatment of hypophosphatemia Phosphate-containing laxatives, antacids*
Drugs	Excess of vitamin D Growth hormone Bisphosphonates

*Most likely presentation relevant to the ED.

In asymptomatic or mildly symptomatic patients, hypophosphatemia may be treated orally with skimmed milk ([PO_4^{3-}] 1 gram/L) or oral preparations like Neutra-Phos®, one to two tabs PO four times daily, or K-Phos®, one tab PO four times daily, which contain 150 to 250 milligrams per tablet (PO_4^{3-}: 1 mmol/L = 3.1 milligrams/dL). A treatment regimen of 50 mmol/d for 7 to 10 days is sufficient to replace deficits, but in severe hypophosphatemia, higher doses may be necessary.

HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as serum [PO_4^{3-}] >4.5 milligrams/dL and is rarely encountered in emergency medicine practice. The causes can be divided in three groups according to mechanism: decrease in renal excretion of PO_4^{3-}, addition or movement of PO_4^{3-} from ICF to ECF, and drugs (**Table 17-34**).[57] In clinical practice, the most important cause of hyperphosphatemia is acute or chronic renal failure.

Hyperphosphatemia worsens renal tubulointerstitial disease, renal osteodystrophies, and cardiovascular disease. The acute symptoms are due to renal failure, hypocalcemia, and hypomagnesemia.

It is important to lower phosphorus intake with a careful protein-containing diet and to avoid excessive vitamin D intake to limit intestinal absorption.[59] In very high PO_4^{3-} levels, it is necessary to remove it with hemodialysis. Phosphate binders like calcium carbonate or calcium acetate bind intestinal phosphate, decreasing its absorption.[60]

CHAPTER 18

Cardiac Rhythm Disturbances

William J. Brady
Thomas S. Laughrey
Chris A. Ghaemmaghami

GENERAL CONSIDERATIONS

INITIAL APPROACH TO THE STABLE PATIENT

The focused evaluation of the patient includes determining the presenting complaint(s), obtaining the medical history, identifying medication use, performing a physical examination, initiating continuous cardiac rhythm monitoring, reviewing the 12-lead ECG, and analyzing the cardiac rhythm on the rhythm monitor, a printer strip, or the ECG.

Presenting symptoms may include palpitations, lightheadedness, fatigue, or weakness. Ischemic symptoms, such as chest pain, nausea, dyspnea, or lightheadedness, may be due to dysrhythmia-induced ischemia.

The medication history includes prescribed medications, herbals, recreational drugs, and caffeine-containing beverages. Especially note recently started new medications or increased medication doses. Symptoms of hyperthyroidism should be sought. Patients with a family history of sudden death, syncope, or dysrhythmias and those with organic heart disease have a higher risk of cardiac dysrhythmias and complications. Panic or anxiety is a diagnosis of exclusion in tachycardic ED patients.

INITIAL APPROACH TO THE UNSTABLE PATIENT

An unstable patient needs rapid assessment and treatment to prevent cardiovascular collapse. Instability means that the dysrhythmia is (1) impairing cardiac output and threatening vital organ function or (2) has the potential to suddenly deteriorate into cardiac arrest (**Table 18-1**).[1] Establish an IV line, initiate cardiac rhythm monitoring, obtain an ECG, and be prepared for drug or electrical therapy.

Dysrhythmia-induced chest pain results from coronary hypoperfusion, and dyspnea results from pulmonary edema, usually with objective evidence: ST segment abnormalities, rales on examination, or low oxygen saturation. As the ventricular rate exceeds 200 beats/min, severe systemic hypoperfusion often results and the RR interval narrows proportionally, increasing the opportunity for malignant ventricular dysrhythmias.

GENERAL APPROACH TO BRADYDYSRHYTHMIAS

Bradydysrhythmia describes rhythms with a ventricular rate slower than 60 beats/min in the adult. Age-appropriate heart rates define pediatric bradydysrhythmia. Bradydysrhythmias can be broadly categorized as bradycardias (atria and ventricles beat at the same slow rate) and atrioventricular (AV) blocks (ventricles beat slower than the atria).[1] The bradycardias include sinus bradycardia, junctional rhythm, idioventricular rhythm, and hyperkalemia-related sinoventricular rhythm. Bradydysrhythmias due to AV blocks include second-degree (usually type II) and third-degree AV block, as well as atrial fibrillation and atrial flutter with a slow ventricular response.

The most common bradycardia is sinus bradycardia, followed by junctional rhythm, and less commonly idioventricular rhythm. These

TABLE 18-1 Instability Indicators in the Patient with Cardiac Dysrhythmias

Hypotension: e.g., systolic blood pressure <90 mm Hg (<12 kPa)
Systemic hypoperfusion
Altered mentation
Ischemic chest pain
Respiratory distress
Extremely rapid ventricular rate: e.g., rate over 200 beats/min in adult

dysrhythmias are found in both stable and unstable patients. Atrial fibrillation and flutter with slow ventricular response are uncommon. If the patient is unstable, the vast majority of AV blocks are third-degree heart block followed much less frequently by second-degree AV block. If the patient is stable, second-degree type I AV block is most frequently seen, third-degree AV block is less common, whereas second-degree type II AV block is quite rare.[2-4]

Bradydysrhythmias result from conditions that affect the automaticity and refractoriness of cardiac cells as well as the conduction of impulses within the cardiac electrical system.[1,4] About 80% of bradydysrhythmias are caused by factors external to the cardiac electrical system including acute coronary syndrome, drug effects or overdose, and hypoxia with cardiac hypoperfusion.[2,3]

Emergent treatment of bradydysrhythmia is not required unless (1) the heart rate is slower than 50 beats/min accompanied by hypotension or hypoperfusion and/or (2) the bradydysrhythmia is due to structural disease of the infranodal conduction system. This first group requires resuscitative treatment while evaluating the cause. The second group of patients does not require immediate treatment but should be closely monitored, with pacing readily available while arranging definitive care.

Medications used to increase heart rate in symptomatic bradycardias include atropine, β-adrenergic agonists, and glucagon (**Table 18-2**; see

TABLE 18-2 Drug Treatment for Cardiac Dysrhythmias in Adults

Drugs for Bradydysrhythmias		
Atropine	0.5-milligram IV push, may repeat every 3–5 min until desired heart rate is achieved or to total dose of 3 milligrams (0.04 milligram/kg)	Most effective for bradydysrhythmias due to sinus and AV nodal disease
Dopamine	IV infusion at rate 2–20 micrograms/kg per min, titrate to desired heart rate	May precipitate myocardial ischemia and ectopy
Epinephrine	IV infusion at rate 2–10 micrograms/min, titrate to desired heart rate	May precipitate myocardial ischemia and ectopy
Glucagon	3–10 milligrams IV infused over 1–2 min, followed by an IV continuous infusion of 1–5 milligrams/h	Used for cardiotoxicity associated with β-blocker and calcium channel blocker overdose Nausea and vomiting are often limiting side effects Tachyphylaxis may develop during infusion
Drugs to Block AV Nodal Conduction		
Adenosine	6-milligram rapid IV push; if after 2 min the dysrhythmia persists, repeat rapid IV push with 12 milligrams; may repeat once more if dysrhythmia persists	Effective in terminating narrow QRS complex reentrant tachydysrhythmias involving the AV node
Verapamil	2.5–5 milligrams IV bolus over 2–3 min; if after 15 min the dysrhythmia persists, may repeat with dose of 5–10 milligrams	Effective in terminating narrow QRS complex reentrant tachydysrhythmias involving the AV node and reducing ventricular rate in atrial fibrillation or flutter
Diltiazem	15–20 milligrams IV bolus over 2 min, followed by IV infusion at 5–10 milligrams/h	
Esmolol	500 micrograms/kg IV bolus over 1 min, followed by IV infusion starting at 50 micrograms/kg per min; titrate infusion to desired heart rate	
Metoprolol	5-milligram IV bolus; may repeat 5 milligrams IV every 5 min up to total dose of 15 milligrams	
Propranolol	30 micrograms/kg IV over 1 min; may repeat same dose every 2 min, up to total dose of 100 micrograms/kg	
Drugs to Terminate Tachydysrhythmias		
Procainamide	15–17 milligrams/kg IV over 30 min, followed by IV infusion at 1–4 milligrams (20–80 micrograms/kg) per min; or 20-50 milligrams/min; or 100 milligrams IV q 5 min	Used in wide-complex tachydysrhythmias and new-onset atrial fibrillation Median time to conversion of new-onset atrial fibrillation about 1 h Caution in patients with AMI and LV dysfunction Infuse initial dose at rate of 20 milligrams/min to reduce adverse effects
Amiodarone	Stable patient: 150 milligrams IV over 10 min; may repeat same dose every 10 min up to total dose of 2 grams OR use IV infusion 0.5 milligram/min Ventricular fibrillation or pulseless ventricular tachycardia: 300 milligrams IV bolus; may repeat with additional dose of 150 milligrams IV bolus	Used in wide-complex tachydysrhythmias and new-onset atrial fibrillation Preferred in setting of AMI or LV dysfunction Contraindicated in pregnancy
Lidocaine	1 milligram/kg IV over 60 s; may repeat 0.5 milligram/kg IV every 5–10 min, up to 300 milligrams in a 1 h period; followed by infusion of 1–4 milligrams/min	Third-line agent for ventricular tachycardia and ventricular fibrillation
Magnesium sulfate	2 grams IV over 2 min, followed by infusion of 1–2 grams/h	Used in torsades de pointes with long QT interval
Ibutilide	Weight <60 kg: 10 micrograms/kg IV over 10 min Weight >60 kg: 1 milligram IV over 10 min	Used for conversion of new-onset atrial fibrillation or flutter Median time to conversion 20–30 min
Flecainide	200 milligrams PO < 70 kg 300 milligrams PO > 70 kg ; or 2 milligrams/kg IV over 10 min*	Used for conversion of new-onset atrial fibrillation or flutter Median time to conversion up to 4 h Avoid in patients with ACS or cardiomyopathy
Propafenone	450 milligrams PO < 70 kg 600 milligrams PO > 70 kg ; or 2 milligrams IV over 10 min*	Used for conversion of new-onset atrial fibrillation or flutter Median time to conversion 2 h Avoid in patients with ACS, cardiomyopathy, or severe COPD
Vernakalant*	3 milligrams/kg IV infusion over 10 min; if dysrhythmia persists after 15 min, a second infusion of 2 milligrams/kg IV over 10 min can be given	Used for conversion of new-onset atrial fibrillation or flutter Median time to conversion 8–11 min Avoid in patients with hypotension, ACS within 30 days, severe aortic stenosis, and prolonged QT interval

Abbreviations: ACS = acute coronary syndrome; AMI = acute myocardial infarction; AV = atrioventricular; COPD = chronic obstructive pulmonary disease; LV = left ventricle.

*Not available in the United States.

chapter 19, "Pharmacology of Antiarrhythmics and Antihypertensives").[1,4] Atropine enhances the automaticity of the sinoatrial (SA) node and potentiates conduction through the AV node by direct vagolytic activity. Atropine is usually effective for sinus bradycardia and junctional rhythms but is not useful (nor particularly harmful) in idioventricular rhythms and second-degree type II and third-degree AV block.[2,3] β-Adrenergic agents stimulate both chronotropic and inotropic cardiac activity, as well as enhancing electrical conduction within the AV node and infranodal system, thus their potential to produce ischemia and ectopy. Glucagon stimulates inotropic and chronotropic cardiac activity independent of the β-adrenergic receptors. Glucagon is primarily used for bradycardias due to cardiotoxicity from β-blocker or calcium channel blocker overdose. Effectiveness of drug treatment for bradycardia varies, and in general, these agents are best used as a temporary bridge to cardiac pacing.

Transcutaneous pacing can be applied quickly and is the most appropriate pacing method for the acutely symptomatic patient (see chapter 33, "Cardiac Pacing and Implanted Defibrillation"). Transvenous pacing requires considerable physician expertise and specialized equipment for insertion and proper placement. Disease-specific therapies can also be effective in reversing a toxin-induced bradycardia (e.g., treatment of hyperkalemia or toxicity from calcium channel blockers, β-blockers, or digitalis).

GENERAL APPROACH TO TACHYDYSRHYTHMIAS

Tachydysrhythmia describes rhythms with a ventricular rate greater than 100 beats/min in an adult, with age-appropriate limits in children. Tachycardias are categorized as supraventricular or ventricular (**Figure 18-1**). Supraventricular tachycardias originate from a focus within or above the AV node and most often present with a narrow QRS complex; thus, they are termed *narrow-complex tachycardias*. Ventricular tachycardias, resulting from a focus below the AV node in the ventricular myocardium, usually demonstrate a widened QRS complex and are referred to as *wide-complex tachycardias*. This classification scheme does have limitations; a supraventricular rhythm can present with a widened QRS complex due to aberrant ventricular conduction, the widened QRS complex resulting from a fixed (i.e., preexisting) bundle-branch block, rate-related conduction block, ventricular preexcitation syndrome (i.e., Wolff-Parkinson-White [WPW] syndrome), or toxic-metabolic condition.[5] The normal QRS complex duration is less than 120 milliseconds for older children and adults; therefore, a wide-complex tachycardia possesses a QRS complex width greater than 120 milliseconds.

Common narrow-complex tachycardias include sinus tachycardia, atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia; less common narrow-complex tachycardias include multifocal atrial tachycardia, atrial tachycardias, and preexcited tachycardias seen in accessory pathway syndromes including WPW syndrome.[6] Wide-complex tachycardias include ventricular tachycardia and supraventricular tachycardia with aberrant conduction.[5,7] Ventricular tachycardia further is subdivided into monomorphic and polymorphic forms; the polymorphic category includes the subtype called *torsade de pointes*.[8]

Treatment for symptomatic tachycardia is primarily intravenous medications for the stable patient and electrical therapy for the unstable patient (see chapter 23, "Defibrillation and Cardioversion"). The QRS width, often indicating the portion of the heart where the dysrhythmia originates, guides therapeutic choices.

Narrow-Complex Tachycardia Sinus tachycardia and multifocal atrial tachycardia are best managed by treating the underlying cause, rather than the dysrhythmia specifically. Other narrow-complex tachycardias require specific antidysrhythmic treatment by a combination of vagal maneuvers (**Table 18-3**), medications (Table 18-2), and electrical cardioversion (**Figure 18-2**).[9] Basic supportive therapy in most patients involves an IV fluid bolus to expand the circulating intravascular volume and supplemental oxygen.

Vagal maneuvers heighten parasympathetic tone and may slow electrical conduction in the heart to a degree that abolishes sustained reentry. If applied early, vagal maneuvers can convert about 20% of patients presenting with reentrant tachycardias, such as paroxysmal supraventricular tachycardia and narrow-complex tachycardia associated with WPW syndrome. Effective vagal maneuvers include carotid sinus massage, the release phase of the Valsalva maneuver, and the diving reflex; the response to these vagal maneuvers is enhanced by placing the patient supine.[10-12]

Adenosine is a very-short-acting agent that blocks conduction through the AV node and can interrupt sustained reentry when the AV node is part of the circuit (Table 18-2). The AV nodal blocking effect of adenosine is very transient, although quite profound, so a brief period of AV nodal blockade with near-immediate recurrence of the reentrant supraventricular tachycardia is not a treatment failure but a consequence of the medication's short duration of effect. In such situations, repeat adenosine with a higher dose (12 milligrams).[13]

β-Blockers and calcium channel blockers slow conduction through the AV node and can convert some supraventricular tachycardias, such as reentrant supraventricular tachycardias, and slow the ventricular response in others, such as atrial fibrillation or flutter. Esmolol, an intravenous β-blocker with a short duration of effect, can be used when temporary AV nodal blockade is desired and a longer period of action is not anticipated (as in conversion of paroxysmal supraventricular tachycardia) or

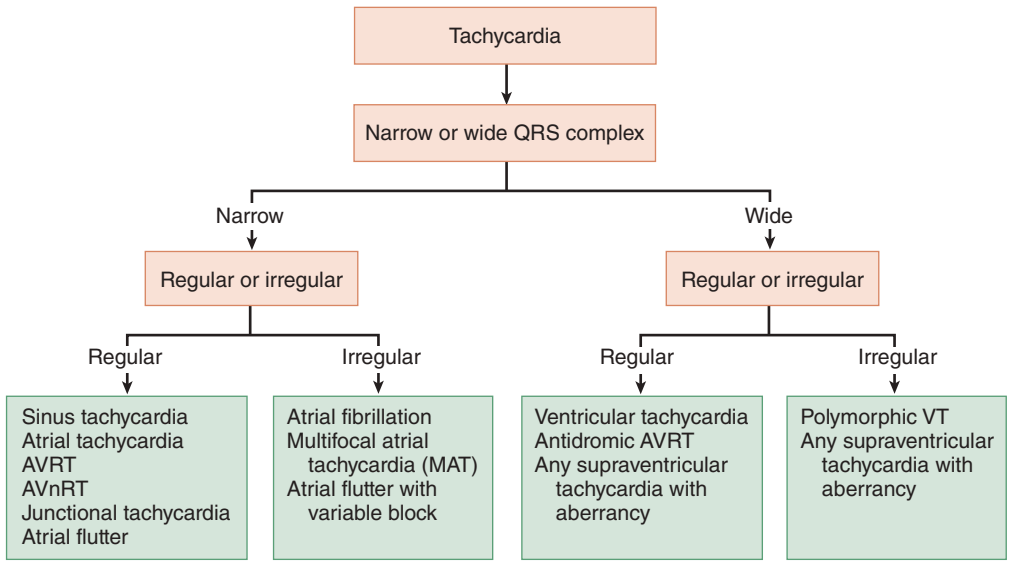

FIGURE 18-1. Tachycardia classification. AVnRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; VT = ventricular tachycardia.

TABLE 18-3 Vagal Maneuvers

Carotid sinus massage	Listen for bruit first; do not massage an artery with a bruit Massage only one side at a time Massage for 20 s or less
Valsalva maneuver	Have patient hold breath and strain against closed glottis while tightening abdominal wall muscles Hold for as long as practical, ideally >20 s Increased vagal tone seen during release phase after breath hold
Diving reflex	More effective in infants than adults Place bag of ice and water on face for 15–30 s

when the patient is unstable and the ability to titrate the degree of drug effect is important. Metoprolol is a longer acting β-blocker used in more stable patients, typically for ventricular rate control in patients with atrial fibrillation. Verapamil is a calcium channel blocker used for conversion of reentrant supraventricular tachycardias, and although it can be used for ventricular rate control, there is potential for hypotension, so diltiazem, which does not have as much potential to induce hypotension, is the calcium channel blocker recommended for ventricular rate control.

Synchronized electrical cardioversion can be used in narrow-complex tachycardias when patients are unstable or do not respond to pharmacologic measures (see chapter 23).

Wide-Complex Tachycardia In the stable patient, pharmacologic agents used to terminate a wide-complex tachycardia include procainamide, amiodarone, lidocaine, and magnesium (Table 18-2 and **Figure 18-3**). **For rapid treatment, amiodarone is the antiarrhythmic of choice, given as an IV bolus.** Procainamide is effective for stable ventricular tachycardia in patients with preserved left ventricular dysfunction, given as an IV infusion.[14] Lidocaine is a less effective alternative.[14] Magnesium is used for tachydysrhythmias associated with QT interval prolongation, such as torsade de pointes.

Electrical cardioversion is the preferred treatment for wide-complex tachycardia with hemodynamic instability, myocardial ischemia, or failure of pharmacologic treatment (see chapter 23).[7,8]

NON-TACHYCARDIC IRREGULAR DYSRHYTHMIAS

SINUS ARRHYTHMIA

Description While some variation in the rate of sinus (or SA) node electrical discharge is normal, sinus arrhythmia is present when the variation in the SA node discharge rate is greater than 120 milliseconds between the longest and shortest P to P wave intervals (**Figure 18-4**). There should be a consistent P-wave morphology indicating that the electrical impulses are all originating from the same atrial pacemaker, usually the SA node (**Table 18-4**). Two or more different P wave morphologies suggest atrial ectopy, wandering atrial pacemaker, or other nonsinus focus.

Clinical Significance Sinus arrhythmia is a normal finding in children and young adults but is less common in the middle-aged and elderly. Sinus arrhythmia is most commonly a respiro-phasic phenomenon; the sinus node rate accelerates during inspiration and decelerates during expiration. This variation is thought to be due to changes in vagal tone occurring with respiration, termed *the Bainbridge reflex*. Any condition or medication that alters vagal tone may exaggerate an underlying sinus arrhythmia. During long intervals of sinus arrhythmia, junctional escape beats may occur.

Treatment None is required.

SINOATRIAL BLOCK

Description The SA node electrical discharge must be conducted into the atria to pace the heart during sinus rhythm. If sinus node discharges are delayed or blocked in their outward propagation (exit block), then SA block is present. SA block is divided into first-, second-, and third-degree varieties, much like the classification system used for AV nodal blockade.

In **first-degree SA block,** the impulse is delayed in its conduction out of the sinus node into the atria, a condition that cannot be recognized on the clinical 12-lead ECG; this entity is diagnosed in the electrophysiology laboratory. In **second-degree SA block,** some impulses get through and some are blocked. **Second-degree SA block** can be suspected whenever an expected P wave and the corresponding QRS complex are absent. Usually, the interval between normal P waves encompassing the missing beat is a simple multiple of the existing P to P rate. **Third-degree SA block** occurs when the sinus node discharge is completely blocked and no P wave originating from the sinus is seen. In addition to

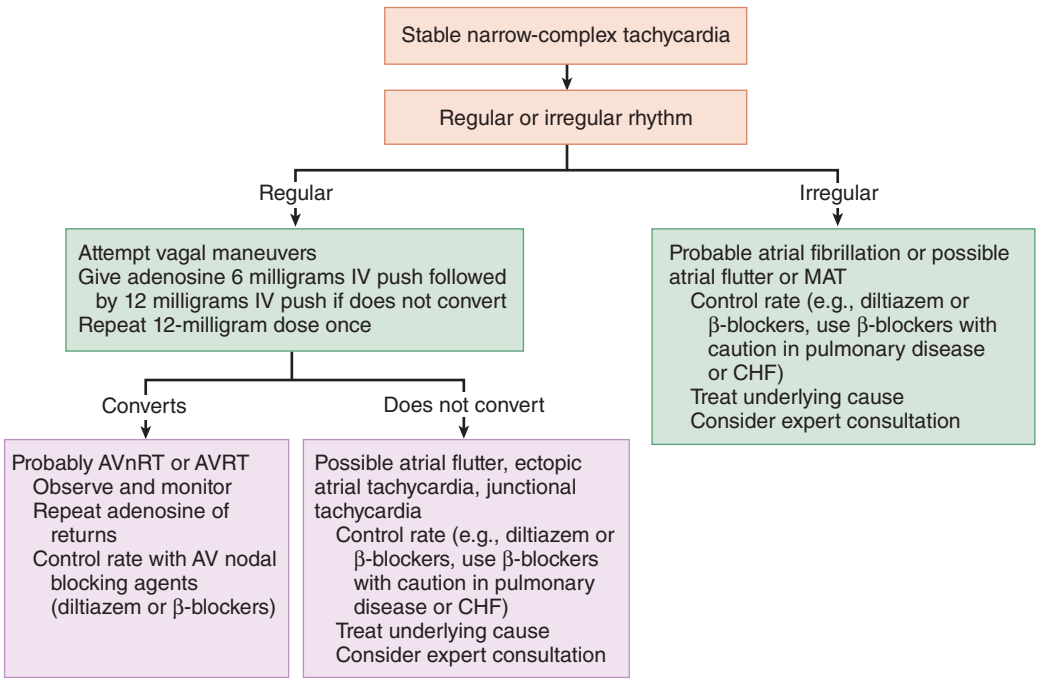

FIGURE 18-2. Treatment of narrow-complex tachycardia. AV = atrioventricular; AVnRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; CHF = congestive heart failure; MAT = multifocal atrial tachycardia; VT = ventricular tachycardia.

FIGURE 18-4. Sinus arrhythmia.

third-degree SA block, absence of a P wave may also be caused by (1) sinus node failure, (2) a sinus node stimulus inadequate to activate the atria, and (3) atrial unresponsiveness.

Clinical Significance SA block usually arises from myocardial disease (acute rheumatic fever, acute inferior MI, or other causes of myocarditis) or drug toxicity (digoxin, quinidine, salicylates, β-blockers, or calcium channel blockers). In rare individuals, vagal stimulation can produce SA block.

Treatment Treatment depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present. Sinus node discharge rate and SA conduction can be facilitated by atropine when clinically required; however, ischemia may result from a rhythm that is accelerated. Cardiac pacing is indicated for recurrent or persistent symptomatic bradycardia.

SINUS ARREST (PAUSE)

Description Sinus pause is a failure of impulse formation within the sinus node. In sinus arrest, the P to P wave interval encompassing the missing beat has no relation to the underlying SA node discharge rate (**Figure 18-5**).

Clinical Significance The same conditions that produce SA block produce sinus arrest, especially digoxin toxicity and aging disease of the SA node. Brief periods of sinus arrest may occur in healthy individuals due to increased vagal tone. If sinus arrest is prolonged, AV junctional escape beats often occur.

TABLE 18-4 ECG Features of Sinus Arrhythmia

Upright P waves in leads I, II, and III
Consistent P wave–QRS complex relationship
Consistent P-wave morphology from beat-to-beat
Variation in the sinus node discharge rate >120 ms between longest and shortest P to P wave intervals

Treatment Treatment is often unneeded and when considered depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present. If sinus arrest is symptomatic, atropine usually will increase the SA node discharge rate. Cardiac pacing is indicated for recurrent or persistent symptomatic bradycardia.

SICK SINUS SYNDROME

Description Sick sinus syndrome (sometimes referred to as the *tachycardia-bradycardia syndrome*) is a heterogeneous disorder consisting of abnormalities of supraventricular impulse generation and conduction that produce a wide variety of intermittent supraventricular tachy- and bradydysrhythmias (**Table 18-5**). The tachydysrhythmias are usually atrial fibrillation, junctional tachycardia, paroxysmal supraventricular tachycardia, and atrial flutter. The bradydysrhythmias are marked sinus bradycardia, prolonged sinus arrest, and SA block, usually associated with AV nodal conduction abnormalities and inadequate junctional escape rhythms.

Clinical Significance Sick sinus syndrome is most commonly seen in elderly patients and is associated with a variety of cardiac diseases that can affect the SA and AV nodes, including ischemic disorders, myocarditis and pericarditis, rheumatologic disease, metastatic tumors, surgical damage, or cardiomyopathies.

Symptoms of sick sinus syndrome are due to the effects of fast or slow heart rate. Common symptoms include syncope or near-syncope, palpitations, dyspnea, chest pain, and cerebrovascular ischemic events. Conditions that increase vagal tone (abdominal pain, increased intracranial pressure), thyrotoxicosis, and hyperkalemia may exacerbate the abnormalities of sick sinus syndrome and increase symptoms. Medications such as digoxin, quinidine, procainamide, disopyramide, nicotine, β-blockers, and calcium channel blockers also can increase symptoms.

Ambulatory ECG monitoring or electrophysiologic studies are usually necessary for diagnosis, because intermittent dysrhythmias may not be evident during the examination.

Treatment By definition, symptomatic patients will have both tachy- and bradydysrhythmias, and each of the elements may need to be

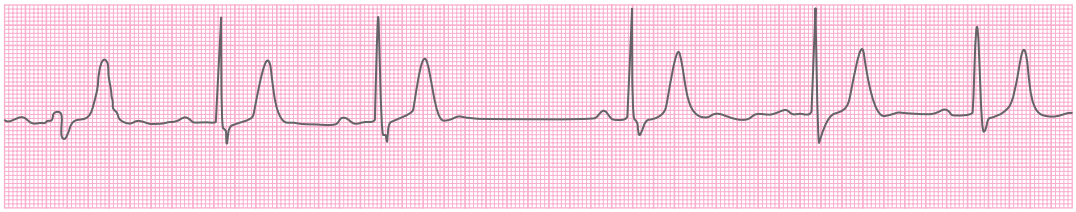

FIGURE 18-5. Sinus pause.

addressed. Aggressive pharmacologic treatments and ablation procedures to reduce tachycardia carry risks of worsening bradycardia, AV block, and pauses. Transcutaneous pacing may be required if the patient is being pharmacologically treated for atrial tachydysrhythmias in the setting of sick sinus syndrome. Permanent pacemaker implantation is frequently indicated.

PREMATURE ATRIAL CONTRACTIONS

Description Premature atrial contractions originate from ectopic pacemakers anywhere in the atrium other than the SA node (**Figure 18-6**) with characteristic ECG features (**Table 18-6**). The ectopic P wave may not be conducted through the AV node if the premature atrial contraction reaches the AV node during the absolute refractory period. When a premature atrial contraction reaches the AV node during the relative refractory period, it may be conducted with a delay, as demonstrated on the ECG by a longer PR interval than seen with a sinus beat. Nonconducted premature atrial contractions are the most common cause of pauses in cardiac rhythm. Premature atrial contractions may occur in a pattern, such as every other beat (atrial bigeminy), every third beat (atrial trigeminy), and so on.

Most premature atrial contractions are conducted with baseline QRS complexes, but some may be conducted aberrantly through the infranodal system, particularly if they reach a bundle branch during the refractory period. The premature atrial contraction will often depolarize the SA node ("reset"), so the interval between normal P waves encompassing the premature atrial contraction will not be twice the existing P to P interval, creating a shorter pause than the fully compensatory pauses seen after most premature ventricular contractions.

Clinical Significance Premature atrial contractions are common at all ages and usually do not indicate underlying heart disease. Increased rates of premature atrial contractions are seen in patients with chronic heart or lung disease. Chemical agents that enhance either sympathetic tone (e.g., cocaine, amphetamines, caffeine, nicotine) or parasympathetic tone (e.g., digoxin) may lead to a higher frequency of premature atrial contractions in an individual patient. Premature atrial contractions can precipitate sustained atrial tachycardia, flutter, or fibrillation under certain circumstances.

Treatment No specific treatment is necessary. If the premature atrial contractions are symptomatic, discontinue any precipitating toxins and treat any underlying disorder that is contributing to symptoms.

PREMATURE JUNCTIONAL CONTRACTIONS

Description Premature junctional contractions are due to an ectopic pacemaker within the AV node or common AV bundle with characteristic ECG features (**Table 18-7**).

Because the premature junctional contraction is usually conducted back into the atria, the SA node is usually affected by the ectopic depolarization, and the postectopic pause is noncompensatory, but a compensatory pause is seen if the premature junctional contraction is not conducted in retrograde fashion. Premature junctional contraction may be isolated, multiple (as in bigeminy or trigeminy), or multifocal.

Clinical Significance Premature junctional contractions are uncommon in healthy hearts and are typically seen in patients with heart failure, digitalis toxicity, ischemic heart disease, and myocardial ischemia (especially of the inferior wall).

Treatment No specific treatment is usually required. Treatment of the underlying disorder is appropriate.

FIGURE 18-6. Premature atrial contractions in an atrial trigeminy pattern.

PREMATURE VENTRICULAR CONTRACTIONS

Description Premature ventricular contractions occur when electrical impulses originate from single or multiple areas in the ventricles. ECG characteristics (**Figure 18-7** and **Table 18-8**) are used to differentiate premature ventricular contractions from other premature beats.

Most premature ventricular contractions do not affect the spontaneous discharge of the SA node, so the interval between normal sinus P waves encompassing the premature ventricular contraction is twice the previous P to P interval, termed a fully compensatory postectopic pause. This fully compensatory pause occurs because the SA node discharges during the refractory period of either the AV node or His bundles induced by the premature ventricular contraction. Less commonly, a premature ventricular contraction may be interpolated between two sinus beats. Many premature ventricular contractions occurring in a bigeminal or trigeminal pattern have a fixed coupling interval (within 40 milliseconds) from the preceding sinus beat (**Figure 18-8**). Occasionally, a **ventricular fusion beat** occurs when both supraventricular and ventricular impulses depolarize the ventricular myocardium almost simultaneously. The QRS configuration of a fusion beat has characteristics of both the normally conducted beat and the ectopic one.

The degree (quantity and quality) of the premature ventricular contractions is categorized as follows: (1) an occasional premature ventricular contraction seen on the rhythm strip is called an isolated premature ventricular contraction (Figure 18-7A), (2) multiple premature ventricular contractions of similar morphology are called unifocal premature ventricular contractions (Figure 18-7B), and (3) multiple premature ventricular contractions with different morphology are called multifocal premature ventricular contractions (Figure 18-7C), implying more than one ventricular focus is producing ectopy. Periods of sustained unifocal premature ventricular contractions may occasionally be seen, often with a fixed ratio and coupling interval to sinus beats.

Clinical Significance Premature ventricular contractions are very common and related to factors that alter the electrophysiology of cardiac tissue or to pathologic conditions of the myocardium itself. Sometimes, infrequent or rare premature ventricular contractions may be observed in patients without any evidence of heart disease. Premature ventricular contractions may trigger sustained runs of ventricular tachycardia (**Figure 18-9**).[15]

There is a correlation between the severity of underlying coronary artery disease and the degree of ventricular ectopy, and in addition, ventricular ectopy is an independent risk factor for sudden cardiac death.[16,17] In acute coronary syndrome, premature ventricular contractions indicate the underlying electrical instability of the heart, but patterns of premature ventricular contractions ("warning dysrhythmias") are not reliable predictors of subsequent ventricular fibrillation.

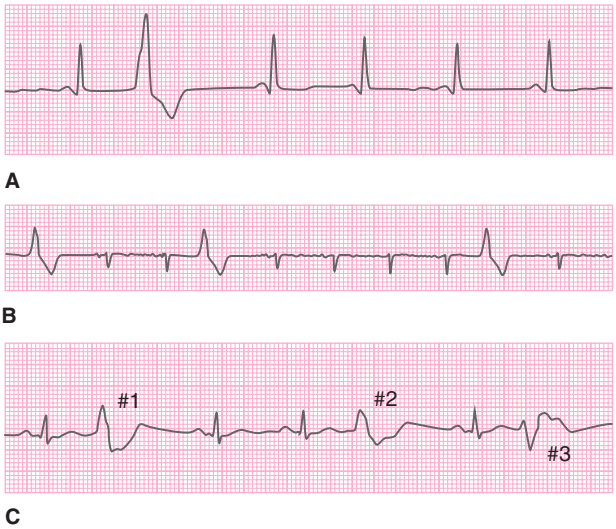

FIGURE 18-7. Sinus rhythm with premature ventricular contractions (PVCs). **A.** Sinus rhythm with a single PVC. **B.** Sinus rhythm with multiple unifocal PVCs. **C.** Sinus rhythm with multifocal PVCs (three different PVC morphologies in this single lead, indicated by #1, #2, and #3).

Abnormally widened QRS complex with different morphology from SA node–initiated QRS complex
Commonly a compensatory postectopic pause following the premature ventricular contraction to next SA node–initiated beat
ST segments and T waves that are directed opposite the major QRS complex deflection

Abbreviation: SA = sinoatrial.

Treatment Review the ECG for evidence of ischemia or infarction, chamber enlargement, QT interval prolongation, or Brugada syndrome. Assess for potentially reversible conditions such as hypoxia, drug effect, or electrolyte abnormalities. In general, treat the underlying cause.[18,19] Typical recommendations for stress reduction and elimination of stimulants such as caffeine or nicotine are not consistently effective.[19] Patients with greater than three premature ventricular contractions in a row are considered to have nonsustained ventricular tachycardia, which can be a marker for sustained tachydysrhythmias and sudden cardiac death. If this is a new dysrhythmia, initiate emergency cardiac investigation.

Pharmacologic suppression of isolated premature ventricular contractions with antiarrhythmic medications in the acute setting does not confer improved survival for the acute condition. Attempts to suppress premature ventricular contractions with long-term oral antidysrhythmics increase mortality due to the dangerous prodysrhythmic properties of the medications themselves.[18,19] Implantable cardioverter defibrillators are used in patients with premature ventricular contractions that have potential to trigger malignant ventricular dysrhythmias or cardiac arrest.

BRADYDYSRHYTHMIAS

SINUS BRADYCARDIA

Description Sinus bradycardia is when the SA node discharge rate falls below 60 beats/min and AV conduction remains intact with a constant PR interval (**Figure 18-10**). The ECG characteristics are identical to sinus rhythm with the exception of a slow heart rate (**Table 18-9**).

Clinical Significance Sinus bradycardia represents a reduction of the SA node discharge rate. Sinus bradycardia can be (1) physiologic (in well-conditioned athletes, during sleep, or with vagal stimulation), (2) pharmacologic (β-blockers, digoxin, opioids, calcium channel blockers), or (3) pathologic (hypoxia, acute inferior wall myocardial ischemia or infarction, increased intracranial pressure, carotid sinus hypersensitivity, hypothyroidism).

Treatment Sinus bradycardia usually does not require specific treatment unless the heart rate is slower than 50 beats/min and there is evidence of hypoperfusion. Correct underlying causes. Use atropine in the unstable patient, followed by transcutaneous cardiac pacing and infusions of dopamine or epinephrine if there is no response to atropine.[1]

JUNCTIONAL RHYTHM

Description Under normal circumstances, the SA node discharges at a faster rate than the AV node, so the pacemaker function of the AV node and all other slower pacemakers are suppressed. If SA node discharges slow or fail to reach the AV node, junctional escape beats will produce a rhythm (**Figure 18-11**) usually at a rate between 40 and 60 beats/min. If the junctional beats continue in sequence, then a junctional rhythm is present. In most cases, junctional escape beats do not conduct retrograde into the atria, so a QRS complex without a P wave is usually seen (Figure 18-11A); rarely, the junctional escape beat does

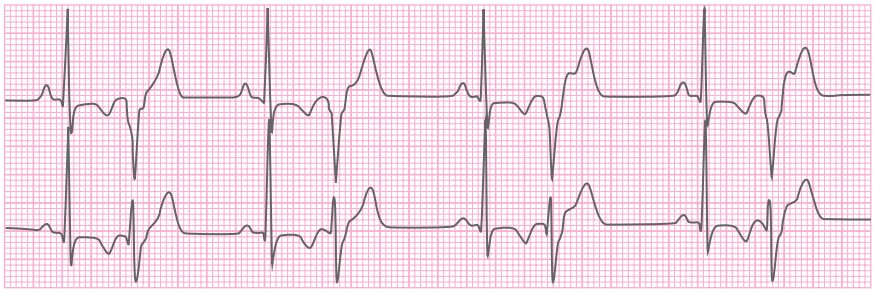

FIGURE 18-8. Premature ventricular contractions producing ventricular bigeminy.

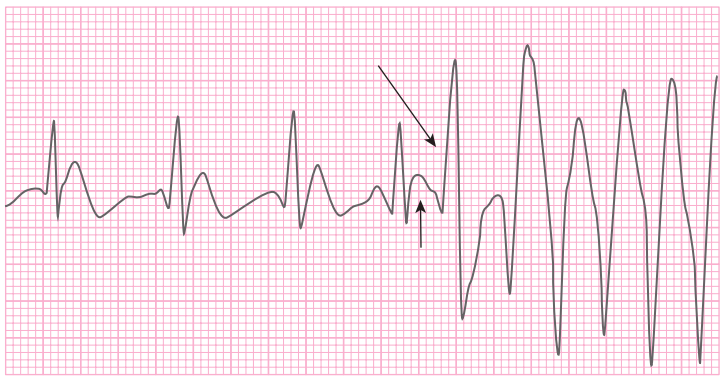

FIGURE 18-9. Sinus rhythm in an ST-segment elevation myocardial infarction patient with a premature ventricular contraction (PVC) initiating ventricular tachycardia. Note the R wave (*large arrow*) of a PVC falling on the T wave (*small arrow*) of the last sinus beat. This R-on-T event produces ventricular tachycardia.

Rate <60 beats/min and regular

Abbreviation: SA = sinoatrial.

conduct retrograde into the atria, producing the retrograde P wave; a P wave usually inverted and found immediately prior to or following the QRS complex (Figure 18-11B).

At times, enhanced AV nodal automaticity overrides the sinus node and produces an accelerated junctional rhythm with a rate of 60 to 100 beats/min or junctional tachycardia with a rate greater than 100 beats/min. Usually, the enhanced junctional pacemaker captures both the atria and ventricles.

Clinical Significance Junctional escape beats may occur whenever there is a long enough pause in the impulses reaching the AV node, as with sinus bradycardia, slow phase of sinus arrhythmia, or during the

A

B

FIGURE 18-11. Junctional rhythm. **A.** Junctional rhythm. **B.** Junctional rhythm with retrograde P waves (*arrow*).

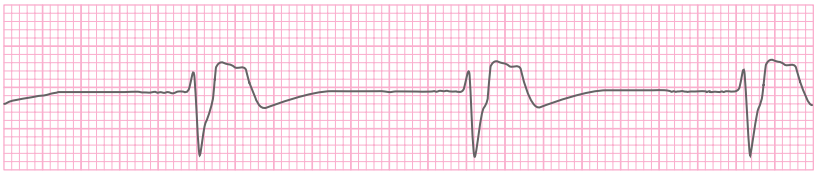

FIGURE 18-12. Idioventricular rhythm with a ventricular rate of approximately 30 beats/min.

pause after premature beats. Sustained junctional escape rhythms may be seen with heart failure, myocarditis, hypokalemia, or digitalis toxicity.

Accelerated junctional rhythm, including junctional tachycardia, may occur from medication toxicity, acute rheumatic fever, or inferior myocardial ischemia. With medication toxicity (particularly digitalis compounds) in a patient being treated for atrial fibrillation, the rate is usually between 70 and 130 beats/min and the ECG is characterized by regular QRS complexes superimposed on atrial fibrillatory waves.

Treatment Isolated, infrequent junctional escape beats usually do not require specific treatment. If sustained junctional escape rhythms are producing symptoms, the underlying cause should be treated. Atropine can be used to accelerate the SA node discharge rate and enhance AV nodal conduction. Accelerated junctional rhythm and junctional tachycardia usually do not produce significant symptoms.

IDIOVENTRICULAR RHYTHMS

Description Idioventricular rhythms are of ventricular origin (**Figure 18-12**), manifesting as regular widened QRS complexes without evidence of atrial activity (**Table 18-11**). An idioventricular rhythm has a ventricular rate of 30 to 50 beats/min, and the accelerated idioventricular rhythm has a ventricular rate of 50 to 75 beats/min. Idioventricular rhythm tends to appear in nonsustained fashion with runs of short duration, ranging from 3 to 30 consecutive beats, and will typically begin with a fusion beat.

Clinical Significance Idioventricular rhythm is seen most commonly in the setting of an ST-segment elevation myocardial infarction. An accelerated idioventricular rhythm that appears during successful fibrinolysis of an occluded coronary artery is termed a *reperfusion dysrhythmia*. Although there is some association with ventricular tachycardia, there is no apparent association with ventricular fibrillation. Idioventricular rhythms, particularly the slower versions, can produce dizziness, weakness, syncope, chest pain, and dyspnea; profound hypoperfusion may occur. Accelerated idioventricular rhythm itself usually produces no symptoms, but the loss of atrial contraction and subsequent fall in cardiac output can produce hemodynamic deterioration.

Treatment With idioventricular rhythm producing hypoperfuson, drugs to increase the heart rate are appropriate. Atropine is recommended, although the likelihood of successful treatment is low. Cardiac pacing is often needed, starting via the transcutaneous route. In most cases of accelerated idioventricular rhythm, treatment is not necessary. If accelerated idioventricular rhythm is the only functioning pacemaker, **suppression with antiarrhythmic agents may lead to asystole**. If sustained accelerated idioventricular rhythm produces symptoms secondary to a decrease in cardiac output, pacing is recommended.

TABLE 18-10 ECG Features of Junctional Rhythm

Absence of normal (sinus-mediated) P waves with normal PR interval
Rare retrograde P wave (usually an inverted P wave and immediately adjacent to QRS complex, pre or post)
Narrow QRS complex
Regular rate
Ventricular rate
Between 40 and 60 beats/min for junctional rhythm
Between 60 and 100 beats/min for accelerated junctional rhythm
>100 beats/min for junctional tachycardia

ATRIOVENTRICULAR BLOCKS

First-degree AV block is characterized by a delay in AV conduction manifested by a prolonged PR interval. Second-degree AV block is characterized by intermittent AV conduction: some atrial impulses reach the ventricles, and others are blocked. Third-degree AV block is characterized by the complete blockage of atrial impulses to the ventricles.

AV blocks are divided into nodal and infranodal blocks because of the clinical significance and prognostic differences.[1] Nodal AV block (block within the AV node) is usually due to reversible depression of conduction, is often self-limited, and generally has a stable infranodal escape pacemaker pacing the ventricles. Infranodal blocks (block below the AV node) usually are due to organic disease of the His bundle or bundle branches; often the damage is irreversible. They generally have a slow and unstable ventricular escape rhythm pacing the ventricles, and they frequently have a bad prognosis.

FIRST-DEGREE ATRIOVENTRICULAR BLOCK

Description In first-degree AV block, each atrial impulse is conducted to the ventricles but less rapidly than normal, as noted by a prolonged PR interval, greater than 200 milliseconds. There is a P wave for each QRS complex; this association is consistent from one beat to the next (**Figure 18-13** and **Table 18-12**). The AV node is usually the site of conduction delay, although this block may occur at an infranodal level.

Clinical Significance First-degree AV block occasionally is found in normal hearts. Other common causes include increased vagal tone of any cause, medication toxicity, inferior myocardial infarction, and myocarditis. Patients with first-degree AV block without evidence of organic heart disease appear to have no difference in mortality compared with matched controls. In the setting of an acute coronary syndrome event, its appearance can indicate an increased chance of progression to complete heart block.

Treatment Usually none is required. Close monitoring in the patient with acute myocardial ischemia is indicated due to the potential for progression to complete heart block.

SECOND-DEGREE MOBITZ TYPE I (WENCKEBACH) ATRIOVENTRICULAR BLOCK

Description In second-degree Mobitz type I (Wenckebach) block, there is progressive prolongation of AV conduction (and the PR interval) until an atrial impulse is completely blocked; when an atrial impulse is blocked, no accompanying QRS complex is seen (**Figure 18-14** and **Table 18-13**). Conduction ratios indicate the ratio of atrial to ventricular depolarizations; for instance, a 4:3 ratio indicates that three of four atrial impulses are conducted into the ventricles. Usually, only one atrial

TABLE 18-11 ECG Features of Idioventricular Rhythm

Widened QRS complex
QRS complexes occurring regularly
No evidence of atrial activity: no P waves
Ventricular rate
30–50 beats/min for idioventricular rhythm
50–75 beats/min for accelerated idioventricular rhythm
Often in nonsustained fashion with runs of short duration: 3–30 consecutive beats

FIGURE 18-13. Sinus rhythm with first-degree atrioventricular block (PR interval, 300 milliseconds).

impulse is blocked. After the dropped beat, the AV conduction returns to normal, and the cycle usually repeats itself with the same conduction ratio (fixed ratio) or a different conduction ratio (variable ratio). This type of block almost always occurs at the level of the AV node and is often due to reversible depression of AV nodal conduction.

Second-degree type I, or Wenckebach, block occurs because each successive depolarization produces prolongation of the refractory period of the AV node. When the next atrial impulse comes upon the node, it is earlier in the relative refractory period, and conduction occurs more slowly relative to the previous stimulus. This process is progressive until an atrial impulse reaches the AV node during the absolute refractory period, and conduction is blocked altogether. The pause allows the AV node to recover, and the cycle repeats. This cyclic occurrence produces a pattern of "grouped beating" and is apparent over successive cycles (**Figure 18-15**).

Clinical Significance This block is often transient and usually associated with an inferior myocardial ischemia, medication toxicity, or myocarditis, or after cardiac surgery. It may occur when a normal AV node is exposed to very rapid atrial rates. This block can also be a normal variant, not indicative of acute or chronic heart disease.

Treatment Specific treatment is usually not necessary unless very slow ventricular rates produce signs of hypoperfusion, where most patients will respond to atropine. The need for an increased rate and increased perfusion must be balanced with the increased myocardial work in the acutely ischemic patient.

SECOND-DEGREE MOBITZ TYPE II ATRIOVENTRICULAR BLOCK

Description In second-degree Mobitz type II block, the PR interval remains constant across the rhythm strip, both before and after the nonconducted atrial beats (**Figure 18-16** and **Table 18-14**). Each P wave is associated with a QRS complex until a nonconducted atrial depolarization (i.e., P wave) is noted without accompanying QRS complex. Mobitz II blocks usually occur in the infranodal conducting system, often with coexistent fascicular or bundle-branch blocks, and the QRS complexes therefore are usually wide. Even if the QRS complexes are narrow, the block is generally in the infranodal system. High-grade AV block is noted when more than one consecutive P wave is not conducted (Figure 18-16C).

TABLE 18-12 ECG Features of First-Degree Atrioventricular Block

Consistent P wave to QRS complex relationship
Prolongation of PR interval >200 ms

When second-degree AV block occurs with a fixed conduction ratio of 2:1, it is not possible to differentiate between type I (Wenckebach) or type II block. If the QRS complex is wide, the block is more likely to be in the infranodal system. If the QRS complex is narrow, then the block is in the AV node or infranodal system with about equal incidence; it is recommended that the "worst case scenario" be assumed in such presentations and to consider the "untypable" second-degree AV block a type II blockage.

Clinical Significance Type II blocks imply structural damage to the infranodal conducting system, are usually permanent, and may progress suddenly to complete heart block, notably with concomitant acute myocardial ischemia.

Treatment Patients should have transcutaneous cardiac pacing pads applied in the ED in anticipation of possible need. Start emergent pacing when slow ventricular rates produce symptoms of hypoperfusion. Atropine can be tried but the effect is inconsistent.[2,3] Most patients, especially in the setting of acute myocardial ischemia, will require eventual transvenous cardiac pacing.

THIRD-DEGREE ATRIOVENTRICULAR BLOCK (COMPLETE HEART BLOCK)

Description In third-degree AV block, there is no AV conduction (**Figure 18-17** and **Table 18-15**). An escape pacemaker (manifested by the QRS complex) paces the ventricles at a rate slower than the atrial rate manifested by the P wave. When third-degree AV block occurs in the AV node, a junctional escape pacemaker takes over with a ventricular rate of 40 to 60 beats/min. The QRS complexes are narrow because the rhythm originates above the bifurcation of the bundle of His. When third-degree AV block occurs at the infranodal level, the ventricles are driven by a ventricular escape rhythm at a rate slower than 40 beats/min. Third-degree AV blocks at the His bundle level can have a narrow or wide QRS complex, whereas blocks in the bundle branches or elsewhere in the Purkinje system invariably have escape rhythms with wide QRS complexes.

TABLE 18-13 ECG Features of Second-Degree Mobitz Type I (Wenckebach's) Atrioventricular Block

Progressive prolongation of PR interval until an atrial impulse is completely blocked: a P wave without accompanying QRS complex

FIGURE 18-17. Two examples of third-degree atrioventricular block. Both have an atrial rate of 83 with ventricular escape rate of 50. Not all P waves are visible; some are hidden by the QRS complex or T wave.

FIGURE 18-18. Sinus tachycardia at a rate of 110 beats/min.

Clinical Significance Nodal third-degree AV block (i.e., with a narrow QRS complex) develops in up to 8% of inferior acute myocardial infarction patients and may last for several days. Infranodal third-degree AV blocks (i.e., with a wide QRS complex) indicate structural damage to the infranodal conducting system, as seen with an extensive anterior acute myocardial infarction. The ventricular escape pacemaker is usually inadequate to maintain cardiac output and the patient is unstable, with periods of ventricular asystole. When third-degree block is seen in acute myocardial infarction, mortality is increased even with pacing.

Treatment Infrequently, patients with complete heart block will present with minimal to no symptomatology; these patients require monitoring and admission. Manage the symptomatic patient with either medication and/or pacing. Nodal blocks may respond to atropine; infranodal blocks are unlikely to respond to atropine or other medications that can enhance AV nodal conduction. Patients should have transcutaneous cardiac pacer pads applied in the ED. If there is no or incomplete response to atropine, use transcutaneous cardiac pacing, recognizing that transvenous pacing is eventually necessary in most patients.

NARROW-COMPLEX TACHYCARDIAS

SINUS TACHYCARDIA

Description Sinus tachycardia (**Figure 18-18** and **Table 18-16**), the most common narrow-complex tachycardia encountered in the ED, is defined as sinus rhythm with rates greater than 100 beats/min.

Clinical Significance Sinus tachycardia should be considered a reactive rhythm, occurring in response to a triggering condition. Generally, sinus tachycardia is a benign rhythm without any end-organ dysfunction.

Treatment Because sinus tachycardia is often a compensatory mechanism resulting from a physiologic stress, address the underlying cause, not the rhythm.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Description After sinus tachycardia, atrial fibrillation is the next most frequent narrow-complex tachycardia encountered in the ED; atrial flutter is a less common dysrhythmia. Atrial fibrillation occurs when there are multiple, small areas of atrial myocardium continuously discharging and contracting.[20] There is no uniform atrial depolarization and contraction but, rather, only a quivering of the atrial chamber walls, resulting in less than effective ventricular filling and diminished cardiac output.

The ECG hallmarks of atrial fibrillation (**Figure 18-19** and **Table 18-17**) include the absence of discernible P waves and an irregularly irregular ventricular rhythm. With the chaotic atrial activity, distinct P waves are not noted; rather either a flat or chaotic baseline is seen, most prominent in lead V_1. The irregularly irregular ventricular rhythm results from the atrial chaos and the variable conduction of impulses through the AV node to the ventricle. The atrial rate in atrial fibrillation is often greater than 600 beats/min, whereas the ventricular rate is markedly lower due to the refractory period of the AV node; in atrial fibrillation where the AV node is unaffected by disease or medications,

TABLE 18-16 ECG Features of Sinus Tachycardia

Normal sinus P waves and PR interval
1:1 atrioventricular conduction
Atrial rate usually between 100 and 160 beats/min

TABLE 18-17 ECG Features of Atrial Fibrillation

Absence of discernible P waves with flat or chaotic isoelectric baseline
QRS complexes narrow unless preexisting bundle-branch block or preexcitation syndrome
Irregularly irregular ventricular rhythm

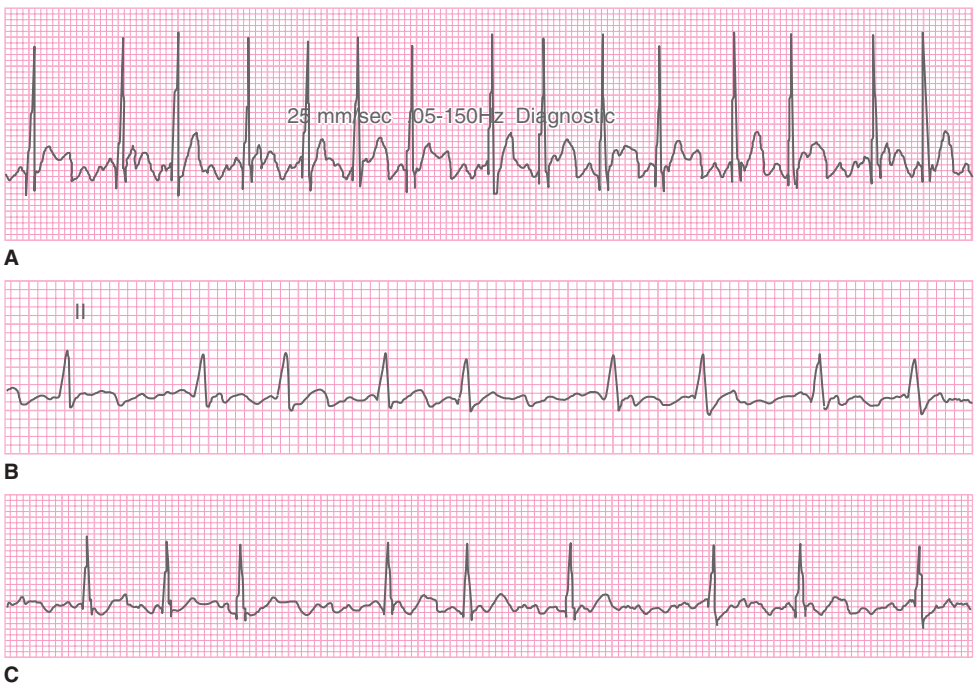

FIGURE 18-19. Three examples of atrial fibrillation with irregular ventricular response.

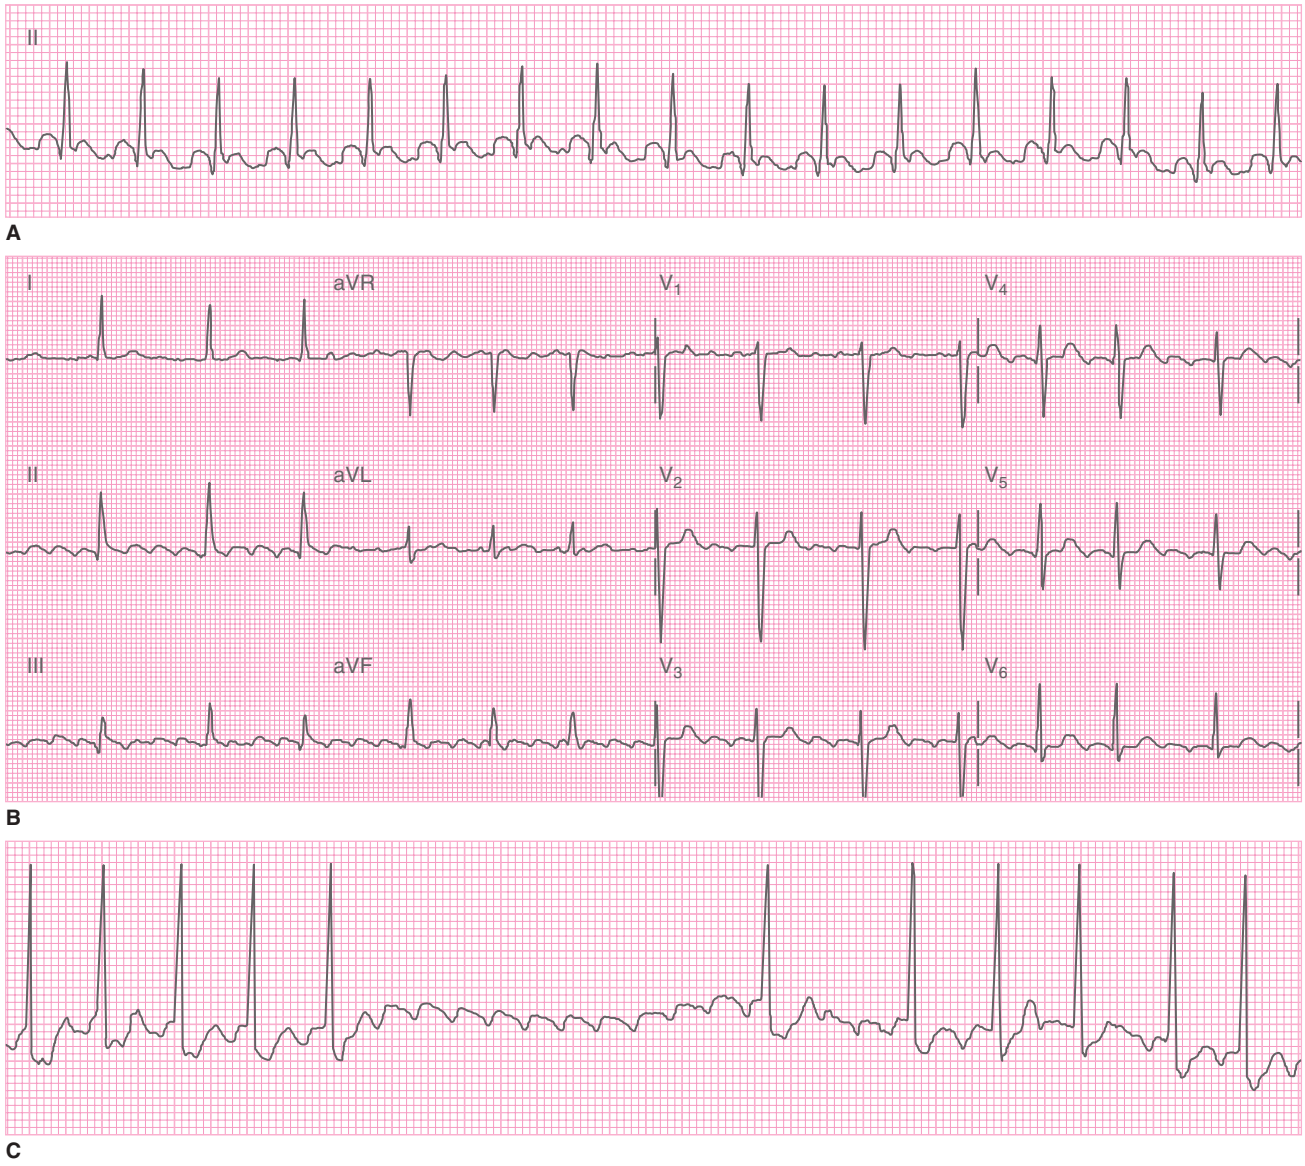

FIGURE 18-20. Atrial flutter. **A.** Regular, narrow-complex tachycardia at a ventricular rate of 155 beats/min. **B.** Atrial flutter with flutter waves most visible in leads 2, 3, and AVF. **C.** Atrial flutter response to carotid sinus massage inducing transient AV block and unmasking flutter waves.

the ventricular rate is typically 120 to 170 beats/min. Illnesses or medications may reduce AV node conduction and markedly slow ventricular response. A very rapid ventricular response (>200 beats/min) may be seen in patients with accessory or bypass tracts (discussed later in this chapter).

In contrast to atrial fibrillation, atrial flutter most often is a regular rhythm (**Figure 18-20** and **Table 18-18**); in rare cases, it can be irregular. P waves are present and of a single morphology, typically a downward deflection, called *flutter waves* resembling a saw blade with a "sawtooth" pattern, best seen in the inferior ECG leads and lead V_1. Most commonly, the atrial rate is regular, classically around 300 beats/min, varying between 250 and 350 beats/min. The ventricular rhythm is frequently regular and is a function of the AV block. AV ratios of 2:1 are common and produce a ventricular rate around 150 beats/min, whereas a 3:1 AV ratio will result in a ventricular rate of 100 beats/min. Although the degree of AV conduction is often fixed, it may also be variable and create an irregular ventricular response. **A regular narrow-complex tachycardia at an approximate rate of 150 beats/min strongly suggests atrial flutter with 2:1 conduction.**

TABLE 18-18 ECG Features of Atrial Flutter

Identifiable P waves
Single morphology
Negative amplitude ("flutter waves" in "sawtooth pattern") best seen in inferior ECG leads and V1
Atrial rate is regular, usually at 300 beats/min
QRS complexes narrow unless preexisting bundle-branch block
Ventricular rate regular although occasional irregularity can be seen
Ventricular rate often 150 beats/min

Clinical Significance Atrial fibrillation is usually associated with ischemic or valvular heart disease; less common causes include congestive cardiomyopathy, myocarditis, alcohol binge ("holiday heart"), thyrotoxicosis, and blunt chest trauma.[20,21] Left atrial enlargement is a common feature of patients with chronic atrial fibrillation. Atrial fibrillation can be paroxysmal (lasting less than 7 days, terminating either spontaneously or with treatment), persistent (sustained longer than 7 days or requiring treatment to terminate), long-standing persistent (lasting continuously longer than 1 year), or permanent (long-standing where a decision has been made not to try to restore normal sinus rhythm).[20]

New or recent onset is applied to symptomatic patients presenting to the ED without a prior history of atrial fibrillation.

The clinical consequences of atrial fibrillation include loss of atrial contraction, potential for rapid ventricular rates, and risk of arterial embolism. In patients with compromised cardiac function, left atrial contraction contributes significantly to left ventricular filling, so the loss of effective atrial contraction, as in atrial fibrillation, may produce heart failure in these patients. A rapid ventricular rate can impact ventricular filling as well as coronary and systemic perfusion. Atrial fibrillation increases the risk of venous and atrial thrombosis, with potential for pulmonary and systemic arterial embolism. If an atrial thrombus has formed, conversion from atrial fibrillation to sinus rhythm can propel a portion of the thrombosis out into the systemic circulation, and this risk increases with duration of the dysrhythmia. Observational studies note that conversion from new-onset atrial fibrillation that has been present for 12 hours or less carries a 0.3% risk of arterial embolism, whereas that risk is about 1% for durations of 12 to 48 hours before conversion.[22] For patients with heart failure and diabetes mellitus, conversion from new-onset (duration <48 hours) atrial fibrillation carries a risk of thromboembolic events as high as 9.8%.[23] Conversely, the incidence of thromboembolic events is 0.2% in patients age <60 years and no heart failure.[23] After a duration of >48 hours, the risk of conversion-induced thromboembolic events is increased across all patient groups and a period of anticoagulation is recommended prior to conversion.[20,24]

Treatment Treatment of atrial fibrillation in the ED involves three issues: ventricular rate control, rhythm conversion, and anticoagulation to prevent arterial embolism.[24-26] Treatment varies according to patient stability, duration of symptoms, and chronicity of atrial fibrillation (paroxysmal, persistent, or permanent). Review prior records to identify past episodes or treatment for atrial fibrillation. For new-onset atrial fibrillation, consider checking thyroid function.[27] For patients on warfarin, check the prothrombin time. Calculate either the $CHADS_2$ or CHA_2DS_2-VASc score to risk-stratify the potential for future arterial embolic complications; a $CHADS_2$ score of 0 or a CHA_2DS_2-VASc score of 0 or 1 identify low-risk patients (**Table 18-19**).[20,21]

For patients with paroxysmal atrial fibrillation or acute medical conditions producing atrial fibrillation, a period of observation and treatment in the ED is appropriate as the atrial fibrillation may spontaneously convert.[12,28] Up to 70% of otherwise healthy ED patients evaluated for acute-onset atrial fibrillation will spontaneously convert within 48 to 72 hours.[29] Ventricular rate control may help control symptoms until conversion. Also, it is more difficult to achieve rate or rhythm control of atrial fibrillation in patients with acute underlying medical illness, and such attempts are associated with an increased incidence of adverse events.[30]

For patients with recent-onset atrial fibrillation and a rapid ventricular response that is producing hypotension, myocardial ischemia, or pulmonary edema, treat with urgent electrical cardioversion.[20,24,25,31] When possible, first determine if the patient has long-standing atrial fibrillation because electrical cardioversion is not likely to succeed, and instead, initiate ventricular rate control treatment. If the patient is at increased risk for embolic complications ($CHADS_2$ or CHA_2DS_2-VASc scores ≥1, mechanical heart value, or rheumatic valvular disease), consider anticoagulation with heparin before or immediately after electrical cardioversion and continue that as a bridge to oral anticoagulants.[31]

For stable low-risk patients in the ED with new-onset atrial fibrillation, either rate-control or rhythm-conversion strategies are appropriate (**Table 18-20**).[20,24,25] The rate-control approach consists of initiating medications that block the AV node to control the ventricular response, initiating oral anticoagulants to prevent thromboembolism (if appropriate), and re-evaluation after 3 to 4 weeks for elective cardioversion. The rhythm-conversion approach uses electrical or pharmacologic methods to convert the patient back into sinus rhythm while in the ED.

Control of the ventricular response is done using a calcium channel blocker (diltiazem) or β-blockers (metoprolol and esmolol) with limited data favoring more effective acute rate control with diltiazem.[32] If β-blockers or calcium channel blockers are ineffective, intravenous procainamide or amiodarone is an option to slow the ventricular response. The goal for rate control is a ventricular rate of <100 beats/min at rest.[25]

Electrical cardioversion using 150 to 200 J can terminate atrial fibrillation allowing for sinus rhythm to resume.[24,31] Conversion to and retention of sinus rhythm is more likely when atrial fibrillation is of short duration (<48 hours) and the atria are not greatly dilated. Observational analysis also notes that administration of rate-control or rhythm-conversion medications prior to electrical cardioversion attempts is associated with a reduced rate of successful conversion to sinus rhythm.[33] Although ED electrical cardioversion is effective in many atrial fibrillation patients[34] and observational studies indicate shorter ED length of stay,[26] there has been mixed acceptance of this approach.[35-37] As noted above, a significant portion of patients with new-onset atrial fibrillation will spontaneously convert to sinus rhythm within 24 hours of onset and evaluation.[12,28,29,38,39] This rate of spontaneous conversion coupled with the results of atrial fibrillation trials demonstrating that rate-control is similar to rhythm-control in terms of several key endpoints indicates no proven benefit for conversion of all new atrial fibrillation patients to sinus rhythm while in the ED.[24,38,39] The patient with new-onset atrial fibrillation who is stable can certainly be managed with rate-control alone, either as an inpatient or outpatient depending overall clinical condition.

The antiarrhythmics procainamide, ibutilide, flecainide, propafenone, and vernakalant can chemically convert atrial fibrillation to sinus rhythm.[24,40,41] Of the five, ibutilide has the highest consistent success rate for conversion. Ibutilide should not be given in the presence of hypokalemia, prolonged QT interval, or history of heart failure, as torsade de pointes may be initiated. This risk of torsade de pointes persists for 4 to 6 hours after the ibutilide is given. Pharmacologic conversion therapy is best avoided if duration is unknown or greater than 48 hours, allowing for heart clot detection and anticoagulation prior to any attempt.

Patients with recurrent paroxysmal atrial fibrillation are sometimes given oral medications (usually flecainide or propafenone) to be taken at the onset of the dysrhythmia; this "pill in a pocket" approach is successful in selected outpatients.[24] This approach should only be used in patients with paroxysmal episodes after SA or AV node dysfunction,

TABLE 18-19 $CHADS_2$ and CHA_2DS_2-VASc scores

Criteria	$CHADS_2$	CHA_2DS_2-VASc
Congestive heart failure	1	1
Hypertension	1	1

Diabetes mellitus	1	1
Stroke, TIA, or thromboembolism	2	2
Vascular disease (CAD, PAD)	–	1
Age 65–74 y	–	1
Sex (female)	–	1
Range	0–6	0–9

Abbreviations: CAD = coronary artery disease; PAD = peripheral artery disease; TIA = transient ischemic attack.

TABLE 18-20 ED Management of New-Onset Atrial Fibrillation in Stable Patients*

Clinical Circumstance	Treatment	Follow-Up Therapy
Duration <48 h Low-risk for embolism†	Chemical or electrical cardioversion to sinus rhythm	If successful conversion, no antithrombotic therapy
Duration <48 h Low-risk for embolism†	Ventricular rate control <100 beats/min	No antithrombotic therapy Close follow-up
Duration >48 h	Ventricular rate control <100 beats/min	Therapeutic anticoagulation for 3–4 wk
High-risk for embolic complications‡	Ventricular rate control <100 beats/min	Therapeutic anticoagulation for 3–4 wk

*See Table 18-2 for drug treatment.

†Low risk = $CHADS_2$ score of 0 or a CHA_2DS_2-VASc score of 0 or 1.

‡High risk = $CHADS_2$ score ≥1 or a CHA_2DS_2-VASc score ≥2.

FIGURE 18-21. Paroxysmal supraventricular tachycardia.

conduction disturbance (bundle branch block, Brugada syndrome), and structural heart disease have been excluded.[2]

Atrial flutter is managed in the same fashion as atrial fibrillation: either rhythm conversion or ventricular rate-control with β-blockers or calcium channel blockers.[24] Atrial flutter is very responsive to electrical cardioversion; as little as 25 to 50 J is often effective. In general, patients in atrial flutter tend to better tolerate the dysrhythmia hemodynamically than patients with atrial fibrillation. This "hemodynamic toleration" results from the organized atrial contraction seen with atrial flutter, as opposed to the lack of organized atrial contraction with atrial fibrillation. Despite organized atrial activity, there is a risk of arterial embolism with atrial flutter,[42] and corresponding recommendations for anticoagulation are based on the same criteria used for atrial fibrillation.[25]

Patients with chronic atrial fibrillation and planned cardioversion should be anticoagulated for 3 to 4 weeks, assuming clinical stability allows such an approach.[20] Patients with permanent atrial fibrillation are at increased risk for embolic stroke, and oral anticoagulation can reduce that occurrence. The benefits of oral anticoagulation are counterbalanced by the potential adverse effects, usually hemorrhagic events. Clinical scoring tools, such as the CHA_2DS_2-VASc, can be used to guide the decision to initiate long-term oral anticoagulation therapy in atrial fibrillation patients.[20,21]

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

Description Paroxysmal supraventricular tachycardia most frequently results from sustained reentry occurring with the AV node, with an ectopic atrial focus accounting for the remaining 15% to 20%. In paroxysmal supraventricular tachycardia (**Figure 18-21** and **Table 18-21**), the QRS complex is of normal width, rapid, and regular. P waves are "buried" within the QRS complex in about 70% of cases. In the others, a P wave (so-called "retrograde" P wave) is found immediately adjacent before, during, or after the QRS complex without a measurable PR interval.

Clinical Significance Paroxysmal supraventricular tachycardia is seen more frequently in females, with a peak in the late teenage and young adult years. The majority of patients are without active cardiovascular disease.[43] Patients may be able to describe the abrupt onset of this reentrant dysrhythmia and also note when it self-terminates. Palpitations, lightheadedness, and dyspnea are common symptoms.

Treatment If applied early in the dysrhythmia course, vagal maneuvers are often effective (Table 18-3).[10,11] Attention to technique is important to maximize success rate. If there is no response to vagal maneuvers, adenosine IV is recommended to convert to sinus rhythm.[9] It is the rare patient who requires β-blocker or calcium channel blocker. In patients with recalcitrant paroxysmal supraventricular tachycardia or who are unstable, use electrical cardioversion to convert the dysrhythmia.

TABLE 18-21 ECG Features of Paroxysmal Supraventricular Tachycardia

Absence of normal (sinus-mediated) P waves with normal PR interval
Rare retrograde P wave (usually inverted P wave and immediately adjacent to QRS complex, pre or post)
Narrow QRS complex, usually <100 ms in duration
Ventricular rate usually 170–180 beats/min; the rate can range from as low as 130 beats/min to as high as 300 beats/min

MULTIFOCAL ATRIAL TACHYCARDIA

Description Multifocal atrial tachycardia is an irregular rhythm resulting from at least three different atrial ectopic foci competing to pace the heart. The electrocardiographic characteristics (**Figure 18-22** and **Table 18-22**) require at least three distinct P-wave morphologies. Due to irregularity and the chaotic appearance of atrial depolarization, multifocal atrial tachycardia is often confused with atrial fibrillation or atrial flutter.

Clinical Significance Multifocal atrial tachycardia is found most often in elderly patients with decompensated chronic lung disease, but may also complicate heart failure or sepsis.

Treatment Treatment is directed toward the underlying disorder. With decompensated lung disease, oxygen and bronchodilators improve pulmonary function and arterial oxygenation and decrease atrial ectopy. Antidysrhythmic treatment is not indicated, and cardioversion has no effect.

WIDE-COMPLEX TACHYDYSRHYTHMIAS

Wide-complex tachydysrhythmias are defined as a rhythm with a QRS complex duration greater than 120 milliseconds and a rate over 100 beats/min. Both ventricular tachycardia and supraventricular tachydysrhythmias with aberrant ventricular conduction present as wide-complex tachydysrhythmias (**Figure 18-23**).[5]

Traditional teaching, derived largely from coronary care units and electrophysiology laboratories, presents that 80% of wide-complex tachycardias are ventricular tachycardia.[44] However, in the ED, there is a range of pathophysiologic conditions that can produce delayed ventricular depolarization that when combined with a sinus tachycardia induced by acute illness result in a wide-complex tachycardia.[7] The conduction abnormality can be the result of a bundle-branch block (new-onset, preexisting, or rate-related), metabolic abnormality (e.g., hyperkalemia), adverse medication effect (e.g., sodium channel blockade), or ventricular preexcitation syndrome. All supraventricular tachycardias can present as a wide-complex tachycardia if intraventricular conduction is abnormal. In addition, two tachydysrhythmias seen in WPW syndrome will present with a widened QRS complex: the antidromic version of the AV nodal reentrant tachycardia and atrial fibrillation or flutter with ventricular depolarization predominantly or exclusively via the accessory tract.

VENTRICULAR TACHYCARDIA

Description Ventricular tachycardia is the occurrence of three or more consecutive depolarizations from a ventricular ectopic pacemaker at a rate faster than 100 beats/min.[8] Ventricular tachycardia can occur in a nonsustained manner,[45] with short episodes, lasting several beats, with spontaneous termination, or it can occur in a sustained fashion, with longer episodes that typically require treatment.[8] Ventricular tachycardia

FIGURE 18-22. Multifocal atrial tachycardia. Note multiple P-wave morphologies with irregular tachycardia rhythm.

can be further characterized according to hemodynamic effect (stable vs unstable), morphology (monomorphic vs polymorphic), or clinical presentation (perfusing vs pulseless as during cardiac arrest).

The electrocardiographic features (**Figure 18-24** and **Table 18-23**) vary between the monomorphic and polymorphic varieties. Morphologic ventricular tachycardia is the most commonly encountered form of ventricular tachycardia, accounting for about 70% of cases, and is usually very regular with rates most often in the 140 to 180 beats/min range. Medications, such as amiodarone, may slow the rate of ventricular tachycardia; such patients may present with ventricular rates of 110 to 130 beats/min. On rare occasions, monomorphic ventricular tachycardia may present with an irregular rhythm, but only minimally irregular as compared to an aberrantly conducted atrial fibrillation, which ordinarily manifests marked irregularity.

TABLE 18-22 ECG Features of Multifocal Atrial Tachycardia

At least 3 distinct P-wave morphologies in a single ECG lead
No consistent P to P, PR, or R to R intervals
Irregularly irregular rhythm with rates usually 100–180 beats/min
Normal QRS complex unless preexisting bundle-branch blocks
Frequently confused with atrial fibrillation or flutter

Polymorphic ventricular tachycardia has varying QRS morphology in any single ECG lead (**Figure 18-25** and Table 18-23). Variations in both the RR interval and electrical axis are also features of this form of ventricular tachycardia. Torsade de pointes, a specific subtype of polymorphic ventricular tachycardia, occurs in the setting of delayed myocardial repolarization manifested on the sinus rhythm ECG by a prolongation of the QT interval.[46] The French term *torsade de pointes* means "twisting of the points" and describes the appearance of the QRS complex as it varies in appearance (Figure 18-25B).

Clinical Significance Ventricular tachycardia is rare in patients without underlying heart disease.[5] The most common causes of ventricular tachycardia are chronic ischemic heart disease and acute myocardial infarction, comprising about 50% of all cases of symptomatic ventricular tachycardia. Less common causes of ventricular tachycardia include dilated or hypertrophic cardiomyopathy, valvular heart disease (including mitral valve prolapse), inherited ion channel abnormalities, and drug toxicity. Hypoxia,

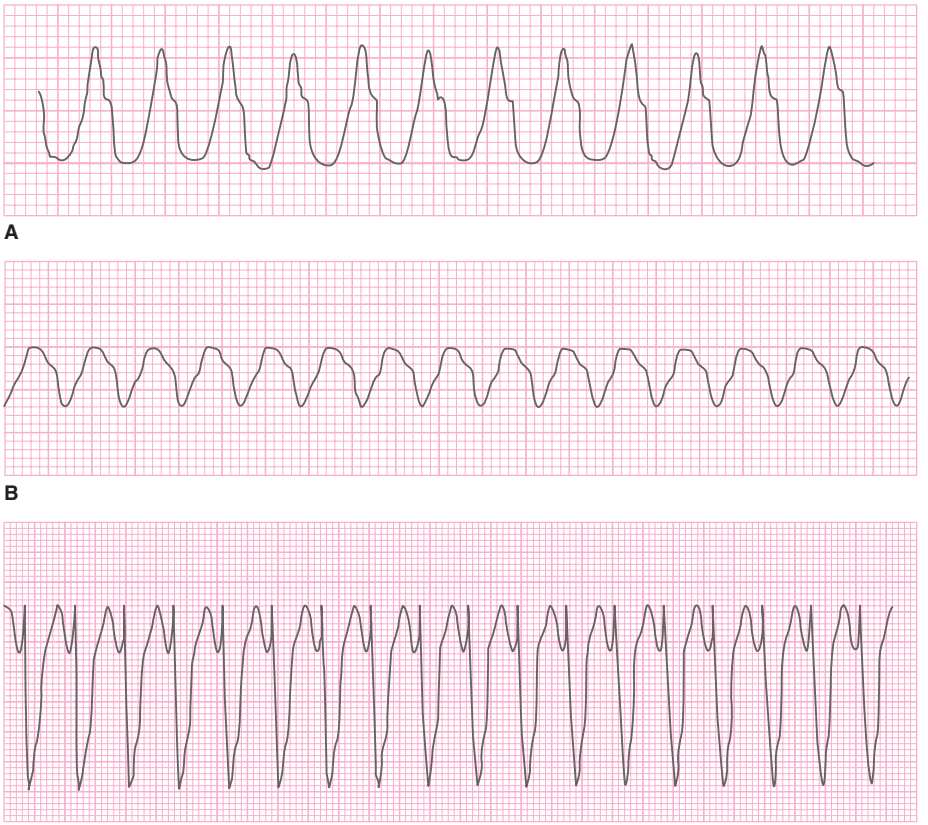

FIGURE 18-24. Three examples of monomorphic ventricular tachycardia. **A.** Ventricular tachycardia with a rate of 270 beats/min. **B.** Ventricular tachycardia with a rate of 220 beats/min. **C.** Ventricular tachycardia with a rate of 180 beats/min.

TABLE 18-23 ECG Features of Monomorphic and Polymorphic Ventricular Tachycardia

Monomorphic
No P waves associated with QRS complex, occasional dissociated P wave
Rapid and regular rhythm
Rate usually 140–180 beats/min (range, 120–300 beats/min)
Widened QRS complex >100–120 ms with consistent beat-to-beat morphology
Polymorphic
No P waves associated with QRS complex; may have occasional dissociated P wave
Rapid and irregular rhythm
Rate 140–180 bpm (range, 120–300 beats/min)
Widened QRS complex >100–120 ms with inconsistent beat-to-beat morphology

alkalosis, and electrolyte abnormalities, especially hyperkalemia, exacerbate the propensity for ventricular ectopy and tachycardia.

Torsade de pointes occurs when repolarization is delayed, and cardiac after-potentials can initiate this form of polymorphic ventricular tachycardia. Delayed repolarization is seen in inherited (congenital long QT syndrome) and acquired (primarily drug toxicity) circumstances.[46] Torsade de pointes often occurs in bursts of up to 30 cycles before spontaneously stopping. Sustained torsade de pointes is uncommon and can potentially degenerate into ventricular fibrillation.

It is a misconception that patients with ventricular tachycardia are clinically unstable. Ventricular tachycardia cannot be reliably differentiated from supraventricular tachycardia with aberrant

FIGURE 18-25. Two examples of polymorphic ventricular tachycardia. **A.** Polymorphic ventricular tachycardia. **B.** Polymorphic ventricular tachycardia of the torsade de pointes subtype, with the characteristic pattern of progressively changing QRS complex amplitude and direction.

conduction on the basis of clinical symptoms or vital signs. Differentiation using the 12-lead ECG can be challenging and, at times, impossible (see discussion in next section).

Treatment The management of ventricular tachycardia is based on the patient's clinical stability. The most extreme form of instability is cardiac arrest; these patients should receive prompt electrical defibrillation, chest compressions, and other advanced life support measures. Patients with a pulse but compromised by the ventricular tachycardia should undergo electrical cardioversion coupled with administration of a procedural analgesia and sedation if clinical status allows time to administer. In the stable patient, pharmacologic agents are first-line therapy.[47]

Drug therapy for ventricular tachycardia includes procainamide, amiodarone, lidocaine, and magnesium. Procainamide is an effective agent for stable ventricular tachycardia in patients with preserved left ventricular dysfunction.[14] Based on limited human comparative studies, procainamide is superior to lidocaine for converting patients with stable ventricular tachycardia.[14] The primary disadvantage of procainamide is the relatively slow dosing because rapid infusions can cause hypotension.

For patients with tenuous hemodynamic status, amiodarone is the antiarrhythmic of choice with lidocaine as the less effective alternative. If pharmacologic interventions are unsuccessful, then sedation-assisted electrical (synchronized) cardioversion is the next option.

Magnesium is primarily used as an antiarrhythmic agent in patients with known hypomagnesemia, QT interval prolongation, polymorphic ventricular tachycardia, or torsade de pointes.[48] Case reports describe the benefits of isoproterenol or phenytoin in torsade de pointes, but controlled studies are lacking.[49-51] Definitive treatment of torsade de pointes is ventricular pacing at a rate necessary to prevent the bursts of polymorphous ventricular tachycardia. Pacing is continued until the cause of QT prolongation (drug toxicity, electrolyte abnormality) is ameliorated.

UNDIFFERENTIATED WIDE-COMPLEX TACHYCARDIA

Description A regular, wide-complex tachycardia can be either of ventricular origin (ventricular tachycardia) or due to a supraventricular tachycardia with aberrant conduction of the electrical impulse through the ventricles. The differentiation between ectopic beats of ventricular origin and those of aberrantly conducted supraventricular origin can be difficult, more so in sustained tachycardias with widened QRS complexes.

Clinical Features Traditional teaching emphasizes five electrocardiographic features as helpful in differentiating ventricular tachycardia from supraventricular tachycardia with aberrant conduction: irregularity, AV dissociation, fusion and capture beats, QRS duration, and QRS complex concordance (**Figure 18-26**).[5,7] Ventricular tachycardia is usually very regular; if irregular, the degree of irregularity is minimal (Figures 18-23A and 18-26C). Marked irregularity is strongly suggestive of atrial fibrillation with bundle-branch block; of course, torsade de pointes is also irregular, but the changing polarity of the QRS complex is usually quite apparent.

AV dissociation, where the atria and ventricles have separate independent pacemakers (Figure 18-26C), if noted, is strongly suggestive of ventricular tachycardia. In cases of ventricular tachycardia without retrograde conduction to the atria, the SA node continues to initiate atrial depolarization. Because atrial depolarization is completely independent of ventricular activity, the resulting P waves will be dissociated from the QRS complexes. AV dissociation is not common; it is noted in only approximately 10% of ventricular tachycardia patients.

Capture and fusion beats (Figure 18-26D) are potentially useful and suggest ventricular tachycardia. In the patient with ventricular tachycardia, an independent atrial impulse may occasionally cause ventricular depolarization via the normal conducting system; such a supraventricular impulse, if conducted and able to trigger a depolarization within the ventricle, will result in a different QRS complex morphology—different than the other wide QRS complex beats. If the resulting QRS complex occurs earlier than expected and is narrow, the complex

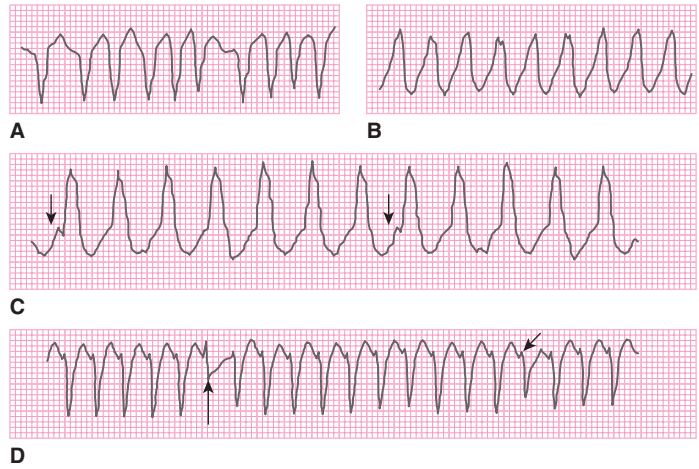

FIGURE 18-26. ECG considerations in the distinction of supraventricular tachycardia with aberrant ventricular conduction from ventricular tachycardia. **A.** Irregular rhythm in Wolff-Parkinson-White–related atrial fibrillation. **B.** Regular rhythm in ventricular tachycardia. **C.** Atrioventricular dissociation in ventricular tachycardia. The *arrows* indicate P waves, indicative of atrioventricular dissociation, which is strongly suggestive of ventricular tachycardia. **D.** Capture (*large arrow*) and fusion (*small arrow*) beats that are indicative of ventricular tachycardia.

is called a capture beat; the supraventricular impulse electrically captures the ventricle, producing a narrow complex. The presence of capture beats strongly supports a diagnosis of ventricular tachycardia. Fusion beats occur when a sinus beat conducts to the ventricles via the AV node and joins, or fuses, with a ventricular beat originating from the abnormal ectopic focus. These two electrical "beats" combine, resulting in a QRS complex of intermediate width and differing morphology when compared to the other beats of ventricular tachycardia. As with capture beats, the presence of fusion beats is strongly suggestive of ventricular tachycardia. Fusion and capture beats occur infrequently and are seen in fewer than 10% of patients with ventricular tachycardia.

Ventricular tachycardia usually has a wider QRS complex than does supraventricular tachycardia with aberrancy, so extreme QRS durations >160 milliseconds argue in favor of ventricular tachycardia. Concordance describes that the polarity of the QRS complexes is consistent across the precordium, either all negative or positive from leads V_1 to V_6. Negative concordance, with all the precordial QRS complexes having a negative or downward deflection, suggests ventricular tachycardia.

In addition to these traditional characteristic, features of the QRS complex on the 12-lead ECG have been analyzed as differentiators of ventricular tachycardia versus supraventricular tachycardia with aberrancy. Since 1991, five different algorithms have been created, studied, and compared (**Table 18-24**).[52-56] The approach varies: the Brugada, Griffith, and Lau approaches use multiple leads and criteria; the Vereckei algorithm uses only lead aVR, although with four criteria; and the Pava algorithm only uses lead II and only one criterion. The Griffith approach is reversed from the other four; it assumes that the wide-complex tachycardia is ventricular in origin and then looks for evidence that favors supraventricular with aberrancy. Published comparisons are mixed regarding the sensitivity and specificity of these different algorithms, and neither has proven consistently superior.[57-61] Simplicity favors the Vereckei or Pava approaches.

Treatment **When in doubt, it is safer to assume a new and symptomatic wide-complex tachycardia is ventricular in origin than the converse. Maintain a focus on treating the entire patient, not solely the ECG.** If rapid treatment is needed, use IV amiodarone. In stable patients, response to adenosine can be helpful in differentiating ventricular from supraventricular wide-complex tachycardias.[62] Not all wide-complex tachycardias require antiarrhythmic agents or urgent electrical therapy. Treatment of the causative syndrome is often the most appropriate action.

TABLE 18-24 Methods for Wide-Complex Tachycardia Differentiation

Author and Year	Favors Ventricular Tachycardia (VT)	Favors Supraventricular Tachycardia with Aberrant Conduction (SVTAC)
Brugada, 1991[52]	VT diagnosed if, analyzed in sequence, any one of these 4 criteria is present: Absence of RS complexes in all precordial leads R to S interval >100 ms in one or more precordial leads AV dissociation Morphologic criteria for VT in leads V_1 and V_6 (V_1: monophasic R, qR, QS, or RS; and V_6: rS, QS, qR, or S > R)	SVTAC diagnosed if no to all 4 criteria for VT
Griffith, 1994[53]	VT diagnosed if no to either criteria for SVTAC	SVTAC diagnosed if both criteria are present: QRS morphology classic for bundle-branch block: LBBB (rS or QS in leads V_1 and V_2; time to S wave nadir in lead V_1 or V_2 >70 ms; R wave and no Q wave in V_6) *or* RBBB (rSR′ in lead V_1; RS in lead V_6; R wave larger than S wave in V_6) No atrioventricular dissociation is seen
Lau, 2000[54]	Bayesian analysis starting with pretest odds for VT then multiply by likelihood ratio for VT associated with each of these factors: QRS duration QRS frontal plane axis V_1 morphology with a RBBB pattern V_1 and V_2 morphology with a LBBB pattern Interval of initial R-wave deflection in V_6 V_6 morphology VT diagnosed if posttest odds >3	SVTAC diagnosed if posttest odds <0.33
Vereckei, 2008[55]	VT diagnosed if, analyzed in sequence, any of these 4 criteria are present in lead aVR: Initial R wave Initial r or q wave >40 ms Notch present on the initial descending limb of a predominately negative QRS Slow conduction at beginning of QRS: ratio of vertical distance travelled in voltage during the initial 40 ms (v_i) and terminal 40 ms (v_t); ratio of v_i/v_t <1	SVTAC diagnosed if none of the 4 criteria for VT are present
Pava, 2010[56]	VT diagnosed if time from isoelectric to peak of R wave in lead II is >50 ms	SVTAC diagnosed if not

Abbreviations: LBBB = left bundle-branch block; RBBB = right bundle-branch block.

VENTRICULAR FIBRILLATION

Description Ventricular fibrillation is disorganized depolarization and chaotic contraction of small areas of ventricular myocardium absent any effective mechanical cardiac activity; there is no cardiac output. The ECG of ventricular fibrillation shows a fine, irregular pattern without discernible P waves or organized QRS complexes. The irregular pattern itself can be coarse, intermediate, or fine in amplitude (**Figure 18-27**).

Clinical Significance Ventricular fibrillation is seen most commonly in patients with severe ischemic heart disease, with or without an acute myocardial infarction. Primary ventricular fibrillation occurs suddenly and without preceding hemodynamic deterioration, whereas secondary ventricular fibrillation occurs after a prolonged period of left ventricular failure and/or circulatory shock. In addition, direct stimulation of the myocardium by catheters or other instruments, electrocution, and direct blunt chest trauma (also known as *comotio cordis*) can induce ventricular fibrillation.

Treatment Treatment of pulseless ventricular tachycardia or fibrillation is with electrical defibrillation along with chest compressions and other advanced life support measures. If resuscitation is successful at restoring spontaneous circulation, address any dysrhythmic triggers including acute ischemia, metabolic derangements, or toxicologic insult.

DYSRHYTHMIA ASSOCIATED CONDUCTION ABNORMALITIES

WOLFF-PARKINSON-WHITE SYNDROME

Description WPW syndrome is a form of ventricular preexcitation involving an accessory conduction pathway that bypasses the AV node

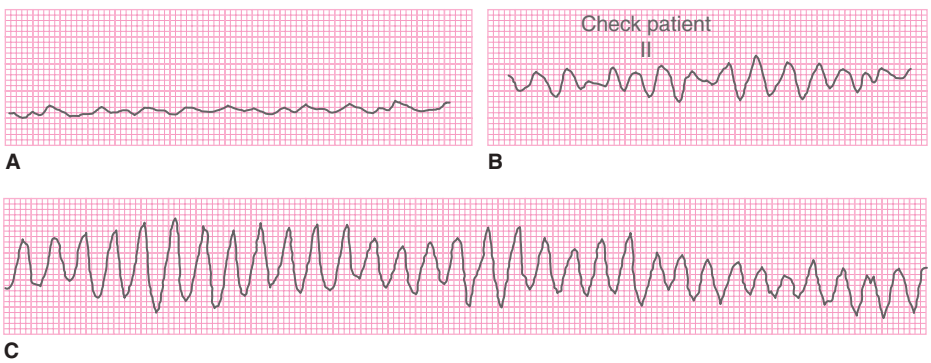

FIGURE 18-27. Three examples of ventricular fibrillation. **A.** Coarse amplitude. **B.** Fine amplitude. **C.** Coarse amplitude mimicking ventricular tachycardia.

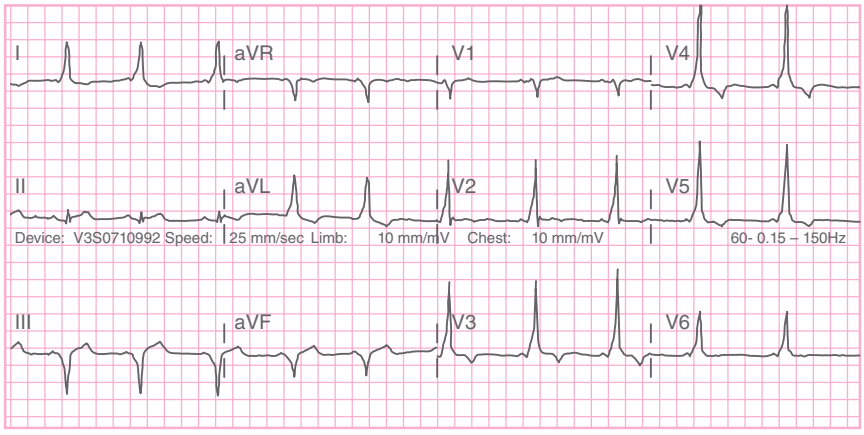
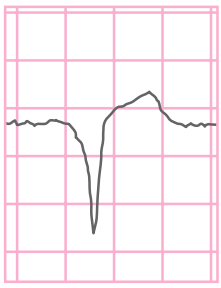
TABLE 18-25 Dysrhythmias Seen in Symptomatic Wolff-Parkinson-White Syndrome

Atrioventricular reciprocating tachycardia (AVRT)
Narrow QRS complex tachycardia (orthodromic AVRT) – 65%
No P wave
Narrow QRS complexes
No delta wave
Rapid and regular
Ventricular rates ranging from 160–220 beats/min
Difficult to distinguish from paroxysmal supraventricular tachycardia
Wide QRS complex tachycardia (antidromic AVRT) – 10%
No P wave
Widened QRS complexes with consistent QRS complex morphology
Delta wave
Rapid and regular
Ventricular rates ranging from 160–220 beats/min
Difficult to distinguish from ventricular tachycardia
Atrial fibrillation – 25%
No P wave
Widened QRS complexes with varying, bizarre QRS complex morphologies
Delta wave
Rapid and irregular
Ventricular rates consistently >200 beats/min



and creates a direct electrical connection between the atria and ventricles.[63] WPW patients are prone to a variety of supraventricular tachydysrhythmias (**Table 18-25**). Ventricular fibrillation is very rare and usually only occurs in the setting of therapeutic misadventure.

Clinical Features The classic triad of ECG findings (**Figure 18-28** and **Table 18-26**) seen in WPW is visible during sinus rhythm and is usually not detectable during tachydysrhythmias. The PR interval is shortened in sinus rhythm because the impulse moving through the accessory pathway is not subject to the physiologic slowing within the AV node. The ventricle is activated by two separate pathways, resulting in a fused, or widened, QRS complex. The initial part of the complex, the delta wave, represents aberrant activation through the accessory pathway, while the terminal portion of the QRS complex represents normal activation through the His-Purkinje system from impulses traveling through the AV node. Due to altered ventricular depolarization, secondary repolarization changes reflected in altered ST segments and T waves that are generally directed opposite (discordant) to the major delta wave and QRS complex. The delta wave may create Q waves that can mimic ECG changes associated with ischemic heart disease.



An incidental ECG may identify WPW in an otherwise asymptomatic individual. While such asymptomatic individuals will never develop tachydysrhythmias, a portion of patients do, and some rare patients experience ventricular fibrillation and cardiac arrest.[64] Electrophysiologic studies can identify patients with multiple accessory tracts and short refractory periods in those tracts and, thus, who are at increased risk for ventricular fibrillation and cardiac arrest.[65]

The most frequent dysrhythmia seen in the WPW patient is a reentrant tachycardia termed AV reciprocating tachycardia. In AV reciprocating tachycardia, the reentry circuit involves the AV node and the accessory pathway. AV reciprocating tachycardia is either orthodromic (anterograde conduction through the AV node) or antidromic (retrograde conduction through the AV node). During orthodromic or anterograde AV reciprocating tachycardia (**Figure 18-29** and Table 18-26), the atrial stimulus is conducted to the ventricle through the AV node with a return of the impulse back to the atria through the accessory pathway. Since the ventricles are stimulated solely via the normal His-Purkinje system, the QRS complexes are narrow and there is no delta wave. Orthodromic AV reciprocating tachycardia accounts for approximately 65% of dysrhythmias seen in WPW patients and is difficult to distinguish from AV nodal reentrant tachycardia (i.e., typical paroxysmal supraventricular tachycardia).

In approximately 10% of symptomatic WPW patients, an antidromic (retrograde) AV reciprocating tachycardia occurs (**Figure 18-30** and Table 18-25). In antidromic AV reciprocating tachycardia, the reentrant

A 12-lead ECG of patient with the Wolff-Parkinson-White (WPW) syndrome in sinus rhythm. **B** and **C.** Single P-QRS-T complex; note the shortened PR interval, delta wave, and widened QRS complex. **D.** The direction of cardiac impulse conduction in the WPW syndrome patient in sinus rhythm. The *two arrows* indicate the direction of the impulse, moving from atrial (A) tissues to ventricular (V) tissues via the accessory pathway (AP) and atrioventricular node (AVN). The impulse arrives at the ventricular tissues via the AVN and moves through ventricular tissues via the right bundle branch (RBB) and left bundle branch (LBB); the impulse also arrives at ventricular tissues via the AP and moves through ventricular tissues using cell-to-cell conduction. SAN = sinoatrial node.

Widened QRS complex

circuit conducts in the opposite direction, with anterograde conduction down the accessory pathway and return of the impulse retrograde to the atria via the AV node. With this pathway, the QRS complexes are wide; the ECG displays a very rapid, wide-complex tachycardia that looks like ventricular tachycardia.

Atrial fibrillation occurs in up to 25% of WPW patients with symptomatic dysrhythmias. The electrocardiographic features (**Figure 18-31** and Table 18-25) of atrial fibrillation with WPW syndrome are a very fast ventricular rate due to the ability of the accessory pathway to conduct impulses into the ventricle faster than through the AV node and significant beat-to-beat variation in the QRS complex morphology resulting from a combination of the two impulses arriving at the ventricle and fusing to form a composite depolarization. This wide-complex dysrhythmia may appear relatively regular and can be misdiagnosed as ventricular tachycardia.[66]

Treatment Treat all three tachydysrhythmias in the WPW patient according to the patient's clinical stability and the electrocardiographic features of the dysrhythmia. Use electrical cardioversion in patients with hemodynamic instability.

In the stable patient, therapy is guided by the QRS complex width and the regularity of the rhythm. In patients with a regular, narrow QRS complex tachycardia (i.e., orthodromic AV reciprocating tachycardia),

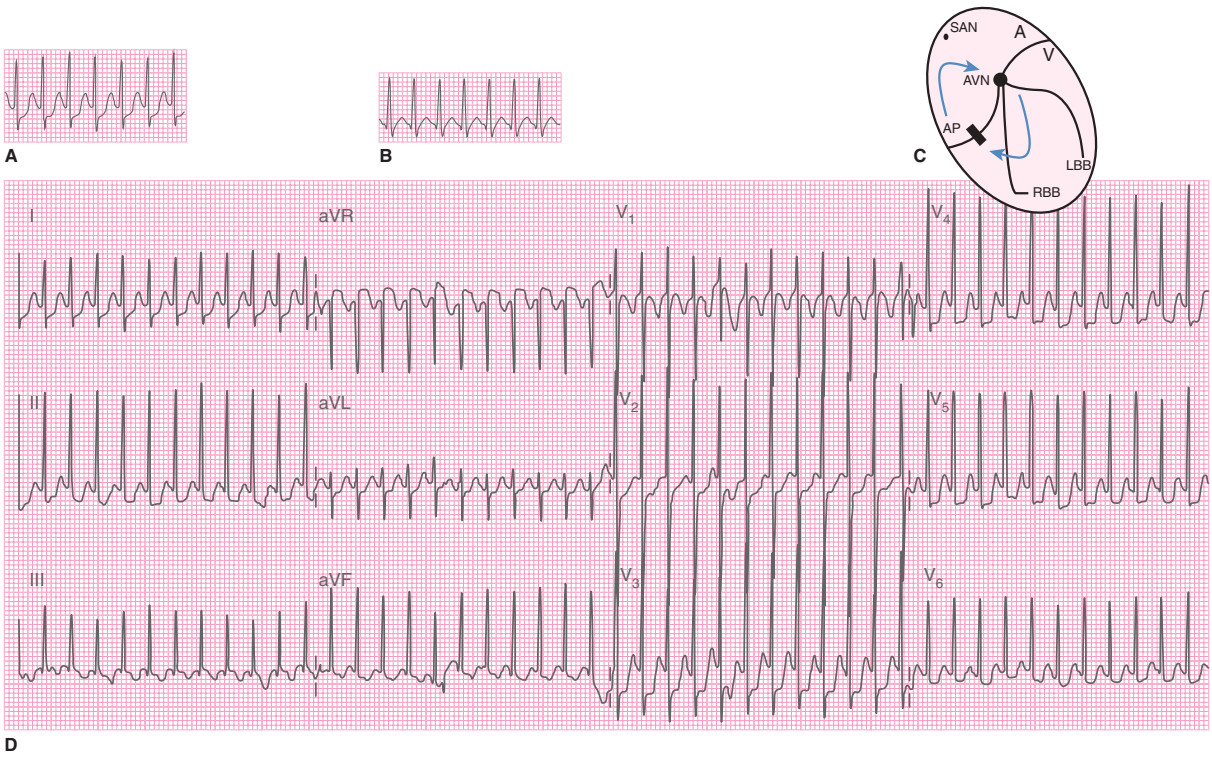

FIGURE 18-29. Narrow-complex tachycardia (orthodromic atrioventricular [AV] reciprocating tachycardia [AVRT]), the most common dysrhythmia of the Wolff-Parkinson-White syndrome. **A** and **B.** Rapid, regular, narrow QRS complexes without delta waves. **C.** The direction of cardiac impulse conduction in orthodromic AVRT; anterograde from atrial (A) tissues to ventricular (V) tissues through the AV node (AVN) and returning to the atrial tissues from ventricular tissues via the accessory pathway (AP). **D.** A 12-lead ECG demonstrating orthodromic AVRT. AP = accessory pathway; LBB = left bundle branch; RBB = right bundle branch; SAN = sinoatrial node.

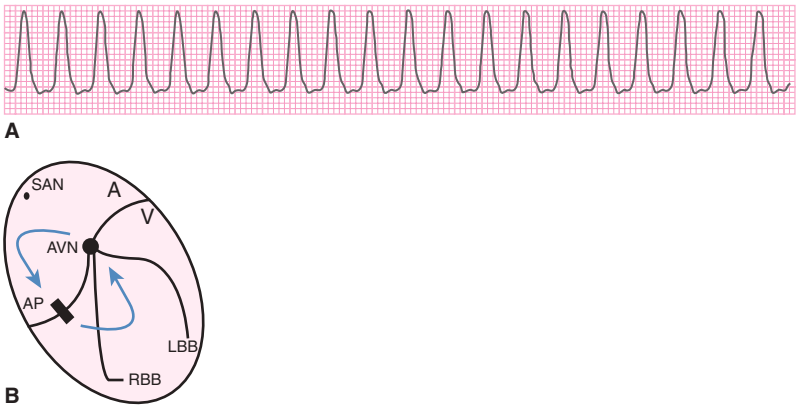

FIGURE 18-30. Antidromic atrioventricular (AV) reciprocating tachycardia (AVRT; wide-complex tachycardia). **A.** Wide-complex tachycardia that mimics ventricular tachycardia. **B.** The direction of cardiac impulse conduction in a Wolff-Parkinson-White syndrome patient during antidromic AVRT. The *two arrows* indicate the direction of the impulse movement, anterograde from atrial (A) tissues to ventricular (V) tissues through the accessory pathway (AP) and returning to the atrial tissues from ventricular tissues via the AV node (AVN). LBB = left bundle branch; RBB = right bundle branch; SAN = sinoatrial node.

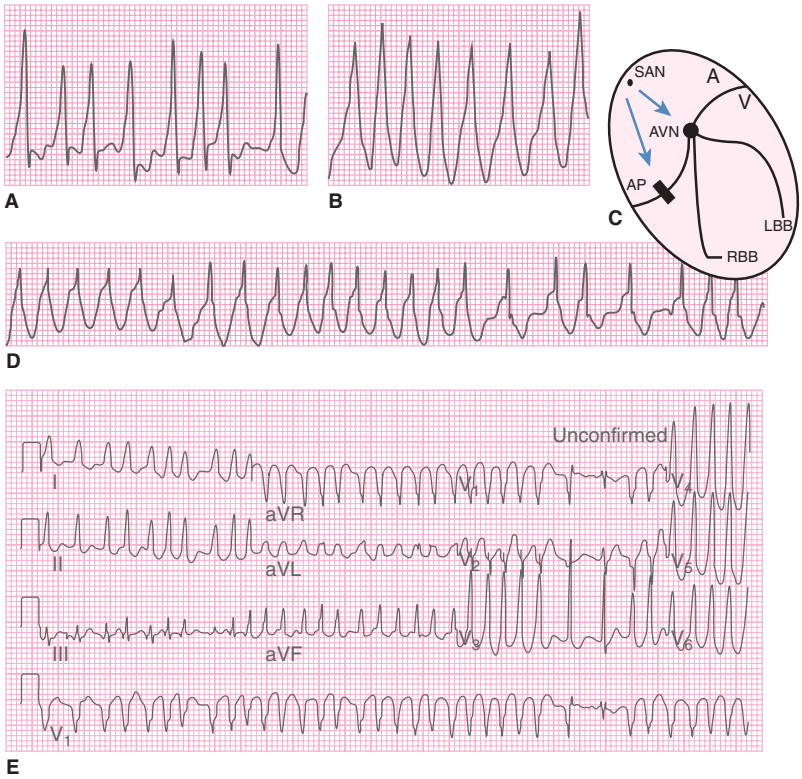

FIGURE 18-31. Atrial fibrillation in Wolff-Parkinson-White (WPW) syndrome. **A, B,** and **D.** Rapid, wide, irregular QRS complex tachycardia with varying QRS complex morphologies. **C.** The direction of cardiac impulse conduction in a WPW syndrome patient during atrial fibrillation. The *two arrows* indicate the direction of the impulse movement, both anterograde from atrial (A) tissues to ventricular (V) tissues through both the accessory pathway (AP) and the atrioventricular node (AVN). The larger of the two arrows indicates that the majority of impulses travel to the ventricular via the AP. **E.** A 12-lead ECG demonstrating a rapid, wide, irregular QRS complex tachycardia with varying QRS complex morphologies. LBB = left bundle branch; RBB = right bundle branch; SAN = sinoatrial node.

the first intervention is vagal maneuver (Table 18-3). If this intervention fails, the next step would be intravenous adenosine (Table 18-2). If adenosine fails, then longer acting AV nodal blocking agents, such as β-blockers and calcium channel blockers are indicated. In refractory cases, procainamide is an effective agent that blocks conduction in the accessory conduction pathway and can terminate this reentrant tachycardia. If all medications are unsuccessful, the patient can be electrically cardioverted with appropriate sedation.

In stable patients with a wide QRS complex tachycardia, either regular (i.e., orthodromic AV reciprocating tachycardia) or irregular (atrial fibrillation), procainamide should be administered.[67] If unsuccessful, electrical cardioversion with appropriate sedation should be considered. Some antiarrhythmic medications can paradoxically enhance condition via the accessory tract, potentially enabling excessively rapid atrial activity to trigger ventricular fibrillation. Also, by blocking conduction through the AV node in WPW patients with atrial fibrillation, more of the rapid atrial depolarizations are able to initiate ventricular depolarization because competition from the normal conducting pathway is impaired, although evidence of adverse clinical outcome by such action is weak.[68] **Agents that can enhance conduction in the accessory tract and/or block conduction in the AV node should be avoided in WPW patients with wide-complex irregular tachycardias; these include adenosine, amiodarone, β-blockers, and calcium channel blockers.[20]**

After conversion, observe the patient with continuous cardiac rhythm monitoring and a repeat ECG. In general, patients who have rare episodes of tachydysrhythmias and who are stable after conversion can be discharged home with routine follow-up. Patients with frequent tachydysrhythmia episodes or who have an episode of atrial fibrillation with a very rapid ventricular response should be promptly referred for ablation of the accessory pathway. Patients who experience loss of consciousness during a known or possible tachydysrhythmia should be kept for observation due to the potential for repeat episode or cardiac arrest. Asymptomatic patients in whom WPW appears as an incidental finding should be referred to a cardiologist for further evaluation.[69]

BRUGADA SYNDROME

Description Brugada syndrome is an inherited disorder of myocardial depolarization that predisposes young individuals to malignant ventricular dysrhythmias and sudden death.[70-72] Congenital Brugada syndrome is due to mutations in the genes responsible for transmembrane sodium, calcium, or potassium ion channels in the heart.[73] Eight genetic mutations have been identified as producing a *channelopathy* that results in the Brugada syndrome. The prevalence of Brugada syndrome varies dramatically among different ethnic groups; it is highest in East and Southeast Asian populations and relatively lower in groups originating from Western Europe.

Clinical Features The majority of patients with Brugada syndrome are asymptomatic and are only found via an incidental ECG. Symptomatic patients present with palpitations, near to complete syncope, or seizures due to ventricular tachydysrhythmias. Characteristic ECG changes are necessary for the diagnosis, but such changes are variable and not always evident (**Table 18-27** and **Figure 18-32**).[74] Fever and provocative testing with a sodium channel blocker (e.g., flecainide) may provoke surface ECG abnormalities associated with Brugada syndrome. The type 1 pattern is considered diagnostic when combined with appropriate clinical

TABLE 18-27 ECG Patterns Associated with Brugada Syndrome in ECG Leads V_1 to V_3

Type 1	Coved-shaped ST-segment elevation >2 mm Followed by an inverted T wave
Type 2	ST segment elevation >2 mm With a trough in the ST segment at least 1 mm deep Followed by a positive or biphasic T wave Producing a "saddleback" pattern
Type 3	Coved-shaped or saddleback pattern ST segment With 1- to 2-mm elevation

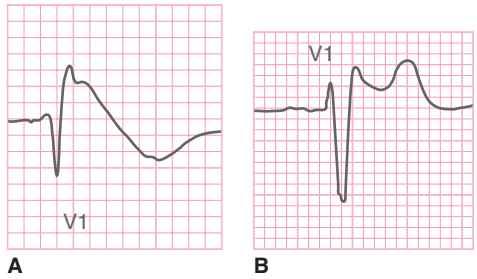

FIGURE 18-32. Brugada ECG pattern. **A.** Type 1. **B.** Type 2.

or family history (**Table 18-28**). Types 2 and 3 are considered suggestive but not diagnostic of Brugada syndrome. Because types 2 and 3 may convert to type 1, either spontaneously or with provocative testing, further evaluation is recommended if there is an appropriate history.

Risk stratification is done to identify patients with Brugada syndrome at significant risk for malignant ventricular tachydysrhythmias.[75] In patients with aborted sudden cardiac death, the risk of recurrence of ventricular fibrillation is over 50% within 5 years.

Treatment An important role for the emergency provider is to recognize this ECG pattern, especially in patients who present with symptoms, and to refer to for appropriate follow up.[76] Avoid exacerbating the underlying pathophysiology; do not use medications that possess sodium channel blockade effects (http://www.brugadadrugs.org). Educate the patient on the importance of treating fever, with even minor infections. The only proven therapy to terminate malignant ventricular arrhythmias and prevent sudden death is implantable cardioverter defibrillator placement. Quinidine, a class Ia antiarrhythmic, is sometimes used as an adjunct with implantable cardioverter defibrillator placement to reduce the incidence of dysrhythmias. Side effects (hepatitis, thrombocytopenia, and diarrhea) and the potential to induce torsade de pointes are cautions to quinidine's routine use.

LONG QT SYNDROME

Description The long QT syndromes are characterized by prolongation of the QT interval (**Figure 18-33**) and a predisposition to ventricular tachydysrhythmias, including torsade de pointes and sudden cardiac death.[77-79] Congenital long QT syndrome is an inherited disorder due to mutations in cation channel genes (*channelopathies*). Of the 13 described variants of congenital long QT syndrome, the three most common, accounting for about 90% of all cases, are mutations in a cardiac potassium channel for long QT syndrome types 1 and 2 and the sodium ion channel for long QT syndrome type 3.[79] With increased awareness and identification, the prevalence of congenital long QT syndrome is estimated to be 1 in 2000 live births. Acquired long QT syndrome can occur from electrolyte abnormalities (hypokalemia, hypomagnesemia), medication effects, and other disease states, such as acute coronary syndrome and severe left ventricular dysfunction.[80,81]

Clinical Features The normal QT interval corrected for heart rate (QTc) is up 440 milliseconds in adult males and 460 milliseconds in adult females. The risk of dysrhythmias associated with long QT syndrome increases as the QTc prolongs, with moderate risk when the QTc is between 480 and 499 milliseconds and significantly higher risk when the QTc is greater than 500 milliseconds.[27] Syncope is the most common symptom, and torsade de pointes is the most common dysrhythmia. A diagnostic scoring system has been created to assist in identifying patients with congenital long QT syndrome (**Table 18-29**).[82]

TABLE 18-28 Risk Stratification in Brugada Syndrome

Personal history	Near or complete syncope Seizure Nocturnal agonal respiration
Aborted sudden cardiac death	Polymorphous ventricular tachycardia Ventricular fibrillation
Family history	Family history of unexplained sudden cardiac death Family history of coved-shaped ST segment (type 1) ECG pattern
Electrophysiologic study	Inducibility of ventricular tachycardia or fibrillation with programmed stimulation

FIGURE 18-33. Long QT interval; QTc is 550 milliseconds.

TABLE 18-29 Diagnostic Score for Congenital Long QT Syndrome

Feature		Points
ECG*		
QTc	≥480 ms	3
	460–479 ms	2
	450–459 (male) ms	1
QTc ≥480 ms at 4th min of recovery from exercise stress test		1
T-wave alternans		1
Notched T waves in three ECG leads		1
Heart rate <2nd percentile for age (<50 in adult age 20–60)		0.5
Clinical history		
Syncope *or* episode of torsade de pointes (not both)	Torsade de pointes	2
	Syncope provoked by stress	2
	Syncope not provoked by stress	1
Congenital deafness		0.5
Family history		
Family members with definite long QT syndrome		1
Immediate family member <30 years old with unexplained sudden cardiac death		0.5
Scoring: Range, 0 to 10; 1.5 to 3 points = intermediate probability; ≥3.5 points = high probability		

*In absence of medications or conditions known to affect QT interval or T wave.

Treatment An important role for the emergency provider is to recognize this ECG pattern, especially in patients who present with syncope, and to refer for appropriate follow-up.[76] Avoid exacerbating the underlying pathophysiology; do not use medications that possess channel blockade effects, impair cardiac repolarization, prolong the QT interval, and provoke tachydysrhythmias (https://crediblemeds.org/healthcare-providers/).[83] Correct underlying electrolyte abnormalities, especially those of potassium and magnesium. β-Blockers are the initial treatment for symptomatic patients with congenital long QT syndrome.[84] Propranolol and nadolol are the most effective β-blockers, and patients with congenital long QT syndrome type 1 are the most responsive.

Lifestyle modifications are beneficial in congenital long QT syndrome.[85] Exercise is a trigger for lethal dysrhythmic events, especially in patients with congenital long QT syndrome type 1, where swimming is notably dangerous. Patients with congenital long QT syndrome type 2 are sensitive to decreased serum potassium and are at risk for lethal cardiac events triggered by emotions or being startled, as being roughly aroused from rest or sleep.

CHAPTER 19

Pharmacology of Antiarrhythmics and Antihypertensives

Sara H. Shields
Rachel M. Holland
R. Dustin Pippin
Benjamin Small

This chapter reviews the pharmacology of selected antiarrhythmics and antihypertensives (β-blockers and calcium channel blockers) used in the ED. Discussion of additional antihypertensives can be found in chapter 57, "Systemic Hypertension."

Antiarrhythmic medications treat cardiac rhythm abnormalities by modifying autonomic function or myocardial ion channels, leading to changes in conduction velocity or duration of the effective refractory period.[1] Failure to reduce mortality has been a criticism of many agents in this class of drugs.[2-5] In general, electrical cardioversion is preferable to pharmacologic conversion in patients who are hemodynamically unstable. The majority of antiarrhythmics are organized based on the Vaughan-Williams classification system (Classes I to IV) (**Table 19-1**). Other medications used to treat arrhythmias include digoxin, atropine, adenosine, magnesium, and isoproterenol.

CLASS I ANTIARRHYTHMICS: FAST SODIUM CHANNEL BLOCKERS

Class I agents block fast sodium channels (I_{Na}) and are further subcategorized based on their degree of blockade into Classes Ia (moderate blockade), Ib (weak blockage), and Ic (strong blockade). Sodium channel blockers increase the excitability threshold, requiring more sodium channels to open in order to overcome the potassium current and generate an action potential. This effect increases refractoriness and can be useful in terminating reentry currents. In addition, some Class I agents block potassium channels (I_K) and exhibit antimuscarinic effects.

CLASS Ia AGENTS

Class Ia antiarrhythmics block open sodium channels and have a slow dissociation from their target, causing an increase in the refractory period. The use of these agents is limited by their side effect profile and proarrhythmic nature. Quinidine and disopyramide are Class Ia agents but are not discussed here because they are infrequently used in the ED. Quinidine can cause **torsades de pointes**. Disopyramide is used orally in patients with hypertrophic cardiomyopathy due to its negative inotropic properties; however, its association with heart failure and hypotension and its anticholinergic effects, including urinary retention, limit its use.

TABLE 19-1 Vaughan-Williams Classification of Antiarrhythmic Medications

Action	Class	Example Medications
Sodium channel blockers	Class Ia	Disopyramide, quinidine, procainamide
	Class Ib	Lidocaine, mexiletine, phenytoin,
	Class Ic	Flecainide, propafenone
β-Blockers	Class II	Esmolol, labetalol, metoprolol, propranolol
Potassium channel blockers	Class III	Amiodarone, dronedarone, dofetilide*, ibutilide, sotalol†, vernakalant‡
Calcium channel blockers	Class IV	Diltiazem, verapamil
Unclassified agents#		Adenosine, atropine, digoxin, isoproterenol, magnesium

*Only available by prescription by specifically trained physicians.

†Also a β-blocker.

‡Not available in the United States.

#Not classified by Vaughan-Williams system.

TABLE 19-2 Procainamide Pharmacokinetics

Distribution	Metabolism	Excretion	Half-Life	Onset/Duration of Action
2 L/kg	Hepatic and renal Active metabolite: NAPA (renally eliminated)	Urine, feces	Procainamide: 2.5–4.7 h NAPA: 6–8 h	Onset: 5–10 min Duration: 1–2 h

PROCAINAMIDE

Actions Procainamide is a Class Ia agent that increases the refractory period, decreases automaticity and conduction, and prolongs cardiac action potentials through intermediate blockade of open sodium and potassium channels. NAPA, the active metabolite of procainamide, lacks sodium channel effects but does block potassium channels, which can lead to QT prolongation.

Pharmacokinetics See **Table 19-2**.[6]

Indications Procainamide is indicated for life-threatening ventricular arrhythmias and supraventricular arrhythmias. Although it can be used to treat supraventricular tachycardia, the proarrhythmic nature of this agent (including torsades de pointes) and the risk of toxicity make procainamide less desirable for this indication. For hemodynamically stable ventricular tachycardias, procainamide can be considered as a therapeutic option; however it should be avoided in patients with prolonged QT intervals or congestive heart failure.[7]

Dosing and Administration See **Table 19-3**.[6]

Adverse Effects The most common adverse effects associated with procainamide are hypotension, cardiac conduction abnormalities, and rash. Serious adverse effects include prolonged QT interval, torsades de pointes, ventricular fibrillation, paradoxical increase in ventricular rate in atrial fibrillation/flutter, hepatotoxicity, and congestive heart failure.

CLASS Ib AGENTS

Class Ib agents have weak sodium channel–blocking properties and a high affinity for both open and inactive sodium channels with very rapid dissociation. The cumulative effects of these agents result in decreased automaticity due to an increase in the threshold for excitability. Because of their quick dissociation, these drugs are less effective on myocardial tissues with rapid conduction, such as atrial tissue.

LIDOCAINE

Actions Lidocaine is a Class Ib agent with weak sodium channel blocker properties that preferentially acts on ischemic myocardial tissue to decrease conduction; in addition, it has local anesthetic properties. Effects exerted on the cardiac action potential are negligible, with very

TABLE 19-3 Procainamide Dosing and Administration

Advanced Cardiac Life Support (ACLS)–Ventricular Arrhythmia
Initial: 20–50* milligrams/min IV until the arrhythmia is suppressed, hypotension ensues, or the QRS complex is prolonged by 50% from its original duration (maximum dose: 17 milligrams/kg)
Maintenance infusion rate: 1–4 milligrams/min
OR
100 milligrams IV every 5 min until the arrhythmia is controlled or one of the above conditions is met

*Slower administration preferred if patient is stable.

TABLE 19-4 Lidocaine Pharmacokinetics

Distribution	Metabolism	Excretion	Half-Life	Onset/Duration of Action
1.1–2.1 L/kg	Hepatic Active metabolites	Urine	Initial: 7–30 min Terminal: 1.5–2 h	Onset: 45–90 s Duration: 10–20 min

minimal decrease to no effect on the QT interval and the refractory period.

Pharmacokinetics See **Table 19-4**.[6]

Indications Lidocaine is indicated in the acute management of ventricular arrhythmias. Per advanced cardiac life support guidelines, lidocaine is considered a second-line therapy, if amiodarone is unavailable, in patients with ventricular fibrillation or pulseless ventricular tachycardia due to the failure of clinical studies to show improved rates of return of spontaneous circulation when compared to amiodarone.[5]

Dosing and Administration See **Table 19-5**.[6]

Adverse Effects Adverse effects of lidocaine are typically dose dependent, with few hemodynamic effects at lower infusion rates. Patients should be monitored for CNS effects, including numbness, speech impairment, somnolence, dizziness, and seizures.

CLASS Ic AGENTS

Class Ic agents are most commonly used for the treatment of supraventricular tachycardia. They have the highest degree of fast sodium channel blockade, resulting in marked prolongation of the QRS interval without QT prolongation. These agents act only on open sodium channels and demonstrate slow dissociation from their targets, leading to increased refractoriness and decreased conduction. They have a high proarrhythmic potential that can be amplified in cases of diseased myocardial tissue, increased sympathetic tone, and higher heart rates. Large clinical studies have associated several Class Ic agents with increased mortality when used in patients with cardiovascular disease or after myocardial infarction.[8,9]

PROPAFENONE

Propafenone is a Class Ic agent with additional β-adrenergic–blocking properties; therefore, it can cause bradycardia and bronchospasm. It is more selective for cells with high rates of conduction. Propafenone is indicated for the conversion of recent-onset atrial fibrillation (<7 days) to sinus rhythm.[10] Under continuous cardiac monitoring, the patient can be given a one-time oral dose of 450 milligrams (weight <70 kg) or 600 milligrams (weight ≥70 kg). Adverse effects include hypotension, bradycardia, bronchospasm, atrial flutter with 1:1 atrioventricular conduction, and ventricular proarrhythmia. This drug should be avoided in patients with coronary artery disease or significant structural heart disease, and should be given with caution to patients with asthma, hepatic dysfunction, or congestive heart failure. Although propafenone carries an indication for paroxysmal supraventricular tachycardia and ventricular tachycardia, it is rarely used for these indications in the ED.

TABLE 19-5 Lidocaine Dosing and Administration

Ventricular Arrhythmia	Ventricular Fibrillation
Loading dose: 50–100 milligrams (0.7–1.4 milligrams/kg) IV over 2–3 min. May repeat in 5 min (up to 300 milligrams in any 1-h period) Maintenance: 1–4 milligrams/min IV (0.014–0.057 milligrams/kg/min)	Initial dose: 1–1.5 milligrams/kg IV If VF/pulseless VT persists, additional doses of 0.5–0.75 milligrams/kg IV every 5–10 min (maximum total dose: 3 milligrams/kg)

Abbreviations: VF = ventricular fibrillation; VT = ventricular tachycardia.

FLECAINIDE

Flecainide is a Class 1c agent that reduces excitability, primarily in the His-Purkinje system and ventricular myocardium. Flecainide is indicated for the conversion of recent-onset atrial fibrillation (<7 days) to sinus rhythm.[10] Under continuous cardiac monitoring, the patient can be given a one-time oral dose of 200 milligrams (weight <70 kg) or 300 milligrams (weight ≥70 kg). Adverse effects include hypotension, atrial flutter with 1:1 atrioventricular conduction, and ventricular proarrhythmia. This drug should be avoided in patients with coronary artery disease, significant structural heart disease, congestive heart failure, or hypokalemia. Although flecainide carries an indication for paroxysmal supraventricular tachycardia and ventricular tachycardia, it is rarely used for these indications in the ED.

CLASS II ANTIARRHYTHMICS: β-BLOCKERS

β-Blockers are used for the treatment of various indications including hypertension, supraventricular tachycardia and ventricular arrhythmias, recurrent atrial fibrillation (rate control), and thyrotoxicosis (symptom control). Although these medications share the principal characteristic of blocking catecholamine effects on β-receptors, individual agents differ with respect to their cardioselectivity, α-adrenergic blocking activity, intrinsic sympathomimetic activity, membrane-stabilizing effect, and pharmacokinetic properties (**Table 19-6**). β-Receptors are divided into two subtypes. β_1-Receptors are found in heart muscle, and β_2-receptors are found in bronchial and vascular smooth muscle. Nonselective β-blocking medications target all β-receptors, thereby affecting heart rate, conduction, and contractility, as well as smooth muscle contraction, thus increasing the risk of bronchospasm. In contrast, cardioselective agents have relative selectivity for β_1-receptors and decrease heart rate and blood pressure. These agents may be a better option for patients with a history of asthma, chronic obstructive pulmonary disease, or insulin-dependent diabetes because they are less likely to act on β_2-receptors. Because cardioselectivity is dose-dependent, it decreases or is lost at higher doses. This is variable between agents, and the dose at which this occurs has not been clearly established.

With the exception of sotalol, all listed β-blockers are indicated for the treatment of hypertension. These agents are also used for ventricular rate control in atrial fibrillation as they slow atrioventricular nodal conduction by decreasing sympathetic tone.

PROPRANOLOL

Actions Propranolol is a nonselective antagonist of β_1- and β_2-receptors.

Pharmacokinetics See Table 19-6.

Indications See Table 19-6.

Dosing and Administration See Table 19-6.

Adverse Effects Serious adverse effects associated with IV propranolol administration include bradycardia, heart block, hypotension, worsening heart failure, and bronchospasm.

ESMOLOL

Actions Esmolol is a short-acting, selective β_1-antagonist that exhibits negative inotropic and chronotropic effects. By blocking β_1-receptors, esmolol prevents excessive adrenergic stimulation of the myocardium, thus causing an increase in sinus cycle length, prolongation of sinoatrial nodal recovery time, and a decrease in conduction through the atrioventricular node.

Pharmacokinetics See Table 19-6.[6] Esmolol is available as a parenteral formulation only and has a rapid onset of action and short duration of action, with complete reversal of medication effects seen within 10 to 30 minutes after discontinuation.

Indications See Table 19-6.[4]

Dosing and Administration All listed doses are in micrograms. For the treatment of supraventricular tachycardia, the dose of esmolol is a 500 microgram/kg bolus (optional) over 1 minute, followed by an

TABLE 19-6 Class II Antiarrhythmics: β-Blockers

Generic Name	Onset of Action	Duration of Action	Metabolism	Half-Life	IV Dose (Adult)	Indications
Noncardioselective						
Propranolol	Oral: 1–2 h IV: ≤1 min	Oral: IR: 6–12 h ER: 24–27 h IV: 4–6 h	Hepatic, extensive first-pass elimination	3–6 h ER formulations: 8–10 h	Tachyarrhythmias: 1–3 milligrams/dose slow IVP; may repeat every 2–5 min up to a total of 5 milligrams *OR* 0.5–1 milligrams over 1 min; may repeat, if necessary, up to a total maximum dose of 0.1 milligram/kg	HTN, SVT arrhythmias, VT
Cardioselective						
Esmolol	IV: 2–10 min	IV: 10–30 min	In blood by RBC esterases	9 min	See text	HTN, SVT arrhythmias, AFib/AFlut (rate control)
Metoprolol	Oral: 1–2 h IV: 20 min	Oral: IR: variable ER: 24 h IV: 5–8 h	Hepatic, extensive first-pass elimination	3–4 h	Initial: 1.25–5 milligrams IV every 5 min up to 15 milligrams initial dose (titrate to response)	HTN, acute MI (oral), angina, rate control in AFib/AFlut
Vasodilatory, Nonselective						
Labetalol	Oral: 20 min–2 h IV: 2–5 min	Oral: 8–12 h IV: 2–18 h	Hepatic, extensive first-pass elimination	Oral: 6–8 h IV: 5.5 h	IV bolus (initial): 20 milligrams IVP over 2 min; may administer 40–80 milligrams at 10-min intervals (up to 300 milligrams total cumulative dose) IV infusion (acute loading): Initial: 2 milligrams/min, titrate to response (up to 300 milligrams total cumulative dose)	HTN

Abbreviations: AFib = atrial fibrillation; AFlut = atrial flutter; ER = extended release; HTN = hypertension; IR = immediate release; IVP = IV push; MI = myocardial infarction; RBC = red blood cell; SVT = supraventricular tachycardia; VT = ventricular tachycardia.

infusion starting at 50 micrograms/kg/min titrated to therapeutic effect in 50 microgram/kg/min increments every 4 minutes. To achieve a more rapid response, two additional 500 microgram/kg bolus doses may be given prior to increasing the infusion rate to 100 micrograms/kg/min (after second bolus) and 150 micrograms/kg/min (after third bolus), as required. After 4 minutes at the rate of 150 micrograms/kg/min, the infusion rate may be increased to a maximum rate of 200 micrograms/kg/min (without an additional bolus dose).

Adverse Effects Cardiovascular adverse effects of esmolol include hypotension (most common), bradycardia, and heart block. Abrupt discontinuation may cause rebound hypertension or angina. Other adverse effects may include injection site reaction, nausea, bronchospasm, and pulmonary edema.

METOPROLOL

Actions Metoprolol is a selective antagonist of β_1-receptors and exerts its antihypertensive effects by decreasing cardiac output, reducing sympathetic outflow, and suppressing renin activity.

Pharmacokinetics See Table 19-6.

Indications See Table 19-6.

Dosing and Administration See Table 19-6 and **Table 19-7**.

Adverse Effects Significant adverse effects associated with metoprolol include bradycardia, heart block, hypotension, and bronchospasm.

LABETALOL

Actions Labetalol is a combined selective α_1-blocking and nonselective β-blocking agent with direct vasodilatory action. The β-blocking effects of labetalol are greater than the α_1-blocking effects, with ratios of 3:1 in the oral and 7:1 in the parenteral formulation. Labetalol is useful as an antihypertensive agent because it decreases heart rate, contractility, cardiac output, and total peripheral resistance.

Pharmacokinetics See Table 19-6.

Indications Labetalol is used primarily for its antihypertensive effects. It is used in patients with acute hypertensive emergencies where rapid blood pressure reduction is indicated (see chapter 57, "Systemic Hypertension") and is considered safe for use in the treatment of hypertension in pregnancy (see chapters 99, "Comorbid Disorders in Pregnancy" and 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period").

Dosing and Administration See Table 19-6 and **Table 19-8**. Labetalol can be administered IV by multiple boluses or as a continuous infusion. Once control of blood pressure has been established, patients may transition to oral labetalol (Table 19-8).[6]

Adverse Effects The most common adverse effect of labetalol is orthostatic hypotension, which occurs primarily with IV administration. Other common adverse effects include nausea, dizziness, and fatigue. Serious adverse effects include heart failure, hyperkalemia, hepatotoxicity, and bronchospasm.

CLASS III ANTIARRHYTHMICS

Class III antiarrhythmic medications inhibit inward potassium currents (**Table 19-9**),[6] which leads to a significantly longer refractory period. Myocardial tissue in a refractory state is resistant to reentrant conduction

TABLE 19-7 IV to PO Conversion of Metoprolol

circuits that may produce arrhythmia. These agents prolong the QT interval, which is associated with significant risk for torsades de pointes. Clinical indications for Class III antiarrhythmics are contrasted in **Table 19-10**.

AMIODARONE

Amiodarone is a highly effective "broad-spectrum" antiarrhythmic indicated in the acute management and chronic suppression of supraventricular tachycardia and ventricular arrhythmias. Potential benefits of amiodarone must be weighed against an array of potentially serious adverse effects, and clinical use is further complicated by distinctive pharmacokinetics and significant drug interactions.

Actions Amiodarone possesses properties of all four classes of antiarrhythmics (**Table 19-11**).[6,11]

Pharmacokinetics The pharmacokinetics of amiodarone are listed in **Table 19-12**.[6] Amiodarone is highly lipophilic and extensively distributed to bodily tissues.[12] Although IV amiodarone produces a rapid antiarrhythmic effect, it quickly redistributes from the serum into tissue, causing a precipitous drop in serum concentration.[13] Therefore, large oral or IV loading doses, generally given over a week or more, are needed to fill this large tissue reservoir and achieve sustained serum concentrations. As tissue stores become saturated after long-term oral therapy, terminal-phase elimination dominates and is characterized by a long half-life (≤55 days) and duration of action (≤50 days). Amiodarone is eliminated primarily by hepatic metabolism and biliary excretion.

TABLE 19-10 Class III Antiarrhythmic Indications

	Clinical Indications	
	Supraventricular Arrhythmias	Ventricular Arrhythmias
Amiodarone	Acute rate control or cardioversion and maintenance of sinus rhythm*	Acute management of life-threatening arrhythmias; chronic suppression
Dronedarone	AFib (history of paroxysmal or persistent, but currently in sinus rhythm) to reduce risk of hospitalization	No
Sotalol	AFib or AFlut	Monomorphic VT†
Dofetilide	AFib or AFlut; conversion to and maintenance of sinus rhythm	No
Ibutilide	Acute cardioversion of AFib or AFlut	No
Vernakalant	Acute cardioversion of AFib‡	No

Abbreviations: AFib = atrial fibrillation; AFlut = atrial flutter; VT = ventricular tachycardia.

*Off label.

†Off label in United States, but guideline recommended with IV formulation if available.

‡Approved in Europe, not in United States.

Indications Specific indications for amiodarone are listed in **Table 19-13**.[7,10,14-16]

Dosing and Administration Amiodarone dosing is detailed in **Table 19-14**.[6] Intravenous amiodarone is associated with bradycardia, hypotension, and phlebitis. Hypotension may be dose and infusion rate dependent; therefore, infusion rates should not exceed 30 milligrams/min, and total daily doses should not exceed 2.2 grams. Preparations of IV amiodarone should be mixed in 5% dextrose in water, as amiodarone has precipitated in compatibility studies with normal saline.[17] Dose adjustments are not required for renal insufficiency but should be considered for severe hepatic dysfunction.

Adverse Effects Adverse effects of amiodarone are listed in **Table 19-15**.[6,18] Long-term amiodarone has many common, serious, and potentially fatal adverse effects that limit widespread clinical use and require regular monitoring of liver, pulmonary, thyroid, and ocular function. As a result, patients should be regularly monitored for these toxicities. Although amiodarone prolongs the QT interval, it has a relatively low incidence of torsades de pointes even in patients with structural heart disease.

Amiodarone is responsible for many clinically significant drug interactions. As a strong inhibitor of liver enzymes, amiodarone increases serum concentrations of many other medications. Amiodarone may also augment the effects of medications that concomitantly prolong the QT_c interval or cause bradycardia. Specific dose reductions are required for digoxin, warfarin, procainamide, quinidine, simvastatin, and lovastatin when used concomitantly with amiodarone. Given amiodarone's extremely long half-life, drug interactions may persist for months after discontinuation of therapy.

DRONEDARONE

Actions Dronedarone is a noniodinated, less lipophilic derivative of amiodarone, designed to have a more favorable adverse effect profile than its predecessor. Dronedarone is categorized as a Class III antiarrhythmic

TABLE 19-11 Electrophysiologic and Electrocardiographic Effects of Amiodarone

Ion Channels and Receptors	Effects on Cardiac Electrophysiology	Effects on the ECG
Blocks inactivated Na^+ channels	Prolongs the refractory period	Decreases heart rate and may cause sinus bradycardia
Noncompetitive blockade of α- and β-adrenergic receptors	Decreases sinoatrial node function	Prolongs:
Blocks inward K^+ channel rectifier	Slows atrioventricular node conduction	PR interval
Blocks myocardial Ca^+ channels	Modifies automaticity of Purkinje fibers	QRS interval*
		QT interval*

*More common with chronic oral administration than with acute IV use.

TABLE 19-13 Acute Intravenous Amiodarone Clinical Indications

Indication	Comments and Cautions
Atrial fibrillation Ventricular rate control	Consider the potential risks of cardioversion (thromboembolic complications)* Consider when other measures are ineffective or contraindicated† Can be used in hemodynamically stable atrial fibrillation with conduction over an accessory pathway such as Wolff-Parkinson-White syndrome† Considered a first-line option in patients with HF†
Atrial fibrillation Cardioversion	Not first line, considered a reasonable option for pharmacologic cardioversion of atrial fibrillation† Slow onset, average time to cardioversion is 24 h Consider risk of thromboembolic complications
VT Monomorphic, sustained	A first-line agent for hemodynamically stable VT*
VT Polymorphic, not associated with long QT interval	If not associated with long QT interval (i.e., torsades)* Polymorphic VT with normal QT interval may be associated with myocardial ischemia, and amiodarone may be effective in arrhythmia suppression*
ACLS Pulseless VT or VF	Antiarrhythmic of choice in ACLS algorithm*

Abbreviations: ACLS = advanced cardiac life support; HF = heart failure; VF = ventricular fibrillation; VT = ventricular tachycardia.

*2010 ACLS guideline recommendation.

†2011 American College of Cardiology Foundation/American Heart Association/Heart Rhythm Society atrial fibrillation management guideline recommendation.

TABLE 19-14 Amiodarone Intravenous Dosing and Administration by Indication

Indications	Dosing and Administration
ACLS Pulseless VT VF (refractory to defibrillation)	300-milligram IV rapid bolus (may give undiluted) May give a single repeat 150-milligram bolus IV if needed
VT Stable monomorphic VT Polymorphic VT with normal QT interval	150 milligrams IV in 100 mL of D5W over 10 min, followed by infusion at 1 mg/min for 6 h, then 0.5 mg/min for the next 18 h
SVT Conversion of atrial fibrillation to sinus rhythm To control rapid ventricular rate due to accessory pathway conduction in pre-excited atrial arrhythmias	If breakthrough arrhythmia occurs, may give repeat 150-milligram IV boluses over 10 min Maximum total daily dose is 2.2 grams

Abbreviations: ACLS = advanced cardiac life support; D5W = dextrose in 5% water; SVT = supraventricular tachycardia; VF = ventricular fibrillation; VT = ventricular tachycardia.

but has all four antiarrhythmic class effects and blocks α-adrenergic receptors. Electrophysiologic action is primarily mediated through Class III antiarrhythmic effects by prolonging the refractory period.[6]

Pharmacokinetics Pharmacokinetics of dronedarone are listed in **Table 19-16**. Dronedarone is ≤94% absorbed, but significant first-pass metabolism decreases the overall bioavailability to ≤15%. With sustained oral dosing, the half-life increases to 27 to 32 hours, and steady-state concentrations are achieved in 4 to 8 days. Dronedarone displays

TABLE 19-15 Amiodarone Adverse Effects*

Cardiovascular	Sinus bradycardia (5% with oral) Ventricular arrhythmias Torsades de pointes (<1%) Increased risk with: Concomitant QT_c prolonging agent Hypokalemia, hypomagnesemia Female gender Thrombophlebitis Atrioventricular nodal block Hypotension (16% with IV); may be related to infusion rate with IV therapy or the IV solution emulsifier polysorbate 80
CNS	Disorders of gait and movement Paresthesias and peripheral neuropathy Dizziness
GI	Nausea/vomiting, anorexia, constipation (10%–33%) Usually responds to a dose reduction or divided doses
Hepatic	Increased liver enzymes (15%–50%) Hepatic injury is typically mild and reversible, but liver failure and death have been reported Monitor baseline LFTs and LFTs every 6 months thereafter
Pulmonary	Pulmonary toxicity (2%–7%, as high as 17%) May be most serious adverse effect other than cardiac. Often reversible, but fatalities have been reported after only 8–14 d of treatment Various manifestations Pulmonary fibrosis, eosinophilia, interstitial pneumonia, allergic alveolitis Monitor baseline PFTs and chest x-ray; repeat chest x-ray annually
Thyroid	Hypothyroidism, more common (4%–22% in some studies) Hyperthyroidism (3%–10%) Hyperthyroidism may diminish antiarrhythmic effect Monitor thyroid function at baseline and every 3–6 months thereafter

Abbreviations: LFTs = liver function tests; PFTs = pulmonary function tests.

*Incomplete listing; excludes nonacute/non–life-threatening dermatologic, ocular, and other effects.

TABLE 19-16 Dronedarone Pharmacokinetics

Absorption	Distribution	Metabolism	Excretion	Half-Life
Bioavailability Fasting: 4% High-fat meal: 15%	**Volume** 1400 L Plasma protein binding: >98%	Hepatic (cytochrome P450 3A) Active metabolite	**Primarily as metabolites** Feces: 84% Renal: 6%	**Single dose** 13–19 h **Sustained oral dosing** 27–32 h

nonlinear kinetics, so doubling a dose may increase plasma concentrations by 2.5- to 3-fold.

Indications Dronedarone is indicated to reduce the risk of hospitalization for atrial fibrillation in patients in sinus rhythm with a history of paroxysmal or persistent atrial fibrillation. It is less efficacious than amiodarone for maintenance of sinus rhythm.

Dosing and Administration The dose of dronedarone is 400 milligrams orally twice daily and should be given with the morning and evening meal to increase bioavailability. Coadministration with grapefruit or grapefruit juice is contraindicated, as this may increase serum concentrations.

Adverse Effects Contraindications and significant adverse effects of dronedarone are highlighted in **Table 19-17**. Compared to amiodarone, dronedarone has lower rates of pulmonary toxicity and has not demonstrated adverse effects on thyroid function. Two clinical trials with dronedarone were prematurely discontinued due to significantly higher rates of serious adverse events in the dronedarone treatment groups, prompting black box warnings that dronedarone is contraindicated in severe or decompensated heart failure and in patients with permanent atrial fibrillation.[5,19] ECGs should be monitored at least every 3 months while on dronedarone. If the patient is found to be in atrial fibrillation, he or she should be cardioverted (if clinically indicated) or dronedarone should be discontinued. Liver function should also be monitored periodically, especially during the first 6 months of therapy.

SOTALOL

Actions Sotalol is a unique, noncardioselective β-blocker that exhibits electrophysiologic characteristics of Class III antiarrhythmics, thus prolonging repolarization and refractoriness without affecting conduction.

TABLE 19-17 Contraindications and Significant Adverse Effects of Dronedarone

Contraindications	In patients with NYHA Class IV HF or NYHA Class II–III HF with recent decompensation requiring referral to a specialized HF clinic
	Permanent atrial fibrillation (in patients in whom sinus rhythm will not or cannot be restored)
	Severe hepatic impairment or previous liver or lung toxicity with amiodarone
	Bradycardia <50 beats/min, QT_c ≥500 ms or PR interval >280 ms, second-degree or third-degree AV block or sick sinus syndrome (except when used in conjunction with a pacemaker)
	Drug–drug interactions with strong cytochrome P450 inhibitors and QT_c prolonging medications
Significant adverse effects	Cardiovascular
	New-onset or worsening HF; QT_c prolongation
	Hepatic
	Severe liver injury, including acute liver failure
	Renal
	Upon initiation, serum creatinine may increase ~0.1 milligram/dL
	Respiratory
	Interstitial lung disease; pulmonary fibrosis and pneumonitis

Abbreviations: AV = atrioventricular; HF = heart failure, NYHA = New York Heart Association.

Pharmacokinetics The onset of action of sotalol is 1 to 2 hours for the oral formulation and 5 to 10 hours after IV administration, with a duration of action of 8 to 16 hours after one dose. The elimination half-life is 12 hours and increases with renal dysfunction. No metabolites are formed, and the drug is primarily eliminated unchanged in the urine.

Indications Sotalol is an effective agent for the suppression of life-threatening ventricular arrhythmias refractory to other antiarrhythmic drugs. It can suppress supraventricular tachycardia and atrial fibrillation but is not indicated for cardioversion of atrial fibrillation.[10]

Dosing and Administration The usual starting dose is 80 milligrams PO twice daily (which can be titrated), and the usual maintenance dose is 160 to 320 milligrams/d; the dose should be reduced by 50% or more in patients with renal insufficiency (creatinine clearance <60 mL/min), and sotalol should not be used (except in special cases) if creatinine clearance is <40 mL/min. IV sotalol is indicated in the current advanced cardiac life support guidelines for hemodynamically stable monomorphic ventricular tachycardia at 1.5 milligrams/kg infused over 5 min. Monitoring of cardiac and renal function is recommended when sotalol is started. During initiation of sotalol therapy (pretreatment QT_c should be <450 milliseconds), QT_c intervals are measured 2 to 4 hours after each oral dose or at the end of an infusion, and therapy is discontinued if QT_c measures ≥500 milliseconds.

Adverse Effects The most common adverse effects of sotalol are bradycardia and hypotension. Sotalol does possess a significant proarrhythmic effect with a 4.3% rate of new or worsened ventricular arrhythmias and a 2.4% rate of torsades de pointes.[20]

DOFETILIDE

Actions/Indications/Dosing Dofetilide is a pure Class III antiarrhythmic and is indicated for the conversion to, and maintenance of, normal sinus rhythm in patients with atrial fibrillation or flutter. Because dofetilide has a significant proarrhythmic effect, it is reserved for patients in whom atrial fibrillation or flutter is highly symptomatic. Dofetilide prescribing is restricted to physicians who have received specific education on dosing and administration and, therefore, is not covered here in detail.[21]

Adverse Effects Serious adverse effects of dofetilide are ventricular tachycardia and QT_c interval prolongation, which can result in torsades de pointes. The risk of developing torsades de pointes is associated with higher dofetilide doses, initiation of therapy, and electrolyte abnormalities.

IBUTILIDE

Actions/Pharmacokinetics Ibutilide prolongs the refractory period in atrial and ventricular cardiac tissues. This action is caused by activation of a slow inward sodium current, as opposed to inhibition of outward potassium currents. Blockade of the delayed rectifier potassium current, which slows repolarization, may also contribute to its clinical effects. The onset of action of ibutilide is ~90 minutes after starting the infusion. Ibutilide is metabolized in the liver, is excreted in the urine and feces, and has a half-life of 2 to 12 hours after IV administration.

Indications/Dosing and Administration/Adverse Effects Ibutilide is indicated for the rapid conversion of recent-onset atrial fibrillation or flutter (greater efficacy) to sinus rhythm.[10] If effective, cardioversion is expected to occur within 1 hour of administration. For patients with atrial fibrillation and an accessory pathway, ibutilide is considered a reasonable option for pharmacologic cardioversion.[16] Serum magnesium and potassium levels should be evaluated and resuscitation equipment made available before ibutilide administration. The loading dose is 1 milligram IV (weight ≥60 kg) or 0.01 milligram/kg IV (weight <60 kg) over 10 minutes and may be repeated once every 10 minutes after completion of the first dose. Electrocardiographic monitoring is continued for at least 4 hours or until the QT_c interval returns to baseline (longer if arrhythmias are observed). Cardiovascular adverse effects of ibutilide include hypotension, hypertension, bradycardia, sinus arrest, syncope, QT_c interval prolongation, congestive heart failure, and torsades de pointes.

TABLE 19-18 Diltiazem and Verapamil Pharmacokinetics

	Absorption	Distribution	Metabolism	Excretion	Half-Life	Onset/Peak/Duration of Action
Diltiazem	Oral BA: IR: 40% ER: 93%–95%	Volume: 5.3 L/kg Plasma protein binding: 70%–80%	Hepatic (cytochrome P450) Active metabolites	Fecal: 60%–65% Renal: 30%	IV/IR 3.4–4.9 h ER: 5–10 h	Onset: IV: 2–3 min PO: 15–60 min Peak: IV: 2–7 min IR: 2–4 h ER: 11–18 h Duration: IV: 1–3 h
Verapamil	Oral BA: 20%–35%	Vd: 3.89 L/kg Plasma protein binding: ~90%	Hepatic (cytochrome P450) Active metabolites	Renal: 70% (as metabolites) Fecal: 16%	3–7 h	Onset/Peak: IV: 1–5 min Duration: IV: 10–20 min

Abbreviations: BA = bioavailability; ER = extended release (controlled release); IR = immediate release; Vd = volume of distribution.

VERNAKALANT

Vernakalant is a Class III antiarrhythmic that inhibits sodium and potassium currents. The atria are more susceptible to vernakalant-induced refractory period prolongation. Vernakalant is not U.S. Food and Drug Administration approved for use in the United States. In Europe, vernakalant is indicated for rapid conversion of recent-onset atrial fibrillation in adults.[22]

CLASS IV ANTIARRHYTHMICS: CALCIUM CHANNEL BLOCKERS

Calcium channel blockers inhibit L-type calcium channels, resulting in slowing of atrioventricular nodal conduction and an increase in the refractory period of nodal tissue. In the myocardium, calcium channels primarily affect the action potential plateau and modulate the strength of muscle contraction. Calcium channel blockers are divided into two categories, dihydropyridine and nondihydropyridine. Nondihydropyridine calcium channel blockers have greater cardioselectivity and are generally used for paroxysmal supraventricular tachycardia and rate control in atrial fibrillation, whereas dihydropyridine calcium channel blockers are more selective for the vasculature and are used to treat hypertension.

DILTIAZEM/VERAPAMIL

Actions Diltiazem and verapamil are nondihydropyridine calcium channel blockers that slow atrioventricular nodal conduction, increase the atrioventricular node's refractory period, decrease automaticity, and prolong the PR interval. Verapamil is more potent than diltiazem resulting in greater atrioventricular nodal depression; therefore, verapamil is used more frequently to abort supraventricular tachycardia than diltiazem.

Pharmacokinetics See **Table 19-18**. Oral diltiazem has a relatively rapid onset of action (15 to 60 minutes); therefore, transitioning from an IV infusion to an oral preparation can be accomplished with relative ease. In addition, diltiazem has a short duration of action (1 to 3 hours), necessitating either a continuous infusion or repeat oral doses. Compared to diltiazem, verapamil has a longer half-life and duration of action. Verapamil also has active metabolites that can accumulate if renal or hepatic disease is present.

Indications Diltiazem and verapamil are indicated for paroxysmal supraventricular tachycardia as well as for rate control in atrial fibrillation[10]; however, verapamil is used more commonly to abort supraventricular tachycardia with a conversion rate to sinus similar to adenosine (90%),[23] whereas diltiazem is used more commonly to control rapid ventricular rate in atrial fibrillation.[10] Both agents are contraindicated for wide-complex tachyarrhythmias, which may be a result of Wolff-Parkinson-White syndrome, due to the high risk of life-threatening ventricular arrhythmia when given to these patients. Other contraindications include sick sinus syndrome, second- or third-degree atrioventricular block, severe hypotension, cardiogenic shock, administration concomitantly or within a few hours of IV β-blockers, and ventricular tachycardia.

Diltiazem Dosing and Administration When initiating diltiazem, an IV bolus of 0.25 milligram/kg over 2 minutes is given, and a continuous infusion is started at 5 to 10 milligrams/h (if bolus is effective). A repeat bolus of 0.35 milligram/kg over 2 minutes may be given if there is inadequate response to initial bolus. The continuous infusion may be increased in 5 milligram/h increments until rate control is achieved to a maximum rate of 15 milligrams/h. Once rate control is achieved, patients may be transitioned to oral diltiazem (**Table 19-19**).

Immediate-release formulations should be used when initially converting the patient to oral diltiazem. Once stable on immediate-release diltiazem, patients can be transitioned to an extended-release formulation by giving an equivalent daily dose.

Verapamil Dosing and Administration For treatment of supraventricular tachycardia, give 2.5 to 5 milligrams IV over 2 minutes. A second dose of 5 to 10 milligrams (~0.15 milligram/kg) may be given 15 to 30 minutes after the initial dose if the patient does not respond to the initial dose and can tolerate a second dose (maximum total dose: 20 to 30 milligrams).[6]

Adverse Effects Diltiazem is generally well tolerated by patients and has a favorable safety profile when compared to other antiarrhythmic agents. Adverse effects associated with diltiazem and verapamil administration are bradyarrhythmia, asystole, fatigue, headache, hypotension, atrioventricular block, peripheral edema, syncope, and dizziness.

NICARDIPINE

Actions Nicardipine is a dihydropyridine calcium channel antagonist that causes relaxation of smooth muscle, thereby lowering blood

TABLE 19-19 IV to PO Conversion of Diltiazem

Medication	IV to PO Conversion	
Diltiazem	After maintenance drip at typical rate of 5–15 milligrams/h has heart rate controlled, may convert to PO. Discontinue infusion 2–3 h after oral dose is given.	
	Diltiazem Drip Rate	**Equivalent PO Dose (Immediate Release)**
	5 milligrams/h	60 milligrams PO every 6 h
	10 milligrams/h	90 milligrams PO every 6 h
	15 milligrams/h	120 milligrams PO every 6 h

TABLE 19-20 Nicardipine Pharmacokinetics

Distribution	Metabolism	Excretion	Half-Life	Onset/Peak/ Duration of Action
Volume: 8.3 L/kg Plasma protein binding: 95%	Hepatic (cytochrome P450)	Fecal: 43% Renal: 49%	2–4 h	Onset: 1 min Peak: 10 min Duration: 3 h

pressure. It has no antiarrhythmic properties and little to no effect on the myocardium.

Pharmacokinetics See **Table 19-20**.

Indications Nicardipine is primarily used for the treatment of hypertension and is contraindicated in patients with aortic stenosis. It is especially useful in patients with acute neurologic emergencies where progressive rapid blood pressure reduction over 15 to 30 minutes is indicated.

Dosing and Administration Nicardipine is administered as an IV infusion with an initial rate of 5 milligrams/h. The infusion may be titrated in 2.5 milligram/h increments every 5 to 15 minutes based on blood pressure response with a maximum infusion rate of 15 milligrams/h.

Adverse Effect Profile Nicardipine is generally well tolerated by patients. Common side effects associated with nicardipine administration include hypotension/orthostatic hypotension, edema, flushing, tachycardia, palpitations, and nausea.

OTHER ANTIARRHYTHMIC MEDICATIONS

DIGOXIN

Actions Digoxin, a cardiac glycoside, has positive inotropic, negative chronotropic, and negative dromotropic effects on the myocardium due to inhibition of the sodium-potassium ATPase.

Pharmacokinetics See **Table 19-21**.[6] Many disease states such as congestive heart failure, hypokalemia, renal failure, and thyroid disease can have a substantial effect on the pharmacokinetics of digoxin. It has a narrow therapeutic index (therapeutic range, 0.5 to 2 nanograms/mL), and toxicity can develop at levels greater than 2 nanograms/mL. In addition, digoxin has numerous drug interactions that can be clinically significant.

Indications Digoxin is indicated for rate control in atrial fibrillation (not first line)[10] and for symptom reduction in congestive heart failure unrelieved by diuretics and angiotensin-converting enzyme inhibitors. Although digoxin is only contraindicated in patients with ventricular arrhythmias, its use should be avoided in patients with Wolff-Parkinson-White syndrome (potential for ventricular fibrillation), acute myocardial infarction, beri-beri heart disease, electrolyte imbalances, sinus node disease, atrioventricular block, and renal impairment. Studies on the mortality associated with digoxin use report conflicting results.[24-28]

Dosing and Administration There are many dosing strategies for digoxin initiation. For atrial fibrillation, current guidelines recommend 0.25 milligram IV every 2 hours up to 1.5 milligrams total. Repeat dosing is necessary when loading digoxin due to the prolonged distribution phase. Maintenance dosing is 0.125 to 0.375 milligram daily. Dose adjustments are often necessary based on age, comorbidities, concomitant medications, and renal dysfunction. Digoxin levels should be monitored for safety and efficacy.

Adverse Effects Adverse effects of digoxin are generally GI. Other more rare adverse effects may include gynecomastia, skin rash, eosinophilia, and thrombocytopenia. Digoxin can also cause cardiac arrhythmias, such as sinus bradycardia, atrioventricular or sinoatrial nodal block, and ventricular arrhythmias.

Symptoms of digoxin toxicity include mental status changes, visual disturbances, delirium, and seizures. Many types of arrhythmias can occur as a result of digoxin toxicity, and the clinician must be able to recognize the signs and symptoms associated with toxicity and treat accordingly.

TABLE 19-21 Digoxin IV Pharmacokinetics

Distribution	Metabolism	Excretion	Half-Life	Onset/Peak/ Duration of Action
Volume: 6–7 L/kg Plasma protein binding: ~25%	GI tract Hepatic	Urine: 50%–70% as unchanged drug	38 h	Onset: 5–60 min Peak: 1–6 h Duration: 3–4 d

TABLE 19-22 Atropine Drug Information

Generic Name	Onset of Action	Metabolism	Half-Life	IV Dose (Adult)	Indications
Atropine	Rapid	Hepatic	2–3 h	0.5 milligram IV every 3–5 min (maximum total dose: 3 milligrams or 0.04 milligram/kg)	Sinus bradycardia (symptomatic)

Use is no longer recommended in the management of asystole or pulseless electrical activity.

ATROPINE

Actions Atropine blocks the effects of acetylcholine at parasympathetic sites in smooth muscle thus increasing cardiac output.[6]

Pharmacokinetics See **Table 19-22**.

Indications Atropine is considered first-line therapy for the treatment of symptomatic bradycardia. Based on the current advanced cardiac life support treatment guidelines, it is no longer recommended for the treatment of asystole or pulseless electrical activity.[7] Atropine should be used with caution in patients with coronary heart disease, acute myocardial ischemia, congestive heart failure, tachycardia, and hypertension.[6]

Dosing and Administration See Table 19-22.[6,7] Doses <0.5 milligram and slow injection have been associated with paradoxical bradycardia.

Adverse Effects The most common adverse effects of atropine include tachyarrhythmia, constipation, xerostomia, blurred vision, and photophobia.

ADENOSINE

Actions Adenosine is an endogenous nucleoside that exerts multiple effects mediated by binding adenosine receptors and inhibiting adenylate cyclase, resulting in the decreased flow of calcium ions in the atrioventricular node. It also decreases sinoatrial nodal depolarization by activation of acetylcholine-sensitive potassium currents. These effects result in hyperpolarization and automaticity in cardiac nodal tissue. Adenosine is a first-line agent used in the treatment of narrow-complex supraventricular tachycardia in patients who have failed vagal maneuvers, and it may also be used in the setting of stable monomorphic, wide-complex tachycardias as a diagnostic tool.

Pharmacokinetics See **Table 19-23**.

Indications Adenosine is used for the treatment of supraventricular tachycardia with or without reentry pathways, after failure of vagal maneuvers. It is ineffective for the treatment of atrial fibrillation and flutter and ventricular tachycardias.

TABLE 19-23 Adenosine Pharmacokinetics

Metabolism	Half-Life	Onset/Duration of Action
Blood, tissue	<10 s	Onset: rapid Duration: very brief

TABLE 19-24 Adenosine Intravenous Dosing and Administration

Indication	Dosing and Administration
Paroxysmal supraventricular tachycardia	Initial dose: 6 milligrams IV If ineffective after 1–2 min, may give second dose of 12 milligrams IV May repeat 12 milligrams IV if needed

Rapid IV push over 1–2 seconds via peripheral line. Flush line after each dose with 20 mL of normal saline. Patients usually experience transient asystole (<5 seconds).

The initial adenosine dose should be reduced to 3 milligrams in patients on concomitant therapy with dipyridamole or carbamazepine, in heart transplant patients, or for central line administration.

Adenosine effects are antagonized by caffeine and theophylline, and patients may require higher doses.

Dosing and Administration See **Table 19-24**.[6]

Adverse Effects The most common adverse effects associated with adenosine administration include transient asystole (treatment goal), chest discomfort/pressure, headache, flushing, and nausea. The adverse effects are usually temporary due to the short half-life of the drug. Bronchospasm and atrial fibrillation can also occur, but the incidence is rare. Severe adverse effects, including cardiac conduction abnormalities and hypotension, are more common with continuous infusion adenosine used in stress testing.

MAGNESIUM SULFATE

Actions/Indications/Dosing and Administration Intravenous magnesium sulfate exerts antiarrhythmic effects in the treatment of torsades de pointes. Its antiarrhythmic activity is mediated by inhibiting calcium currents that cause pathologic early after-depolarizations and thereby cardiac dyssynchrony. Magnesium slows sinoatrial node activity, prolongs myocardial conduction time, stabilizes excitable membranes, and is a cofactor in ion movement.[29] IV magnesium sulfate has a rapid onset of action and is indicated in the treatment of torsades de pointes, polymorphic ventricular tachycardia associated with a prolonged QT interval, and cardiac arrest when ventricular fibrillation/pulseless ventricular tachycardia is associated with torsades de pointes. In patients with a pulse, 1 to 2 grams IV is diluted in normal saline or 5% dextrose in water and administered as a rapid bolus. Rapid IV administration of magnesium sulfate is associated with vasodilation, flushing, and hypotension.

ISOPROTERENOL

Actions/Pharmacokinetics/Indications Isoproterenol exerts antiarrhythmic effects by stimulating β_1- and β_2-receptors. The β_1-receptor interaction results in increased chronotropic and inotropic activities in the myocardium and vasodilation by β_2-receptor–mediated relaxation of smooth muscle. Isoproterenol has an immediate onset of action, a half-life of 2.5 to 5 minutes, and a duration of 10 to 15 minutes. It is indicated for refractory bradyarrhythmias, atrioventricular nodal block, and refractory torsades de pointes. Isoproterenol is contraindicated in patients with angina, preexisting ventricular arrhythmias, tachyarrhythmias, or digoxin toxicity.

Dosing and Administration Isoproterenol should be initiated at 2 micrograms/min (maximum rate, 10 micrograms/min) and titrated every 5 to 10 minutes based on patient response.

Adverse Effect Profile Serious adverse effects of isoproterenol include hypotension, premature ventricular beats, tachyarrhythmia, ventricular arrhythmia, dyspnea, and pulmonary edema.

CHAPTER 20

Pharmacology of Vasopressors and Inotropes

Sara H. Shields
Rachel M. Holland

INTRODUCTION

Vasopressors are potent pharmacologic agents that are used to increase blood pressure and mean arterial pressure by vasoconstriction, thus increasing systemic vascular resistance. As such, they should be reserved for cases of persistent hypotension and tissue hypoperfusion after volume resuscitation has failed. Most vasopressors have multiple actions on the heart and vasculature and have a propensity to cause arrhythmias. Some vasopressors are also inotropes and are used to improve cardiac output, particularly in patients with left ventricular pump failure or cardiogenic shock. **Table 20-1**[1-3] provides a summary of common vasopressor and inotropic agent doses, effects, and uses.

VASOPRESSORS

DOPAMINE

Actions Dopamine is an endogenous catecholamine and a metabolic precursor of norepinephrine and epinephrine that acts on dopaminergic, α_1, β_1, and β_2 receptors in a dose-dependent fashion. At intermediate doses (5 to 15 micrograms/kg/min), dopamine increases renal blood flow, heart rate, cardiac contractility, and cardiac output. At high doses (>15 micrograms/kg/min), the α-adrenergic effects of dopamine dominate, leading to vasoconstriction and increased blood pressure. Low-dose (renal dose) dopamine is no longer recommended for renal protection due to lack of data support.[4]

Pharmacokinetics See **Table 20-2**.[3]

Indications Dopamine increases cardiac output, blood pressure, and peripheral perfusion and is indicated for reversing hemodynamically significant hypotension caused by myocardial infarction, trauma, heart failure, and renal failure, when fluid resuscitation is unsuccessful or inappropriate. Based on the 2012 Surviving Sepsis Campaign guidelines, dopamine is no longer recommended as an initial vasopressor of choice for septic shock, based on data showing lower short-term mortality and arrhythmias in patients receiving norepinephrine versus dopamine.[5] Dopamine can be considered as an alternative vasopressor agent to norepinephrine only in highly selected patients (i.e., patients with low risk of tachyarrhythmias and absolute or relative bradycardia).[4] Although not considered a first-line agent, dopamine can also be used for the treatment of symptomatic bradycardia (particularly if associated with hypotension) that is unresponsive to atropine.[5]

Dosing and Administration See Table 20-1. Dopamine is administered as a continuous IV infusion (central line recommended) and should be titrated to desired response. When discontinuing the infusion, the dose should be gradually decreased to avoid hypotension.

Adverse Effects Adverse effects of dopamine include chest pain, hypotension (low doses), hypertension (higher doses), ectopic beats, palpitations, nausea, vomiting, headache, gangrene, and tachycardia. Extravasation of dopamine may cause tissue necrosis and sloughing and can be treated by local infiltration with phentolamine. Dopamine is contraindicated in patients with pheochromocytoma or tachyarrhythmias/ventricular fibrillation.

EPINEPHRINE

Actions Epinephrine, an endogenous catecholamine, is a nonselective α- and β-adrenergic agonist that causes increases in systemic vascular resistance, heart rate, cardiac output, and blood pressure. It is used as a

TABLE 20-1 Summary of Common Vasopressor Doses, Effects, and Uses

Drug	Dose Range	Receptor Activation	Cardiovascular Effects	Use
Dopamine	2–20 micrograms/kg/min	Dose dependent <5 micrograms/kg/min: DA_1, DA_2 5–10 micrograms/kg/min: β_1 >10 micrograms/kg/min: α_1	*↑HR, BP, CO, SVR	Cardiogenic shock, vasodilatory shock

*Dose dependent.

†Renal adjustment required.

bronchodilator in acute asthma and for the treatment of anaphylactic reactions. Epinephrine also increases cerebral and coronary perfusion and cerebral perfusion pressure during resuscitation and is therefore used in various advanced cardiac life support algorithms including cardiac arrest.

Pharmacokinetics See **Table 20-3**.[3,6]

Indications Epinephrine is indicated for the treatment of anaphylaxis, hypersensitivity reactions, and acute asthma exacerbations. Based on current advanced cardiac life support guidelines, it is indicated in the treatment of cardiac arrest (i.e., pulseless ventricular tachycardia/ventricular fibrillation, pulseless electrical activity, and asystole) because it improves return of spontaneous circulation (but does not improve survival or function), and it can also be used for symptomatic bradycardia unresponsive to atropine or pacing.[5] In addition, the 2012 Surviving Sepsis Campaign guidelines recommend epinephrine (added to and potentially substituted for norepinephrine) when an additional agent is needed to maintain adequate blood pressure in patients with severe sepsis or septic shock.[4]

Dosing and Administration See **Table 20-4**.[3]

Adverse Effects Adverse effects of epinephrine include angina, palpitations, arrhythmias, hypertension, tachycardia, nausea, vomiting, headache, anxiety, and pulmonary edema. Extravasation of epinephrine may cause tissue necrosis and sloughing and can be treated by local infiltration with phentolamine.

NOREPINEPHRINE

Actions Norepinephrine is an endogenous catecholamine that stimulates α-adrenergic receptors, resulting in peripheral vasoconstriction and increased blood pressure, as well as β-adrenergic receptors ($\beta_1 > \beta_2$), leading to inotropic stimulation of the heart and coronary artery vasodilation. It is used for the treatment of sepsis and septic shock refractory to fluid resuscitation and in severe hypotension.

TABLE 20-2 Dopamine Pharmacokinetics (IV)

Metabolism	Excretion	Half-Life	Onset/Duration of Action
Renal, hepatic, plasma; 75% to inactive metabolites by monoamine oxidase and 25% to norepinephrine	Urine (as metabolites)	~2 min	Onset: ≤5 min Duration: <10 min

Pharmacokinetics See **Table 20-5**.[3,6]

Indications Norepinephrine is indicated for the treatment of acute hypotension and profound hypotension in post–cardiac arrest patients. Based on the 2012 Surviving Sepsis Campaign guidelines, it is also considered the initial vasopressor of choice for the treatment of severe sepsis and septic shock refractory to adequate fluid resuscitation.[4]

Dosing and Administration See **Table 20-6**.[3,6]

Adverse Effects Adverse effects of norepinephrine include bradycardia, arrhythmias, peripheral (digital) ischemia, hypertension, nausea, vomiting, headache, anxiety, and cardiac arrest. Extravasation of norepinephrine may cause tissue necrosis and sloughing and can be treated by local infiltration with phentolamine.

PHENYLEPHRINE

Actions Phenylephrine is a selective α_1-adrenergic agonist that essentially lacks β-adrenergic activity. The cumulative effect of phenylephrine results in systemic arterial vasoconstriction, leading to increased systemic vascular resistance and dose-dependent elevations in systolic and diastolic blood pressure. Phenylephrine has no direct effects on heart rate; however, reflex bradycardia and reduced cardiac output may occur, especially in patients with heart failure or cardiogenic shock.[6,7]

Pharmacokinetics See **Table 20-7**.[3]

Indications Phenylephrine is indicated for the treatment of hypotension and shock. Use of phenylephrine is not recommended for the treatment of cardiogenic or septic shock.

Dosing and Administration Phenylephrine is administered as a continuous IV infusion. The typical starting dose of phenylephrine is 50 to 150 micrograms/min or 0.02 to 2 micrograms/kg/min and should be titrated based on hemodynamic parameters and clinical effect. The com-

ACLS (asystole, pulseless arrest, pulseless VT/VF)†	Bradycardia	Hypotension/Shock	Anaphylaxis
1 milligram IV/IO every 3–5 min until ROSC (1:1000 solution) **2–2.5 milligrams ET every 3–5 min until IV/IO access established or ROSC (dilute in 5–10 mL NS or SW)**	IV infusion: 2–10 micrograms/min *or* 0.05–0.5 micrograms/kg/min (titrate to desired effect)	IV infusion: 0.05–0.5 micrograms/kg/min (titrate to desired response)	0.2–0.5 milligrams IM/SC every 5 min as needed (1:1000 solution) 0.1 milligram IV (1:10,000 solution) over 5 min; may infuse at 1–4 micrograms/min to prevent frequent repeat injections *or* may initiate with an infusion at 5–15 micrograms/min (with crystalloid administration)*

Abbreviations: ET = endotracheal; IO = intraosseous; NS = normal saline; ROSC = return of spontaneous circulation; SW = sterile water; **VT = ventricular tachycardia; VF = ventricular fibrillation.**

*In general, IV administration should be reserved for patients who are profoundly hypotensive or are in cardiopulmonary arrest refractory to volume resuscitation and several epinephrine injections. **When administering as a continuous IV infusion, central line administration is preferred.**

†Current at the time of publication, epinephrine is recommended in ACLS guidelines for pulseless rhythms, however, some studies have shown worse outcomes, while others have shown no improvement in long term survival or neurologic function.

mon maintenance infusion range is 40 to 60 micrograms/min to maintain blood pressure. Phenylephrine can also be given as an IV bolus for acute blood pressure management. The normal bolus dose range is 100 to 500 micrograms/dose IV every 10 to 15 minutes as needed.

Adverse Effects Adverse effects of phenylephrine include hypertension, decreased cardiac output, reflex bradycardia, and arrhythmias (rare). Phenylephrine use can also lead to renal, mesenteric, and myocardial ischemia, as well as ischemia and necrosis to the extremities. Because phenylephrine is a vesicant, IV extravasation can result in local necrosis and sloughing of affected tissue. If extravasation occurs, the infusion should be stopped immediately and phentolamine should be administered.

Phenylephrine should be used with caution in patients with bradycardia, hyperthyroidism, heart block, and coronary artery disease. The use of phenylephrine is not recommended for cardiogenic shock because it can further worsen cardiac output due to reflex bradycardia.[6] The 2012 Surviving Sepsis Campaign guidelines recommend against the use of phenylephrine for septic shock unless a trial of norepinephrine was associated with serious arrhythmias, cardiac output is known to be high, or it is used as add-on therapy when other first-line vasopressor agents fail to achieve goal mean arterial pressure.[4] Appropriate volume resuscitation should occur before phenylephrine is used in hypotensive patients.

TABLE 20-5 Norepinephrine Pharmacokinetics (IV)

Metabolism	Excretion	Half-Life	Onset/Duration of Action
Via monoamine oxidase and catechol-o-methyltransferase	Urine (84%–96% as inactive metabolites)	3 min	Onset: 1–2 min Duration: 5–10 min

Hepatic via oxidative deamination (50%); undergoes sulfation (8%) and some glucuronidation; forms inactive metabolites	Urine (mostly as inactive metabolites)	Alpha phase: ~5 min Terminal phase: 2–3 h	Onset: immediate Duration: ~15–20 min

VASOPRESSIN

Actions Vasopressin, an endogenous nonadrenergic vasopressor, stimulates V_1 receptors in vascular smooth muscle, causing direct peripheral vasoconstriction and subsequent increases in systemic vascular resistance and blood pressure, as well as improved cerebral and cardiac perfusion. It does not exhibit inotropic or chronotropic effects on the heart and can cause a decrease in heart rate and cardiac output. Vasopressin also acts on V_2 receptors in the kidneys causing an antidiuretic effect.

Pharmacokinetics See **Table 20-8**.[3,6]

Indications Vasopressin is indicated for the treatment of diabetes insipidus. Based on current advanced cardiac life support guidelines, a single dose of vasopressin can be used to replace the first or second dose of epinephrine in the treatment of cardiac arrest (i.e., pulseless ventricular tachycardia/ventricular fibrillation, asystole, and pulseless electrical activity) to improve return of spontaneous circulation.[5] According to the 2012 Surviving Sepsis Campaign guidelines, vasopressin (up to 0.03 unit/min) may be added to norepinephrine to either raise mean arterial pressure to target or to decrease norepinephrine dose but should not be used as the single initial vasopressor for treatment of sepsis-induced hypotension. Doses higher than 0.03 to 0.04 unit/min should be reserved for salvage therapy (failure to achieve adequate mean arterial pressure with other vasopressor agents).[6]

Dosing and Administration See **Table 20-9**.[3]

Adverse Effects Adverse effects of vasopressin include diaphoresis, nausea, vomiting, headache, urticaria, gangrenous disorder, arrhythmias, mesenteric ischemia, chest pain, myocardial infarction, bronchial

TABLE 20-8 Vasopressin Pharmacokinetics (IV)

constriction, venous thrombosis, and cardiac arrest. Extravasation of vasopressin may cause tissue necrosis and sloughing and can be treated by local infiltration with phentolamine.

INOTROPES

DOBUTAMINE

Actions Dobutamine is a synthetic dopamine analog with potent inotropic and mild vasodilatory and chronotropic effects. It competitively binds and stimulates α- and β-receptors ($\beta_1 > \beta_2 > \alpha$), resulting in the major effects of increased contractility and heart rate, with mostly neutral effects on blood pressure.

Pharmacokinetics See **Table 20-10**.[3]

Indications Dobutamine is indicated for the short-term management of patients with acute cardiac decompensation, particularly in patients presenting with cardiogenic shock. Dobutamine can also be used for septic shock as monotherapy or in addition to vasopressors in patients presenting with myocardial dysfunction, low cardiac output, or persistent signs of hypoperfusion.[4]

Dosing and Administration Dobutamine is administered as a continuous infusion with a normal starting dose of 2 micrograms/kg/min titrated up to a maximum dose of 40 micrograms/kg/min based on clinical effect. The maximum recommended dose for septic shock is 20 micrograms/kg/min.[4]

Adverse Effects Adverse effects associated with dobutamine include hypertension, hypotension, tachycardia, arrhythmias, myocardial ischemia, angina, and hypokalemia. Dobutamine IV extravasation can cause phlebitis, local inflammation, and rarely tissue necrosis.

The use of dobutamine in patients with atrial fibrillation is cautioned due to the potential to increase ventricular response. It should also be used with caution in post–myocardial infarction patients because of increased myocardial oxygen demand. Dobutamine is ineffective in the presence of aortic stenosis and should be avoided. Concomitant use of monoamine oxidase inhibitors may result in prolonged hypertension and should be avoided. Dobutamine should be limited to short-term use when possible. Prolonged inotrope therapy has been associated with increased mortality.[8]

MILRINONE

Actions Milrinone is an inotrope with vasodilator properties ("inodilator") that selectively inhibits the phosphodiesterase type III enzyme, resulting in the inhibition of the breakdown of cyclic adenosine monophosphate in myocardial and vascular smooth muscle cells. Increased cyclic adenosine monophosphate levels result in increased cardiac contractility as well as peripheral arterial and venous vasodilation. The cumulative effects of milrinone include increased cardiac output and reduced systemic vascular resistance .[9]

Pharmacokinetics See **Table 20-11**.

Indications Milrinone is indicated for the short-term treatment of acute decompensated heart failure.

Dosing and Administration Milrinone is administered as an optional IV loading dose and a continuous infusion. The typical loading dose of milrinone is 50 micrograms/kg IV over 10 minutes, while the maintenance infusion should be started at 0.25 to 0.75 micrograms/kg/min and titrated to effect. The loading dose is commonly omitted, particularly in patients who are hypotensive. Milrinone must be renally adjusted if the creatinine clearance is less than 50 mL/min.

TABLE 20-10 Dobutamine Pharmacokinetics (IV)

Metabolism	Excretion	Half-Life	Onset of Action/ Peak Effect
In tissues and hepatically to inactive metabolites	Urine (as metabolites)	2 min	Onset: 1–10 min Peak: 10–20 min

TABLE 20-11 Milrinone Pharmacokinetics (IV)

Metabolism	Excretion	Half-Life	Onset of Action
Hepatic (12%)	Urine (85% as unchanged drug)	~2.5 h, prolonged in renal dysfunction	Onset: 5–15 min

Adverse Effects Adverse effects associated with milrinone use include ventricular and supraventricular arrhythmias, hypotension, angina, and headache. Thrombocytopenia and abnormal liver function tests are rare but may also occur.

Unlike dobutamine, milrinone use is not recommended for use in septic shock. Milrinone can exacerbate hypotension and arrhythmias; consequently, extreme caution is warranted when used in these circumstances. Fluid resuscitation and electrolyte correction should occur before initiating milrinone. Long-term treatment of inotropic therapy has been associated with increased mortality and should be limited to short-term therapy in most cases.

CHAPTER 21

Hyperbaric Oxygen Therapy

David S. Lambert
Stephen R. Thom

INTRODUCTION

Hyperbaric oxygen (HBO) therapy involves breathing oxygen with the body exposed to an ambient pressure greater than that of sea level. HBO therapy results in the systemic delivery of oxygen that produces supraphysiologic oxygen tension in perfused tissues. The effects of HBO therapy are due to the combined effects of both increased ambient pressure and increased oxygen tension.[1]

HBO therapy is delivered in a hyperbaric chamber. Monoplace chambers accommodate a single occupant and are typically clear, acrylic, plastic, cylindrical units with a door at one end (**Figure 21-1**). An attendant monitors the patient from the outside and communicates via intercom. Specially designed cardiopulmonary monitoring devices, intravenous infusion pumps, and ventilators enable critically ill patients to be treated in most monoplace chambers. Multiplace chambers can simultaneously treat multiple patients and will accommodate medical personnel inside the chamber (chamber tender or assistant) to perform hands-on patient assessment and care (**Figure 21-2**). Monoplace chambers generally use 100% oxygen for pressurization, whereas multiplace units are pressurized with air and patients breathe oxygen using tight-fitting facemasks, a hood, or endotracheal tube while inside. Most HBO chamber facilities have equipment and treatment protocols analogous to an intensive care unit.

Ambient pressure is an important concept in HBO therapy. At sea level, the pressure exerted by the air column (the atmosphere) above is quantified as 1 atmospheres absolute of pressure (1 ATA), 14.7 lb per square inch, 760 mm Hg, or 760 torr. Once a patient is placed inside a chamber, the ambient pressure is increased by the gradual inflow of compressed gas, either oxygen or air. Most HBO therapy takes place with an ambient pressure between 2.0 and 3.0 ATA.

In hyperbaric and diving medicine, the increased ambient pressure was originally described as of feet of sea water (fsw) or meters of sea water (msw) for both HBO treatment and during scuba diving. One atmosphere is equal to the pressure exerted by 33 fsw (10 msw), so starting at sea level, the ambient pressure is 1 ATA, and at a depth of 33 fsw,

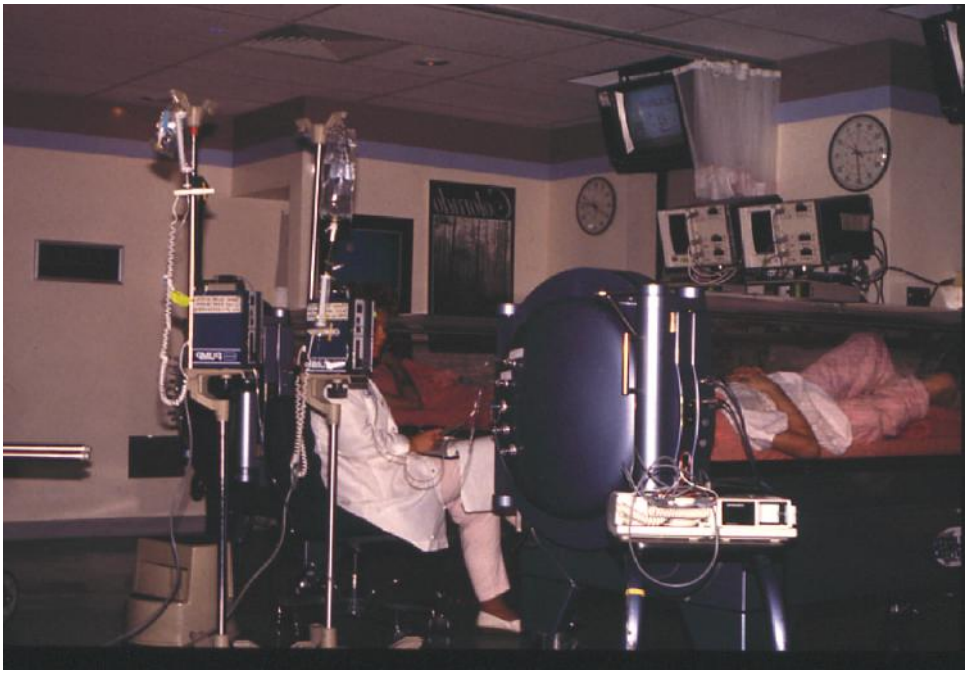

FIGURE 21-1. Monoplace hyperbaric chamber.

the ambient pressure would be 2 ATA. Describing an HBO treatment at either 2 ATA or 33 fsw communicates equivalent pressure.

A typical HBO treatment lasts 90 to 120 minutes. The initial pressurization phase is done over 10 to 15 minutes to allow for equalization of pressures within the sinuses and middle ear as ambient pressure increases. Pressure is then maintained at the desired levels for 40 to 90 minutes, followed by depressurization over 5 to 10 minutes. In a monoplace chamber, the patient is surrounded by and breathes 100% oxygen during the entire treatment. If desired, air breaks are done for 5 to 10 minutes with the patient breathing air from a mask while in the chamber. In a multiplace chamber, the patient is surrounded by air during the entire treatment and breathes 100% oxygen via a face mask or hood. Air breaks in a multiplace chamber are accomplished by removing the mask or hood and breathing the surrounding air. HBO treatments are done using preset protocols that define the level of pressurization, duration of each individual treatment, the use of air breaks, and the number of individual sessions in a course of therapy.

GAS LAWS

The physics of HBO therapy are governed by the ideal gas laws. Boyle's law states that for gases kept at a constant temperature, the volume of that gas is inversely proportional to the pressure exerted on it. If pressure doubles, then the volume is halved. Boyle's law is the principal behind HBO treatment of decompression sickness and air or gas embolism—

FIGURE 21-2. Multiplace hyperbaric chamber.

reducing the size of gas bubbles within tissues and circulation by increasing ambient pressure. Boyle's law also explains the occurrence of pain in the sinuses and ears during pressurization and decompression, as trapped pockets of gas contract or expand as ambient pressure changes.

Gay-Lussac's law states that at a constant volume (e.g., a hyperbaric chamber) the absolute pressure is directly proportional to the absolute temperature. This explains why the ambient temperature inside a chamber increases transiently as it is pressurized and cools with decompression.

Henry's law specifies that the partial pressure of a gas dissolved in a liquid is proportional to the pressure exerted on that gas. HBO therapy increases the ambient partial pressure of oxygen (Po_2), producing an increase in the amount of dissolved oxygen carried by the blood. A patient in a hyperbaric chamber compressed to 2 ATA (equivalent to a diver at 33 fsw) breathing 21% oxygen is exposed to a Po_2 of 320 mm Hg, twice the Po_2 at ambient pressure before starting the treatment. Although the percentage of oxygen at 2 ATA is still 21%, the patient is inhaling twice as many molecules of oxygen with each breath. This is functionally equivalent to breathing 42% oxygen at sea level or 1 ATA.

The oxygen content of the blood is the sum of the oxygen carried by hemoglobin and oxygen dissolved in the plasma. Hemoglobin becomes fully saturated around a Po_2 of 100 mm Hg; fully saturated hemoglobin carries approximately 20 mL of oxygen per 100 mL of blood, which is expressed as 20 vol%. At 1 ATA breathing room air, dissolved oxygen in the plasma is typically only 0.3 vol%. At a pressure of 3 ATA inside an HBO chamber pressurized with 100% oxygen, the arterial oxygen tension (Pao_2) will approach 2200 mm Hg, which will bring the dissolved oxygen content up to about 5.4 vol%.[2] This amount of dissolved oxygen can sustain basal metabolic functions in the complete absence of hemoglobin.

PHYSIOLOGIC EFFECTS

HBO therapy should be viewed as a drug and the hyperbaric chamber as a delivery device. HBO affects tissues in two ways: there are effects related to mechanical forces of increased pressure and effects due to hyperoxygenation. Of the two, elevating tissue oxygen tension is the primary effect.

Hyperoxygenation induces the formation of reactive oxygen species (superoxide, hydrogen peroxide, hypochlorous acid, and hydroxyl) and reactive nitrogen species (primarily nitric oxide). Levels generated during HBO therapy have beneficial effects seen after tissue oxygen levels return to normal (**Table 21-1**). Reactive oxygen species are natural byproducts of metabolism that can oxidize proteins and membrane lipids, damage DNA, and mediate tissue and organ damage seen in oxygen toxicity. The body has scavenger antioxidant systems to reverse the oxidative damage caused by reactive oxygen species generated during a typical HBO treatment of about 2 hours, so that oxygen toxicity is rare.

INDICATIONS

The Undersea and Hyperbaric Medical Society has defined clinical indications for HBO therapy, some of which are within the scope of emergency medicine practice (**Table 21-2**).[3]

TABLE 21-1 Beneficial Effects of Reactive Oxygen and Nitrogen Species

Inhibit microbial endotoxin and exotoxin production
Enhance oxygen-dependent transport of antibiotics across cell walls
Improve neutrophil oxygen-dependent peroxidase bactericidal activity
Induce vasoconstriction that reduces posttraumatic tissue edema
Stimulate angiogenesis by promoting the production of oxygen-dependent collagen matrix
Promote wound healing by amplifying oxygen gradients at the periphery of ischemic wounds
Blunt endothelial ischemia-reperfusion injury

TABLE 21-2 Indications for Hyperbaric Oxygen Therapy

Arterial gas embolism with neurologic symptoms*
Decompression sickness*
Carbon monoxide poisoning*
Crush injury, compartment syndrome, and other acute traumatic ischemias*
Exceptional blood loss anemia*
Delayed radiation injury (osteoradionecrosis and soft tissue)
Compromised skin grafts and flaps
Acute thermal burns*
Arterial insufficiencies (enhancement of healing in selected problem wounds, central retinal artery occlusion)
Necrotizing soft tissue infections*
Clostridial myonecrosis (gas gangrene)*
Osteomyelitis (refractory)
Intracranial abscesses

*Conditions that lend themselves to emergency medicine practice.

AIR OR GAS EMBOLISM

Air or gas embolism can occur as a consequence of a deep sea dive–related accident[4] or as the result of a medical procedure.[5] Iatrogenic air or gas embolism has been reported in association with cardiovascular, obstetric/gynecologic, neurosurgical, and orthopedic procedures, generally associated with disruption of a vascular wall.[6] Nonsurgical processes reported to cause air or gas embolism include overexpansion during mechanical ventilation, hemodialysis, and after accidental opening of central venous catheters. Air or gas embolism can occur either on the venous or arterial side of the circulatory system.

The consequences of an arterial gas embolism depend on location and magnitude of arterial occlusion. Often skeletal muscle, connective tissue, and skin can tolerate small emboli, but bubbles entering the coronary or cerebral arteries can precipitate acute coronary syndrome or stroke. Air entering the spinal cord circulation can produce weakness or paralysis. Any diver who surfaces with sudden onset of neurologic symptoms, such as confusion, speech difficulty, focal weakness, or paralysis, in less than 5 to 10 minutes should be assumed to have arterial gas embolism unless proven otherwise. Imaging with CT or MRI may help exclude an ischemic stroke or intracerebral hemorrhage. CT scan of the brain may show air in the cerebral vessels; however, this finding is variable and can be difficult to recognize (**Figure 21-3**).

Venous gas embolism is common after compressed-gas diving and surgical procedures.[6] The amount of gas is typically small, and the bubbles are trapped in the pulmonary capillaries and resorbed without symptoms. Large quantities of gas in the pulmonary vasculature can stimulate cough, dyspnea, and pulmonary edema. A paradoxical arterial gas embolism may develop when a venous gas embolism travels to the arterial system by way of an intrapulmonary shunt or through an atrial septal defect or patent foramen ovale.

Administer oxygen to support arterial oxygenation and hasten bubble resorption. Place the patient in the supine position; there is no proven benefit to a head-down position to lower the risk of additional cerebral air embolization or a left lateral decubitus position to trap gas within the apex of the right ventricle and minimize migration. Catheter aspiration of trapped air in the right ventricle may be attempted in those rare instances when it is visualized.

HBO is recommended for air or gas embolism with neurologic or cardiovascular impairment.[3] The faster the patient receives HBO, the greater is the chance for complete neurologic recovery. Various protocols are used for air or gas embolism. A standard one is Treatment Table 6 from the U.S. Navy Diving Manual, which uses compression to 2.8 ATA for 75 minutes (with three air breaks), following by decompression to 1.8 ATA for 150 minutes (with two air breaks) for a total treatment time of 285 minutes. For patients whose symptoms are not improved or worsen, a protocol using pressurization up to 6 ATA (Treatment Table 6A) is recommended. For patients with residual symptoms after the initial HBO treatment, additional treatments are recommended until there is no further neurologic improvement, typically one to two additional treatments.

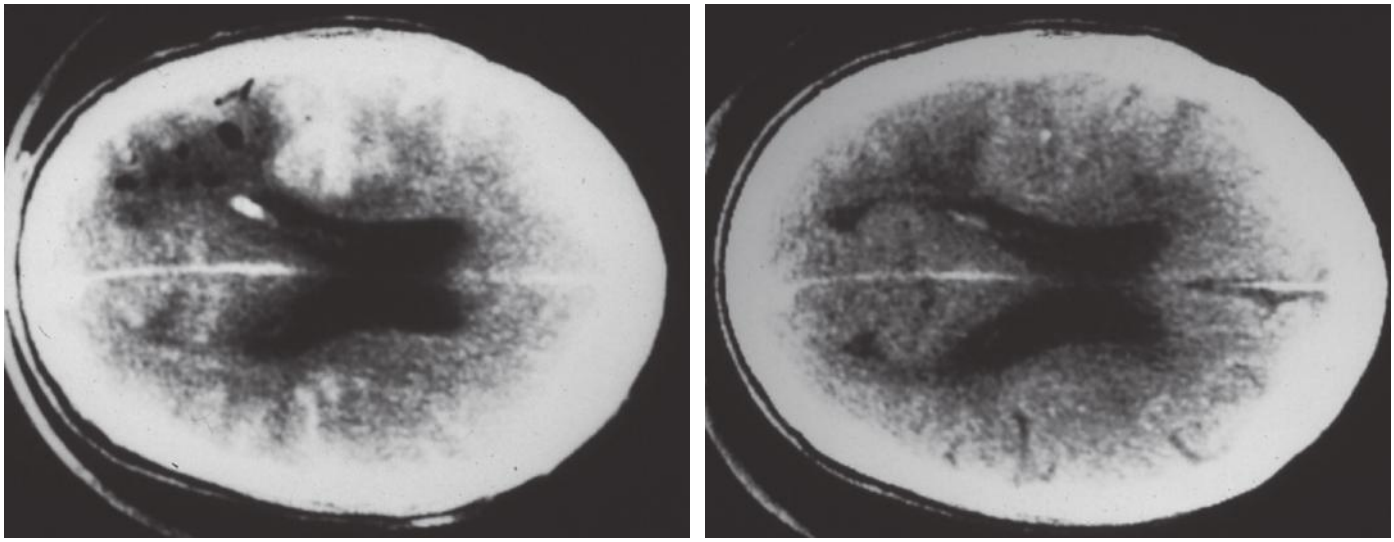

FIGURE 21-3. Head CT demonstrating air in cerebral vessels before hyperbaric oxygen treatment (*left*) and eradication after treatment (*right*).

DECOMPRESSION SICKNESS

Decompression sickness is due to the formation of nitrogen bubbles in body tissue and circulation during decompression (see chapter 214, "Diving Disorders").[7] During pressurization, inert gas (nitrogen if breathing air) is dissolved in body fluids. Upon reduction in ambient pressure, the dissolved gas comes out of solution and forms small bubbles in the tissue and circulation. HBO is an effective treatment because the increase in ambient pressure reduces gas bubble volume and the supplemental oxygen hastens inert gas diffusion out of the body.

Decompression sickness should be treated with HBO when such therapy is available and no contraindication exists. If HBO therapy is not available, patients with mild symptoms and neurologic stability for longer than 24 hours may be treated with supplemental oxygen therapy alone. If a patient must be transported by air to a hyperbaric facility, use pressurized aircraft to maintain sea-level pressure or transport at the lowest possible altitude in a nonpressurized craft, such a helicopter.

A variety of HBO regimens are used to treat decompression sickness,[8] but most have in common pressurization to 2.8 ATA for 60 to 90 minutes, followed by stepwise decompression, similar to U.S. Navy Diving Manual Treatment Table 6. Most patients respond to a single treatment. Gas bubbles can persist for several days, and HBO may be beneficial even when begun after long delays.[8]

CARBON MONOXIDE POISONING

Carbon monoxide (CO) toxicity develops from impairment of hemoglobin function and direct CO-mediated cellular damage (see chapter 222, "Carbon Monoxide"). The affinity of CO for hemoglobin, forming carboxyhemoglobin, is more than 200-fold greater than that of oxygen. Carboxyhemoglobin cannot carry oxygen, so as the level rises, the oxygen-carrying capacity of blood decreases, inducing hypoxic stress initially on organs most dependent on oxidative metabolism—the brain and heart. After removal from continued CO exposure, the CO slowly dissociates from the hemoglobin and is metabolized or exhaled, and the carboxyhemoglobin levels fall. Treatment with HBO enhances the decline of carboxyhemoglobin levels, more rapidly restoring oxygen-carrying capacity of the blood. In animal models of CO poisoning, HBO treatment ameliorates pathophysiologic events associated with CNS injuries mediated by CO, such as improvement in mitochondrial oxidative processes,[9] inhibition of lipid peroxidation,[10] and impairment of leukocyte adhesion to injured microvasculature.[11] Animals poisoned with CO and treated with HBO have more rapid improvement in cardiovascular status,[12] lower mortality,[13] and lower incidence of neurologic sequelae.[14]

Five prospective, randomized trials have assessed clinical efficacy of HBO for acute human CO poisoning.[15-19] Three did not find benefit,[15,17,18] but have been criticized for methodologic weaknesses that may have affected results.[20-23] The clinical trial from Salt Lake City found a significant reduction in neuropsychological sequelae at 6 weeks in HBO-treated patients.[19] This study has been analyzed and debated by advocates and critics of HBO treatment.[24] The results have been considered an outlier by meta-analysis that concluded there is no evidence that HBO reduces incidence of adverse CO-mediated neurologic outcomes.[25,26] Despite the uncertainties, HBO treatment should at least be considered in cases of serious acute CO poisoning because 1) the neurologic sequelae can be severe, 2) retrospective analysis found that HBO was associated with diminished acute mortality,[20] and the Salt Lake City trial found benefit.[27]

The Salt Lake City protocol for CO poisoning uses pressurization to 3 ATA for 60 minutes, with two air breaks, followed by a reduction in pressure to 2 ATA for 65 minutes with one air break.[19] Two additional treatments are given in 6- to 12-hour intervals. An alternative protocol uses 2.8 ATA for 30 minutes followed by 2.0 ATA for 90 minutes.

CYANIDE POISONING

Concomitant cyanide and CO poisoning may be seen in patients rescued from closed-space fires in which synthetic materials are burned. Experimental evidence suggests that cyanide and CO can produce synergistic toxicity.[28-30] HBO may directly reduce cyanide toxicity[31,32] or augment other antidote treatments.[33] However, clinical experience with HBO for cyanide toxicity is sparse.[34-38]

Cyanide is among the most lethal poisons, and toxicity is rapid, so standard antidotal therapy for isolated cyanide poisoning is of primary importance. HBO can be considered in case of dual CO and cyanide poisoning and in cyanide poisoning when vital signs and mental status do not improve with antidote treatment.

EXCEPTIONAL BLOOD LOSS ANEMIA

In cases of severe anemia where transfusion cannot effectively improve oxygen content to sustainable levels (e.g., Jehovah's Witness, Rh incompatibility/transfusion reactions, patient refusal), HBO aids in sustaining life.[39] Anecdotal reports describe using 100% oxygen at 2.5 to 3.0 ATA to raise Pao_2 in plasma to meet metabolic needs.[40-43] Treatments are administered for 3 to 4 hours, with air breaks, with sessions up to four times per day, and continued until red blood cell concentration improves.

ACUTE THERMAL BURN INJURY

Some burn centers use adjunctive HBO for severe burns. This is not a universal practice, and controversy persists.[44] Animal models have documented benefits with HBO in reducing partial- to full-thickness skin loss, hastening epithelialization, and lowering mortality.[2] Randomized clinical trials with small patient numbers have reported improved rates

of healing with shorter hospitalization stays.[45-48] Uncontrolled series have reported mixed results.[49-51] A typical HBO protocol for thermal burns uses pressurization to 2.4 ATA for 100 minutes with two air breaks. Treatments are initiated at three sessions a day, then decreased to twice a day as healing occurs, and continued up to a total of 45 sessions.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infections, such as necrotizing fasciitis and Fournier's gangrene, are typically mixed aerobic-anaerobic infections. HBO is potentially beneficial due to its ability to suppress growth of anaerobic microorganisms and improve bactericidal action of leukocytes that function poorly in hypoxic conditions.[52-55]

Variation in time of diagnosis and clinical status at time of admission make analysis of the six nonrandomized comparisons and four case series using HBO to treat necrotizing soft tissue infection too complex to yield a straightforward conclusion.[56-65] Most studies have reported that when HBO is added to surgery and antibiotic therapy, mortality is reduced. Typical HBO therapy for necrotizing soft tissue infection uses pressurization to 2.4 ATA for 100 minutes with two air breaks, with treatments started at two sessions per day and then decreased to once a day for up to a total of 30 sessions.

CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)

Gas gangrene is a serious infection with high morbidity and mortality. When tissue Po_2 reaches about 250 mm Hg, α toxin production stops. Once production is halted, α toxin is rapidly cleared.[66] In addition, HBO suppresses the growth of clostridial organisms.[66] HBO therapy of gas gangrene has been the subject of five retrospective comparisons and 13 case series, along with separate analysis.[2,67-69] Assessment of HBO therapy efficacy based on mortality or "tissue salvage" rates is difficult due to variation in patients and clinical practice. Most authors report clinical benefit from treatment, especially the often dramatic temporal improvement of vital signs. A typical HBO therapy protocol for gas gangrene follows the U.S. Navy Diving Manual Treatment Table 21-5: pressurization to 2.8 ATA for 45 minutes with one air break, followed by a slow reduction in pressure over 30 minutes to 1.8 ATA, maintaining pressure there for 30 minutes with two air breaks, followed by decompression, for a total treatment time of 135 minutes. Three treatments are done the first day, and two treatments are done each day for 4 to 5 days more.

CRUSH INJURY, COMPARTMENT SYNDROME, AND OTHER ACUTE TRAUMATIC ISCHEMIAS

The rationale for considering HBO therapy in crushed and ischemic tissues is to temporarily improve oxygenation to hypoperfused tissues and promote arterial hyperoxia, which will cause vasoconstriction and diminish edema formation.[70] This latter mechanism has been convincingly demonstrated in experimental compartment syndrome.[71] A single randomized controlled trial (involving 36 patients) with crushed limbs found that HBO therapy improved healing and reduced infection and wound dehiscence.[72] In a case series of 23 patients, HBO resulted in limb preservation.[73] Comparative evaluation of HBO treatment for complex extremity wounds sustained from bullets or explosions also showed considerable benefit.[74] HBO therapy can be considered when complications or poor outcomes are thought to be likely despite appropriate surgical and medical care.

A typical HBO protocol for these injuries is pressurization to 2.4 ATA for 100 minutes, with two air breaks. Treatments are started at three sessions per day for 2 days, then decreased to twice a day for 2 days and then once a day for 2 days, for a total of 12 sessions.

CENTRAL RETINAL ARTERY OCCLUSION

Central retinal artery occlusion is rare yet devastating and can result in permanent vision loss. There is fair to good evidence based on retrospective case series that HBO therapy started with 24 hours after the onset of symptoms will improve outcome.[3,75] Standard therapies, such as supplemental oxygen and lowering intraocular pressure, are recommended until HBO can be initiated.[1,3]

A typical HBO therapy protocol would be pressurization to 2.0 ATA; if vision improves with this pressure, the patient is treated for 90 minutes with two air breaks. Treatments are done twice a day and continued until there is no improvement in vision after 3 consecutive days. If pressurization to 2.0 ATA does not produce improvement, pressurization to 2.8 ATA is used.

COMPLICATIONS

BAROTRAUMA

Middle ear barotrauma is the most common adverse effect of HBO treatment.[76] As the ambient pressure within the hyperbaric chamber increases, a patient must be able to equalize the pressure within the middle ear by auto-insufflation (pinching the nose while trying to blow through the nose) or else ear pain, tympanic hemorrhage, serous effusion, or rupture will develop. Standard protocols include instruction of patients on auto-insufflation techniques and adding oral or topical decongestants when needed. When these interventions fail, tympanostomy tubes must be placed in order for HBO therapy to continue. The reported overall incidence of aural barotrauma is between 1.2% and 7% of patients who undergo a course of treatment.[77,78] One series reported a 4% incidence of tympanostomy tube placement.[79]

Pulmonary barotrauma during HBO treatment is extremely rare but should be suspected when significant chest or hemodynamic symptoms occur during, or shortly after, decompression. If symptoms develop and the patient is in a multiplace chamber, stop decompression and evaluate for pneumothorax. If the patient is in a monoplace chamber, slowly decompress and provide supplemental oxygen upon returning to ambient pressure.

OXYGEN TOXICITY

Biochemical oxygen toxicity can injure the brain, lungs, and eyes. Acute oxygen toxicity manifests as a grand mal seizure, reported to occur approximately 1 to 4 times per 10,000 patient treatments.[77,80-82] The risk of seizure is higher in hypercapnic patients and possibly those who are acidotic or septic. One case series of HBO therapy for gas gangrene reported a seizure incidence of 7%.[67] Seizures are managed by reducing the inspired oxygen tension while leaving the patient at the same pressure (to avoid pulmonary overexpansion injury when a patient is in tonic convulsion phase).

Chronic oxygen toxicity can impair lung mechanics (elasticity), vital capacity, and gas exchange.[2] These changes are typically observed only when treatment duration and pressures exceed typical therapeutic protocols.[83-85]

Progressive myopia has been reported in patients who undergo prolonged daily therapy, but this typically reverses within 6 weeks after termination of treatments.[86] There is a risk for nuclear cataract development, most typically when treatments exceed a total of 150 to 200 hours, but they may arise with less provocative exposures.[87,88] Current experimental and clinical evidence does not indicate that typical HBO therapy protocols have detrimental effects on neonates or the unborn fetus.[89] This is likely due to the relatively short duration of hyperoxia.

MISCELLANEOUS COMPLICATIONS

Confinement anxiety may occur and is typically managed with sedating agents. Any environment with an elevated concentration of oxygen presents a risk for fire. Scrupulous avoidance of an ignition source is standard in HBO therapy programs.[90]

Resuscitative Procedures

CHAPTER 22

Basic Cardiopulmonary Resuscitation

Adam D. Friedlander
Jon Mark Hirshon

INTRODUCTION

The purpose of CPR is to temporarily provide effective oxygenation of vital organs, especially the brain and heart, through artificial circulation of oxygenated blood until the restoration of normal cardiac and respiratory activity occurs. The intended effect is to stop the degenerative processes of ischemia and anoxia caused by inadequate circulation and inadequate oxygenation.[1] A key component of the 2005 American Heart Association guidelines was the recognition that immediate high-quality CPR is crucial for optimal patient outcome after sudden cardiac arrest.[2] However, the **2010 American Heart Association guidelines** identify several barriers to providing immediate high-quality CPR and address them.[3] Furthermore, even after defibrillation, most victims demonstrate asystole or pulseless electrical activity for several minutes, and high-quality CPR immediately following defibrillation can convert nonperfusing rhythms to perfusing rhythms.[2,3] The time sensitivity of CPR in sudden cardiac death is emphasized in the American Heart Association **"Chain of Survival"** (**Table 22-1**).

This chapter reviews basic CPR for adults and children ≥8 years old, including the approach to an unresponsive patient; the physiology and mechanics of closed chest compression techniques; and basic airway opening procedures, including initial management of an obstructed airway. This chapter is specifically directed toward healthcare providers, although key updates for lay rescuers are noted, given the healthcare provider's role in layperson education.

SUMMARY OF KEY UPDATES TO PREVIOUS ALGORITHMS[3]

1. "Look, listen, and feel" has been removed from all algorithms. Simply put, subjectivity plays too large a role in this step and has been shown to lead to delays. ***Immediate* high-quality CPR is strongly emphasized**, and should begin in any person who is unresponsive without respirations or with abnormal breathing.
2. Lone rescuers no longer follow the "ABCs." **The sequence "CAB" has been adopted instead.** Two rescue breaths are no longer recommended prior to initiating chest compressions.
3. **Compression rate should be *at least* 100/minute**, not approximately 100/minute.
4. **Compression depth should be *at least* 2 inches**, not 1½ to 2 inches.
5. Untrained bystanders should begin **"compression only" CPR**, "hard and fast" in the center of the chest. They may be directed to do so by EMS or by a healthcare provider. This effectively removes the barrier of lack of training or fear of having to perform mouth-to-mouth resuscitation on a stranger.
6. **Pulse checks** are deemphasized for all rescuers, with a **maximum of 10 seconds allowable** for a pulse check. End-tidal carbon dioxide monitoring, when available, is superior to pulse checks, showing an abrupt rise in end-tidal carbon dioxide when spontaneous circulation has returned.
7. For trained rescuers delivering breaths, cricoid pressure is no longer recommended.
8. Postresuscitation care, including therapeutic hypothermia, consideration of cardiac catheterization, and hemodynamic optimization, is emphasized.

Table 22-2 outlines the sequence of steps to be taken when someone is found unresponsive.

STEP 1 AND STEP 2 IN BASIC CPR

Before approaching a collapsed individual, assess the scene for risks to healthcare providers. Potential risks include the presence of hazardous materials, an unstable physical environment, or personal violence. Once the patient is reached, determine the patient's level of responsiveness to noxious stimuli. If the patient is without normal breathing, get help first before starting chest compressions. In a hospital, this may mean calling for the arrest team and requesting the arrest cart. Outside the hospital, this is likely to mean asking a bystander to activate the local EMS system. Look around to see if an automatic external defibrillator is nearby. Rapid application of defibrillation for unstable ventricular tachycardia or ventricular fibrillation is critical for patient survival.

STEP 3 IN BASIC CPR (HEALTHCARE PROVIDER ONLY)

The carotid artery is generally the most reliable and accessible location to palpate a pulse. The artery is located by placing two fingers on the trachea and then sliding them down to the groove between the trachea and the sternocleidomastoid muscle. Simultaneous palpation of both carotid arteries should not be performed because, in low-pressure states, this could obstruct cerebral blood flow and may interfere with the ability to detect a pulse. The femoral artery may be used as an alternative site to palpate a pulse. This can be found just below the inguinal ligament approximately halfway between the anterior superior iliac spine and the pubic tubercle. If no definite pulse is felt within 10 seconds, chest compression should begin.

STEP 4 IN BASIC CPR

Physiology of Closed Chest Compressions There has been an active debate as to the exact mechanism that causes blood flow since the technique of closed chest compressions was put forth in the 1960s.[4,5] In a closed system, liquid flows when pressure gradients develop. There are three basic theories for how pressure gradients and flow are produced during **closed chest cardiac massage**.[6,7] The conventional theory of blood flow during compressions is called the **cardiac pump theory**. The pump theory postulates that direct compression of the heart between the spine and the sternum leads to increased pressure in the ventricles. This causes closure of the mitral and tricuspid valves, leading to blood flow into the aorta and the pulmonary arteries. The **thoracic pump theory** postulates that compressions lead to an increase in pressure throughout the thoracic cavity, leading to a pressure gradient from intrathoracic to extrathoracic arteries. The third mechanism described is the **abdominal pump theory**, which has both an arterial and a venous component. The arterial component postulates blood flow into the peripheral arterial system from increased arterial pressure caused by abdominal compressions that forces blood from the abdominal aorta against the closed aortic valve. The venous component leads to blood return via the inferior vena cava from abdominal pressure. However, regardless of the mechanism, conventional chest compressions generate one fourth to one third of physiologic cardiac output. Lower ratios can

TABLE 22-1 American Heart Association Chain of Survival

Links in Chain	Comment
Immediate recognition/ early access	Phone 911 (or local emergency medical telephone number).* Early recognition of the emergency and activation of the EMS or local emergency response system.
Early CPR	Immediate bystander CPR can double or triple the victim's chance of survival from ventricular fibrillation.
Early defibrillation	CPR plus defibrillation within 3 to 5 min of collapse can produce survival rates as high as 49%–75%.
Early advanced care	Postresuscitation care delivered by healthcare providers.
Postarrest care	High-quality, integrated post–cardiac arrest clinical care.

*For a global list of emergency numbers and mobile phone use, see http://en.wikipedia.org/wiki/Emergency_telephone_number.

be expected with delays in initiating compressions. The techniques of closed chest compression are detailed in **Table 22-3**.

When the lack of a pulse is confirmed, begin serial rhythmic closed chest compressions. Place the victim supine on a firm surface, with the rescuer at the victim's side. Place the heel of one hand midline on the lower half of the sternum, 4 to 5 cm (~2 in.) cephalad of the xiphoid process (**Figure 22-1**). The heel of the hand should be parallel with the long axis of the patient's body. Then place the second hand on top of the first hand, so the hands are parallel with each other. The fingers of the two hands may be interlaced if desired, but they should not be touching the chest. Keep the arms straight and the elbows locked. The vector of the compression force should start from the rescuer's shoulders and be directed downward. Lateral compressive forces will decrease the efficiency of the compressions and increase the likelihood of

TABLE 22-2 Systematic Approach to CPR

CPR Steps	Comments
Step 1: Recognition	Assess for responsiveness, lack of breathing, or presence of abnormal breathing/gasping. Continue to step 2.
Step 2: Phone 911 and get an automatic external defibrillator	If possible, call for an assistant to do so. If no assistant is available and underlying etiology is asphyxia (e.g., drowning), call 911.* Automatic external defibrillator may be delayed to provide five cycles (or 2 min) of CPR.
Step 3: Assess circulation (*healthcare provider only*)	If no pulse after 10-second maximum check, go to step 4. (*Pulse checks are for healthcare providers only.*)
Step 4: Begin cycle of 30 closed chest compressions and two breaths	Compressions: "Push hard and fast." *At least* 100 compressions/min. Compress *at least* 5 cm (*at least* 2 in.). Allow for complete chest recoil, and minimize frequency and duration of interruptions. Ratio of 30 compressions to two breaths.
Step 5: Use the defibrillator when available and indicated	Healthcare provider to consider providing five cycles (or 2 min) of CPR before defibrillation for unwitnessed arrest. This recommendation is especially important when the interval from the call to scene response is >4 min. Provide five cycles (or 2 min) of CPR between rhythm checks during treatment of pulseless arrest.
Step 6: Rescue breathing	Rescue breaths can be initiated once chest compressions have been started. Deliver each breath over 1 second with sufficient tidal volume to see a visible chest rise. Continue 30 closed chest compressions and two breaths, minimizing interruptions.

*For a global list of emergency numbers and mobile phone use, see http://en.wikipedia.org/wiki/Emergency_telephone_number.

TABLE 22-3 Techniques of Closed Chest Compression

Closed chest compressions	Depth: *At least* 5 cm (*at least* 2 in.). Rate: *At least* 100/min. Allow complete recoil of the chest between compressions, with approximately equal compression and relaxation times. Minimize interruptions.
Ventilations	Single rescuer or two rescuers, nonintubated patient: give two breaths after every 30 compressions. Two rescuers, intubated patient: give breaths at a rate of 8–10 breaths/min. Do not pause chest compressions during ventilations.

complications. **Depress the sternum *at least* 5 cm (*at least* 2 in.) in an adult, at a rate of *at least* 100 compressions per minute.** Rates lower than this are inadequate. The compression-release phases should be roughly equal in length. **With a single rescuer or with two rescuers if the patient is not intubated, give two ventilations after every 30 compressions. With two rescuers assisting an intubated patient, ventilate at a rate of 8 to 10 per minute, without interrupting chest compressions.** Of note, although assisting ventilation is important, not everyone is willing to perform mouth-to-mouth breathing due to concerns over infectious disease transmission. **Chest compressions alone can be effective and should be provided even if rescue breathing is not being performed.**[8,9]

Open Chest Cardiac Compressions Open chest cardiac massage is an alternative to standard CPR and improves blood flow in animal models. Although there are no data showing improved clinical outcomes with the use of open chest cardiac massage versus closed chest cardiac massage, this technique may be considered in a number of situations, including (1) after penetrating chest trauma; (2) the perioperative period before or after cardiothoracic surgery; (3) cardiac arrest caused by hypothermia, pulmonary embolism, pericardial tamponade, or abdominal hemorrhage; (4) cases of chest deformity in which closed chest CPR is ineffective; (5) penetrating abdominal trauma with deterioration and cardiac arrest; and (6) blunt trauma with cardiac arrest.[10] However, the use of this technique requires a well-coordinated multidisciplinary team (see chapter 262, Cardiac Trauma).

STEP 5 IN BASIC CPR

Defibrillation is discussed in chapter 23, Defibrillation and Cardioversion.

COMPLICATIONS OF CPR

Ventilations can cause insufflation of the stomach, leading to regurgitation and aspiration and possibly to gastric rupture. Closed chest compressions can lead to fractures of the sternum or the ribs, separation of the ribs from the sternum, pulmonary contusion, pneumothorax, myocardial contusion, hemorrhagic pericardial effusions, splenic laceration, or liver laceration. Proper techniques can minimize these complications but cannot totally prevent them. Late complications include pulmonary edema, GI hemorrhage, pneumonia, and recurrent cardiopulmonary arrest. Anoxic brain injury can occur in a resuscitated individual subjected to prolonged hypoxia; it is the most common cause of death in resuscitated patients.

STEP 6 IN BASIC CPR

The sixth step is to **assess the upper airway of the victim**. This usually requires positioning the individual supine on a flat, firm surface with the arms along the sides of the body. Unless trauma can be definitely excluded, any movement of the victim should consider the possibility of a spine injury. As the patient is placed supine, stabilize the cervical spine by maintaining the head, neck, and trunk in a straight line. If the neck is not already straight, then it should be moved as little as possible

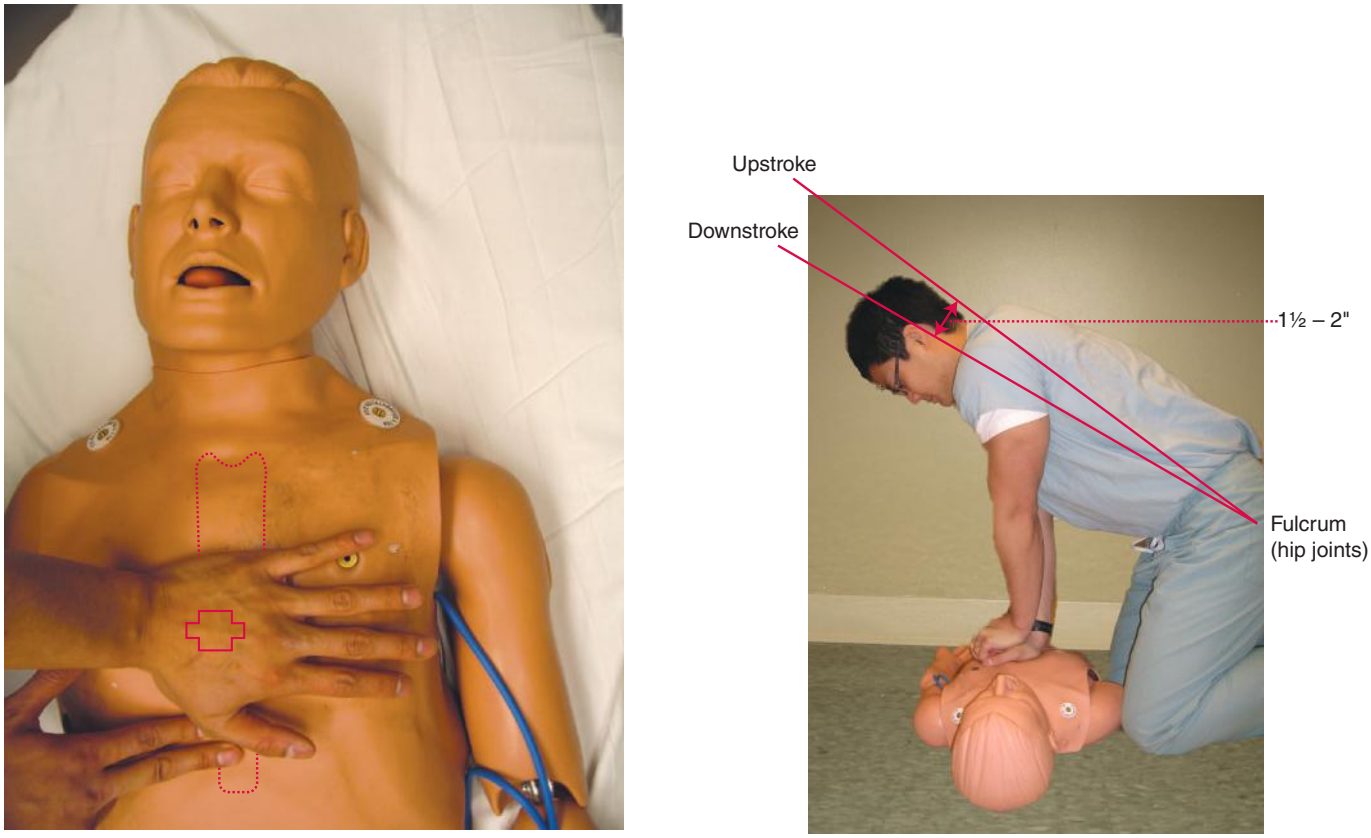

FIGURE 22-1. Proper hand (**A**) and rescuer (**B**) positioning for chest compression. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

to establish the airway. If the patient cannot be placed supine, the jaw thrust maneuver (see "Jaw Thrust Maneuver" section) can be applied with the rescuer at the victim's side. **Common causes of airway obstruction in an unconscious patient are occlusion of the oropharynx by the tongue and laxity of the epiglottis.** With loss of muscle tone, the tongue or the epiglottis can be forced back into the oropharynx upon inspiration. This can create the effect of a one-way valve at the entrance to the trachea, leading to airway obstruction. After positioning the patient, inspect the mouth and oropharynx for secretions, foreign objects, loose (floppy) dentures, partial dentures, or broken teeth. If dentures fit properly, keep them in place if possible, as they will allow for a better seal. If secretions are present, they can be removed with the use of oropharyngeal suction if available; a visualized foreign body may be dislodged by use of a finger sweep and then manually removed. **In contrast to earlier recommendations, a blind finger sweep should never be performed as there is a risk of worsening airway obstruction** (see "Finger Sweep" section).

Once the oropharynx has been cleared, two basic maneuvers for opening the airway may be tried. These are the head tilt–chin lift and the jaw thrust. These maneuvers help to open the airway by mechanically displacing the mandible and the attached tongue out of the oropharynx.

Head Tilt–Chin Lift Maneuver To perform the **head tilt–chin lift maneuver**, gently extend the patient's neck by placing one hand under the patient's neck and the other on the forehead and extending the head in relation to the neck. This maneuver should place the patient's head in the sniffing position, with the nose pointing up. In conjunction with the head tilt, perform the chin lift. The chin lift is done by carefully placing the hand that had been supporting the neck for the head tilt under the symphysis of the mandible, taking care not to compress the soft tissues of the submental triangle and the base of the tongue. Then lift the mandible forward and up, until the teeth barely touch. This supports the jaw and helps tilt the head back.

Jaw Thrust Maneuver The **jaw thrust** is the safest method for opening the airway if there is the possibility of cervical spine injury. This maneuver helps to maintain the cervical spine in a neutral position. The rescuer, who is positioned at the head of the patient, places the hands at the sides of the victim's face, grasps the mandible at its angle, and lifts the mandible forward (**Figure 22-2**). This lifts the jaw and opens the airway with minimal head movement.

After opening the airway, assess respiratory effort and air movement. Look for chest expansion, and listen and feel for airflow. The simple act of opening the airway may be adequate for the return of spontaneous respirations. However, if the victim remains without adequate respiratory effort, then further intervention is required. **If rescuers are reluctant to**

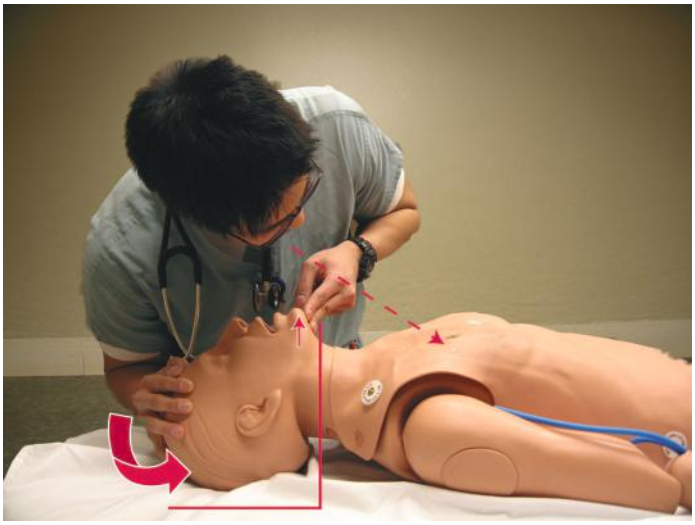

FIGURE 22-3. Determine breathlessness. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

FIGURE 22-4. Mouth-to-mouth rescue breathing. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

perform mouth-to-mouth ventilation and the patient is in cardiac arrest, chest compressions alone can be effective (**Table 22-3**).

Two breaths over 1 second each should be given with sufficient volume to cause visible chest rise. At this point, if a foreign body obstruction is noted, as indicated by a lack of chest rise or airflow on ventilation, the obstruction requires removal (**Figure 22-3**). Agonal respirations in an individual who has just suffered a cardiac arrest are not considered adequate for ventilation. Intermittent positive-pressure ventilation, with oxygen-enriched air if possible, should be initiated.

Ventilation Techniques **Table 22-4** outlines the recommendations for delivery of rescue breaths during cardiac arrest.[3] When an advanced airway (e.g., endotracheal tube, Combitube, or laryngeal mask airway) is in place during two-person CPR, ventilate at a rate of 8 to 10 breaths per minute without attempting to synchronize breaths between compressions. There should be no pause in chest compressions for delivery of ventilations.[2]

In an adult with normal perfusion, 8 to 10 mL/kg tidal volume is required for adequate oxygenation and ventilation. However, in the setting of CPR, where cardiac output is only 25% to 33% of normal, a lower minute ventilation, and thus tidal volume, can be satisfactory. **Approximately 6 to 7 mL/kg will suffice.** Use an appropriately sized bag for bag-valve mask ventilation. A pediatric bag will provide inadequate tidal volumes for an adult.

There are a number of techniques for ventilating an individual, including mouth to mouth, mouth to nose, mouth to stoma, and mouth to mask. **Rescue breaths with an inspiratory time of 1 second each should be given at a rate of 8 to 10 per minute, with a volume adequate to make the chest rise visibly (approximately 6 to 7 mL/kg; 500 to 600 mL in adults). Supplemental oxygen should be delivered as soon as possible.** Expired air has a fraction of expired oxygen of 16% to 17%. Too large a volume or too rapid an inspiratory flow rate can cause gastric distention, which can lead to regurgitation and aspiration.

Mouth-to-Mouth Ventilation With the airway open, gently pinch the patient's nose shut with the thumb and index finger (**Figure 22-4**). This prevents air escape. After taking a deep breath, place the lips around the patient's mouth, forming an airtight seal. Slowly exhale. Release the seal and allow adequate time for passive exhalation by the victim, and then repeat the procedure. Protective devices such as face shields decrease the risks to the provider of contracting an infectious disease and can be purchased from most medical equipment stores.

Mouth-to-Nose Ventilation In some cases, as with severe maxillofacial trauma, mouth-to-nose ventilation may be effective. With the airway open, lift the patient's jaw, closing the patient's mouth. After a deep breath, place the lips around the patient's nose, forming an airtight seal. Slowly exhale.

Mouth-to-Stoma or Tracheostomy Ventilation After laryngectomy or tracheotomy, the stoma or tracheostomy becomes the patient's airway. As with the other techniques, a seal is made around the stoma or tracheostomy tube, and the rescuer slowly exhales.

Mouth-to-Mask Ventilation Proper and secure placement of the mask on a victim's face is important when using a mask for ventilation, either with a bag or via mouth to mask. Place the mask over the bridge of the patient's nose and around the mouth. Place the thumb on the part of the mask that is sitting on the patient's nose and place the index finger of the same hand on the part of the mask sitting on the patient's chin (**Figure 22-5**). The

TABLE 22-4 Delivery of Rescue Breaths During CPR

Deliver each rescue breath over 1 s (Class IIA recommendation).
Give a sufficient tidal volume (by mouth-to-mouth/mask or bag-mask with or without supplementary oxygen) to produce visible chest rise (Class IIA recommendation).
Avoid rapid or forceful breaths.
Avoid hyperventilation.

FIGURE 22-5. Mouth-to-mask rescue breathing with proper mask placement. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

three other fingers of the same hand are then placed along the bony margin of the jaw. The mask can then be firmly sealed to the patient's face. Two hands may be used for this technique if a second rescuer is available. Ventilations are then performed through the mask. Some masks also allow for supplemental oxygenation.

Foreign Body Obstruction It is important to recognize and be able to assist someone with an airway obstruction due to a foreign body.[11] An individual in distress from a compromised airway is likely to use the **universal sign for an airway obstruction**, which is for the individual to grab his or her neck with both hands. Foreign bodies can cause partial or complete obstruction. With a partial airway obstruction, air exchange may be adequate or inadequate. If the victim is able to speak, cough, and exchange air, then he or she should be encouraged to continue spontaneous efforts. Obtain assistance, such as activation of the local EMS system. Do not interfere with the patient's attempts to cough or expel the foreign body **and do not perform a blind finger sweep**. If air exchange becomes inadequate, as indicated by an inability to speak, increased difficulty breathing, weak and ineffective cough, worsening stridor, or cyanosis, immediate medical intervention is needed (see next section, "Obstruction-Relieving Maneuvers"). Inadequate air exchange from a severe partial or a complete airway obstruction should be managed the same way. In an unconscious person, the presence of airway obstruction may be ascertained by noting inadequate airflow and poor chest rise with efforts to ventilate.

Obstruction-Relieving Maneuvers Maneuvers used to relieve foreign body obstructions include the **Heimlich maneuver** (subdiaphragmatic abdominal thrusts), **chest thrusts**, and the finger sweep. In a conscious individual, the obstructed airway (Heimlich) maneuver is the recommended maneuver in most adults for relieving airway obstruction due to a solid object. It is not useful for liquids. In an unconscious individual suspected of having an aspirated foreign body and in whom the foreign body is visualized, the recommended first step is the finger sweep. **A blind finger sweep is no longer recommended** as it may worsen airway obstruction by pushing an unseen object into an even less favorable position. Otherwise, in an unconscious patient, the recommended sequence is to perform the obstructed airway maneuver up to five times, open the mouth and perform a finger sweep if a foreign body has become visible, and then attempt to ventilate. This sequence may be repeated as often as needed until the patient recovers or additional assistance arrives.

Obstructed Airway (Heimlich) Maneuver The **Heimlich maneuver** creates an artificial cough by forcefully elevating the diaphragm and forcing air from the lungs.[12] It may be repeated multiple times. Each individual thrust should be performed aggressively, with the intention of removing the obstruction. The maneuver can be performed with the victim standing, sitting, or lying down, or it can be self-administered (**Figure 22-6**). To perform the maneuver with the patient standing or sitting, stand behind the patient and place the thumb side of a fist against the victim's abdomen midline just above the umbilicus and well below the xiphoid process (**Figure 22-6**). Grasp the fist with the other hand, and forcefully push the fist into the victim's abdomen with a quick upward thrust. Repeat until the item is dislodged or the patient becomes unconscious. For an unconscious patient, place the victim supine on a firm surface and sit astride the victim's thighs (**Figure 22-7**). Place the heel of the dominant hand midline just above the patient's umbilicus, and the other hand directly on top of the first. Then deliver quick upward thrusts. To self-administer thrusts, the individual can either use his or her own fist to deliver the thrusts or lean forcibly against a firm object, such as a porch rail or the back of a chair. Potential complications of the Heimlich maneuver include injury or rupture of abdominal or thoracic viscera and regurgitation of stomach contents.

Chest Thrusts The **chest thrust** maneuver is used primarily if someone is morbidly obese or in the late stages of pregnancy, and the rescuer cannot reach around the patient's abdomen to perform abdominal thrusts (**Figure 22-8**). To perform chest thrusts with the patient standing or sitting, stand behind the patient and place the thumb side of a fist against the victim's sternum, avoiding the costal margins and the xiphoid process. Grasp the fist with the other hand, and press the fist into the victim's chest with a quick backward thrust. Repeat until the item is dislodged or the patient becomes unconscious. For an unconscious patient, place the victim supine on a firm surface and kneel close to the victim's side. Place the hands in the same position as for chest compression (i.e., the lower sternum), and deliver quick thrusts.

FIGURE 22-6. Standing Heimlich maneuver administered to conscious victim of foreign body airway obstruction. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

FIGURE 22-7. Prone Heimlich maneuver administered to unconscious victim of foreign body airway obstruction. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

FIGURE 22-8. Standing chest thrust maneuver administered to conscious victim of foreign body airway obstruction.

Finger Sweep The **finger sweep** maneuver is used only in unconscious patients (**Figure 22-9**). Using the thumb and fingers of one hand, grasp both the tongue and the mandible and lift them. This may partially relieve the obstruction by lifting the tongue away from the back of the throat. With the other hand, insert the index finger into the back of the throat, and use a hooking action in an attempt to dislodge the foreign body to move it into the mouth for manual removal. Use care so the foreign object is not pushed deeper into the throat.

EXPERIMENTAL TECHNIQUES AND NEW DIRECTIONS

There are currently several experimental techniques and devices for improving the effectiveness of closed chest cardiac massage. To date, none have consistently proven to be superior to the use of manual CPR and a defibrillator.[2,3,13] Devices that deliver real-time audiovisual feedback to rescuers may improve CPR performance.[14] Studies evaluating adjuncts, such as hypothermia during resuscitation and extracorporeal circulation plus CPR, are also ongoing (see chapter 21, Hyperbaric Oxygen Therapy).[15-17]

One observational study reported that the addition of extracorporeal life support to CPR in patients requiring CPR for >10 minutes was associated with an increased short-term and 1-year survival in patients who experienced in-hospital cardiac arrest.[16] The success of this method is best explained by the presumption that coronary blood flow and thus myocardial viability are enhanced by extracorporeal circulation. Another advantage of this technique is that hypothermia can be easily induced in situations in which doing so may be beneficial, such as hypoxic brain injury[17] (see chapter 21, Hyperbaric Oxygen Therapy).

A final new direction is cardiocerebral resuscitation, which emphasizes current American Heart Association guidelines of high-quality chest compression, but further delays airway intervention. Data indicate that patients receiving hands-only CPR have similar 30-day and 1-year neurologic outcomes as those receiving conventional CPR. These outcomes, combined with the reluctance of bystanders to perform the mouth-to-mouth component of CPR at all, resulted in a 2008 "call to action" (distinct from a recommendation) by the American Heart Association calling for "hands-only" CPR in certain scenarios and is now a formal component of the 2010 guidelines.[3] Animal studies and extrapolation from clinical evidence suggest that rescue breathing during the first 5 minutes of CPR for ventricular fibrillation or sudden cardiac death may not be necessary. The suggestion is that occasional gasps and chest recoil between compressions likely provide sufficient ventilation in a setting where a normal ventilation–perfusion ratio requires a lower than normal minute ventilation.[2] Further studies suggest that withholding airway intervention for 5 to 10 minutes, in favor of continuous, high-quality check compressions, improves both resuscitation rates and neurologic survival.[18-20] Expert opinion has strongly suggested the incorporation of cardiocerebral resuscitation into current guidelines.[21]

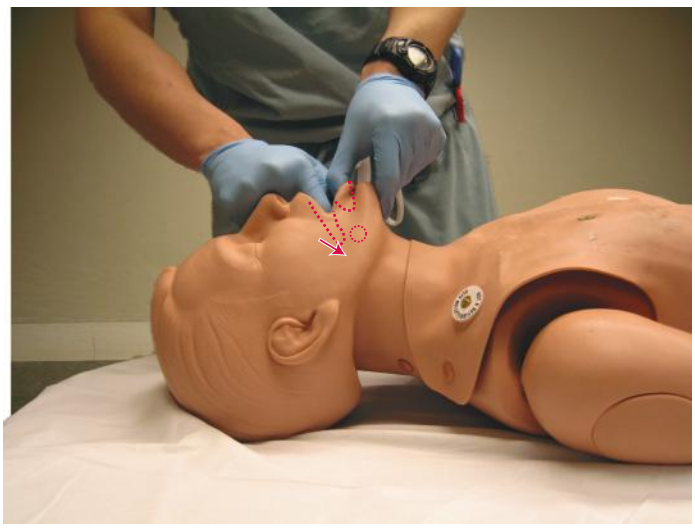

FIGURE 22-9. Finger sweep maneuver administered to unconscious victim of foreign body airway obstruction. [Image used with permission of Rita K. Cydulka, MD, MS, MetroHealth Medical Center.]

TERMINATING RESUSCITATION

Efforts at resuscitation should be continued until the patient recovers spontaneous respirations and cardiac output, the rescuer becomes exhausted, or the patient is pronounced dead. An atraumatic individual who recovers spontaneous respirations and circulation should be placed on his or her side—the ***recovery position***. Recovery from cardiac arrest depends on time to CPR and rhythm-specific intervention. Resuscitation and long-term outcome in normothermic patients with arrest times of 20 minutes or more are very poor.

ETHICAL CONSIDERATIONS IN RESUSCITATION

During the initiation of resuscitation attempts, try to discover whether or not the victim has advance directives that prohibit CPR.[22] Family members may wish to be present during resuscitation attempts,[22] and support from social services and clergy should be sought early (see chapter 27, Ethical Issues of Resuscitation).

CHAPTER 23

Defibrillation and Cardioversion

Marcus E. H. Ong
Swee Han Lim
Anantharaman Venkataraman

PURPOSE OF PROCEDURE

Defibrillation is the therapeutic use of electricity to depolarize the myocardium so coordinated contractions can occur. The term *defibrillation* is usually applied to an attempt to terminate a nonperfusing rhythm (e.g., ventricular fibrillation or pulseless ventricular tachycardia).

Cardioversion is the application of electricity to terminate a still perfusing rhythm (e.g., ventricular tachycardia with a pulse, supraventricular tachycardias including atrial arrhythmias) to allow a normal sinus rhythm to restart. By this definition, cardioversion is a less urgent procedure compared to defibrillation, although the patient requiring cardioversion may be hypotensive or hemodynamically unstable, rather than in cardiac arrest.

PATIENT SELECTION

Indications for defibrillation include ventricular fibrillation (VF) (**Figure 23-1**) and pulseless ventricular tachycardia (VT) (**Figure 23-2**). Defibrillation is not indicated for asystole and pulseless electrical activity and is contraindicated for sinus rhythm, a conscious patient with a pulse, or when there is danger to the operator or others (e.g., from a wet patient or wet surroundings).

Cardioversion is indicated for a hemodynamically unstable patient with VT, supraventricular tachycardia, atrial flutter, or atrial fibrillation. It is also possibly indicated after failed pharmacologic therapy for the previously mentioned arrhythmias, especially if the patient becomes hemodynamically unstable. **Cardioversion should be synchronized, which means the electric current will be timed with the patient's intrinsic QRS complexes**, to minimize the risk of inducing VF.

RISKS AND PRECAUTIONS

Electrical energy can terminate an abnormal rhythm, but if inappropriately delivered, it can also induce VF. This can happen if the electric shock is delivered during the relative refractory portion of the cardiac electrical activity.[1]

FIGURE 23-1. Ventricular fibrillation.

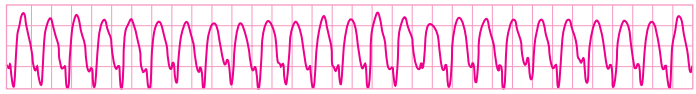

FIGURE 23-2. Ventricular tachycardia.

When preparing for defibrillation, check the patient and rhythm to ensure that a shock is truly indicated. Movement artifacts or loose leads may look like VF. New defibrillator technology is available that can filter compression or movement artifacts to "see through" the underlying rhythm. **However, when using automated external defibrillators (AEDs), all manufacturers currently still recommend stopping all compressions and patient movement (e.g., during transport) before initiating analysis mode.**

Make sure that no rescuer is inadvertently in contact with the patient when a shock is delivered. Neither single nor double gloves provide the rescuer with complete safety from current,[2] so we still recommend "stand clear" drills during defibrillator training, "stand clear" practice during actual defibrillation, and minimizing rather than eliminating the pause in compressions for defibrillation. **If the patient is on a wet or conducting surface, move the patient to a safe area and dry the body before delivering the shock.** When using manual defibrillation paddles, make sure that the paddles are either on the defibrillator cradle or on the patient's chest, with minimal time in transit from one position to the other. To prevent inadvertent discharges, always point the paddles downward and never wave the paddles around or face them toward each other, especially when charged. This is to prevent inadvertent discharges or "sparking."

To avoid skin burns, remove all metallic objects and nitroglycerin patches from the patient. Ensure correct placement of defibrillation paddles/pads and **remove all direct sources of oxygen to avoid fire.**[3,4] If paddles are used, do not allow the conducting gel to spread to within 5 cm of the other paddle. In patients with an internal pacemaker requiring defibrillation, ensure that the paddles/pads are placed well away (12.5 cm or 5 inches) from the pacemaker before discharging.

Avoid prolonged pauses (>10 seconds) to CPR when performing defibrillation.[5,6] Thus, the emphasis is on minimal interruptions to CPR for analysis, a single shock instead of three "stacked" shocks, and immediate resumption of CPR without a pulse or rhythm check immediately after defibrillation. In addition, if a mechanical CPR device is being used, defibrillation can be safely performed without stopping ongoing mechanical compressions to reduce unnecessary pauses.

EQUIPMENT

1. Defibrillator: This can be a manual, semi-automated, or fully automated external defibrillator.
2. Paddles or self-adhesive defibrillation pads.
3. Conductive gel or gel pads for defibrillation paddles.
4. Related resuscitation equipment (e.g., bag-valve mask device, airway devices, suction, IV cannulation, drugs).

Defibrillators should be properly maintained and in a constant state of readiness. We recommend the use of checklists[7] to identify defibrillator malfunction and ensure proper maintenance of batteries. Users should be trained in the proper use of checklists, and checks should be performed frequently (as often as every shift). Perform cardioversion in a resuscitation area with appropriate monitoring and standby resuscitation equipment, in case the patient deteriorates or develops cardiac arrest.

PATIENT POSITIONING

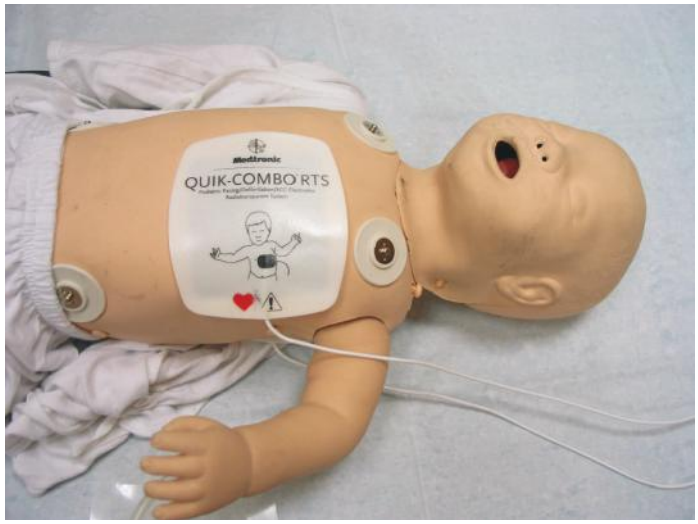
Place the patient in the supine position. Expose the chest, and remove jewelry and medication patches. If the chest is very hairy in the areas where electrodes are to be placed, quickly shave the hair to ensure the electrodes stick onto the chest. If the chest is wet (because of sweat or because the patient has been in water), wipe dry immediately. Sweat or moisture on the chest will reduce adhesion of the electrodes.

ANESTHESIA AND PROCEDURAL MONITORING

For a patient in cardiac arrest, defibrillation is part of the immediate resuscitation process. However, for an elective or semi-elective cardioversion, procedural sedation and monitoring—before, during, and after the procedure—are essential. Provide cardiac, blood pressure, and pulse oximetry monitoring; place an IV line; and make sure airway equipment, suction, and oxygen are immediately available. Obtain informed consent when possible. Sedation is typically provided with an IV agent such as etomidate, propofol, or midazolam.

STEP-BY-STEP TECHNIQUE

PLACEMENT OF PADDLES/PADS



Regarding placement of defibrillation paddles or pads, there are several alternative positions:

1. **Antero-apical position:** Place one paddle/pad to the right of the upper half of the sternum (breastbone), just below the patient's right clavicle (collarbone), and place the other pad just below and to the left of the left nipple (in the axilla). With a female patient, place the paddle/pad just below and to the left side of the breast. Do not place it over the breast (**Figure 23-3**).

   This is the preferred position for a supine patient and when using defibrillation paddles. The idea is to maximize current flow through the cardiac chambers rather than along the chest wall.

FIGURE 23-3. Antero-apical positioning of defibrillation pads. [Image used with permission of Institute for Medical Simulation & Education.]

A

B

FIGURE 23-4. Anteroposterior positioning of defibrillation pads in an infant. [Reproduced, with permission, from Children's Emergency, KK Women's and Children's Hospital, Singapore.]

2. **Anteroposterior position:** Place one pad/paddle at the left lower sternal border and the posterior pad/paddle below the left scapula (**Figure 23-4, A and B**).
3. **Apex-posterior position:** Place one pad/paddle at the apex, just below and to the left of the left nipple, and the posterior pad/paddle below the left scapula.

When using paddles (**Figure 23-5**), apply conducting gel or a gel pad and firmly place the paddles onto the chest wall (25 lb/square inch or 2 cm^2 of pressure). When using defibrillation pads, ensure the electrodes are firmly attached and there is good contact by pressing gently with fingers over the center and around the edges to check for good adhesion. Good contact increases shock efficiency. In the AED mode, if contact is insufficient for the defibrillator to operate, the "Check Electrodes" message will also be heard. Outcomes are better with larger electrodes (12 cm) than with smaller electrodes (≤8 cm).

MANUAL DEFIBRILLATION

1. Prepare the patient and equipment as described earlier. CPR should be ongoing.
2. Check that the rhythm is VF or pulseless VT.
3. Check that the defibrillator is in *unsynchronized* mode.

FIGURE 23-5. Antero-apical positioning of defibrillation paddles in an adult.

FIGURE 23-6. Internal defibrillation paddles.

4. Select the appropriate energy level. For biphasic machines, select according to the manufacturer's recommendation (150 to 200 J with biphasic truncated exponential waveforms and 120 J for rectilinear biphasic waveforms). For monophasic defibrillators, it is reasonable to begin with an initial 360-J shock.[6]
5. Apply the paddles or pads (may be applied beforehand) and charge.
6. Check that no one is in contact with the patient or trolley and call out, "Stand clear."
7. Discharge the shock.
8. Continue CPR and manage according to the local resuscitation protocol. The advanced cardiac life support universal cardiac arrest algorithm is shown in Figure 23-2.

AUTOMATED EXTERNAL DEFIBRILLATION

1. Prepare the patient and equipment as described earlier. **CPR should be ongoing.**
2. Open the package containing the defibrillation pads with attached cable and connector. With the chest prepared, carefully pull off the protective backing from the pads. Attach the pads.
3. Turn on the device (follow the voice prompts according to your device).
4. Initiate analysis of the rhythm, and ensure there is no movement during analysis. If a shock is indicated, the device will automatically charge up to a preset level.
5. Check that no one is in contact with the patient or trolley and call out, "Stand clear."
6. Discharge the shock (note that fully automated defibrillators do not require the operator's input to discharge a shock).
7. Continue CPR and manage according to the local resuscitation protocol. The advanced cardiac life support universal cardiac arrest algorithm is shown in Figure 23-2.

CARDIOVERSION

1. Prepare the patient and equipment as described earlier. Ensure the patient has adequate monitoring and that there is resuscitation equipment on standby.
2. Check the patient and the rhythm.
3. Check that the defibrillator is in *synchronized* mode.
4. Select the appropriate energy level. For monophasic defibrillators, start at 50 J for paroxysmal supraventricular tachycardia and atrial flutter and at 100 J for VT and atrial fibrillation. For biphasic defibrillators, follow the manufacturer's recommendations.
5. Provide sedation with an appropriate agent when ready.
6. Apply the paddles or pads (may be applied beforehand) and charge.
7. Check that no one is in contact with the patient or trolley and call out, "Stand clear."
8. Discharge the shock.
9. Continue to monitor and manage according to local protocols.

INTERNAL DEFIBRILLATION

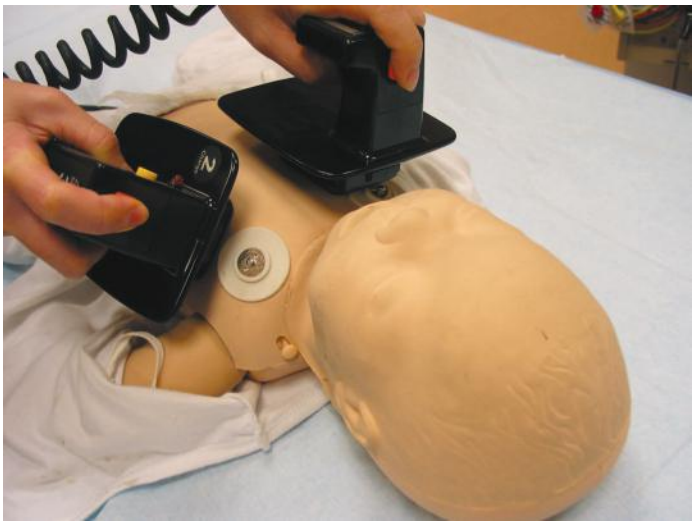
Internal defibrillation is indicated in a patient with VF or pulseless VT with an open thoracotomy. This could be in a patient with traumatic cardiac arrest, for example, or during open heart surgery. The procedure requires a special set of internal defibrillator paddles (**Figure 23-6**), which should be connected to the defibrillator.

Moisten the internal defibrillator paddles with saline, and then place one paddle posteriorly over the left ventricle and the other anteriorly over the right ventricle. Hold the paddles firmly against the myocardium to ensure good contact. Begin with 10 J for defibrillation and increase as needed.

PEDIATRIC DEFIBRILLATION

VF in children is relatively uncommon, and the most frequent cause of cardiac arrest is usually respiratory. Thus, treatment should be directed toward preventing cardiac arrest by supporting ventilation and respiration. In the event of VF, use a weight-related dose of 4 J/kg body weight for the first and any subsequent shocks. For VT with a pulse, cardiovert with 1 J/kg synchronized. This can be increased to 4 J/kg subsequently if needed. Special pediatric paddles (**Figure 23-7, A and B**) or pads are available. Some AEDs also come with pediatric attenuator pads. In an infant, it is possible to defibrillate with the patient propped on the side using anteroposterior paddle placement.

OUTCOMES ASSESSMENT



The aim of defibrillation or cardioversion is termination of the abnormal rhythm and restoration of a normal perfusing rhythm.

COMPLICATIONS

Possible complications include skin burns, inadvertent electric shock to others, and defibrillation-induced myocardial damage. However, these complications are minimal compared to the ultimate complication of patient death if defibrillation is unsuccessful or not attempted.

B

FIGURE 23-7. (**A**) Pediatric defibrillation paddles. (**B**) Antero-apical positioning of defibrillation paddles in an infant. [Reproduced, with permission, from Children's Emergency, KK Women's and Children's Hospital, Singapore.]

FOLLOW-UP

Patients requiring defibrillation or cardioversion will require intensive monitoring and close postresuscitation care.

CHAPTER 24

Advanced Cardiac Life Support

Anantharaman Venkataraman
Swee Han Lim
Marcus E. H. Ong
Kenneth B. K. Tan

INTRODUCTION AND EPIDEMIOLOGY

Every year, approximately 6.8 to 8.5 million persons throughout the world[1] sustain cardiac arrest. About 70% of cardiac arrests occur out of hospital. The proportion of cardiac arrest patients who are treated varies from about 54.6% (United States) to about 28.3% (Asia). The proportions with ventricular fibrillation (VF) and survival vary from 11% and 2%, respectively, in Asia, to 28% and 6% in North America, 35% and 9% in Europe, and 40% and 11% in Australia.[2] About half of cardiac arrest victims are <65 years old.

Ventricular tachyarrhythmias are the initiating event in about 80% of patients with out-of-hospital primary cardiac arrest. During ambulatory electrocardiogram (ECG) monitoring of 157 witnessed cardiac arrests, Bayés de Luna et al[3] documented 70% with ventricular tachycardia (VT) and VF, 13% with torsades de pointes, and 17% with bradyarrhythmias. Untreated VF deteriorates to asystole in about 15 minutes.[4] For patients with sudden cardiac arrest, the rate of survival declines rapidly by about 7% to 10% for each minute without defibrillation.[5] If delay to defibrillation exceeds 12 minutes,[6] survival is of the order of 0% to 5%.

THE CHAIN OF SURVIVAL

The structured emergency care system concept for treatment of cardiac arrest is called the **Chain of Survival and includes four components: Early Access, Early CPR, Early Defibrillation, and Early Advanced Care**. If a community's prehospital EMS can be activated promptly, reach the patient within 5 minutes of collapse, and deliver the first shock shortly thereafter, survival in excess of 15% to 20% can be expected, with recent reports of >30% survival.[7,8] With delayed initiation of CPR, defibrillation, and access to the patient by the emergency services, the impact of advanced life support measures is small (**Figure 24-1**). Improved survival can only occur if structured emergency care systems allow trained providers to access the patient rapidly and deliver the appropriate treatment in a timely fashion. Delays in initiating the various links weaken the chain and adversely affect the next link, resulting in a decreased chance of a good outcome for the patient.

ADVANCED CARDIAC LIFE SUPPORT (ACLS)

The basic life support assessments and interventions are often called the **Primary ABCD Survey**, and the advanced life support assessments and interventions are often called the **Secondary ABCD Survey**.

An organized approach to resuscitation begins with the Primary ABCD and blends smoothly with the Secondary ABCD. These are summarized in the **Universal ACLS Algorithm** (**Figure 24-2**). This method helps any ACLS provider remember the sequence of resuscitation actions and, therefore, be less likely to miss any of the vital steps in the care of the patient.

PRIMARY ABCD SURVEY

The **Primary ABCD Survey** addresses the identification of cardiac arrest and performance of good-quality CPR (including ventilation) and defibrillation. The procedures for the ABCs of the primary ABCD are described in chapters 22 and 23.

For ventilation, bag-valve masks deliver 21% oxygen if using room air, 60% oxygen when connected to an oxygen source with flow at 12 L/min,

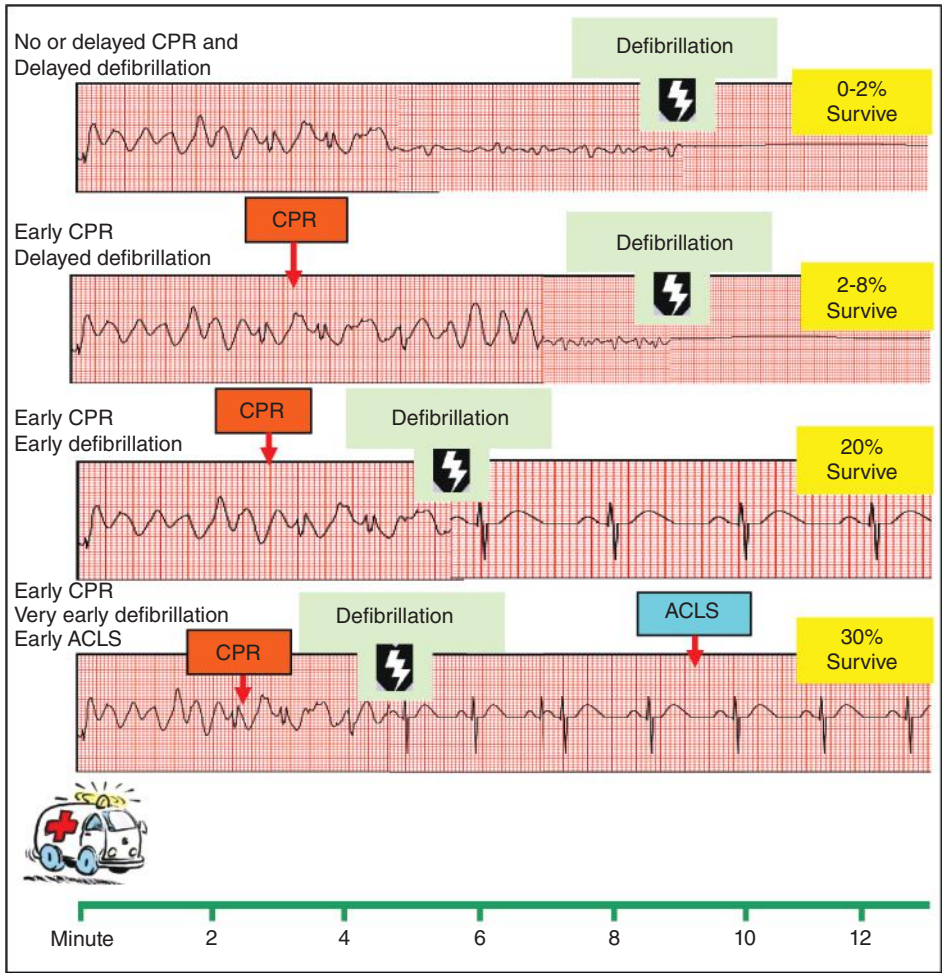

FIGURE 24-1. Incremental survival benefits by the links in the Chain of Survival. ACLS, advanced cardiac life support. [Reproduced, with permission, from the National Resuscitation Council, Singapore.]

and 90% to 95% with a reservoir bag. Chest compressions need not be stopped to initiate or continue ventilation.

The rescuer also needs to focus on providing good chest compressions (30 compressions for every 2 ventilations [30:2] with compression rate of ≥100/min, compression depth of at least 5 cm or 2 inches, and relaxation of pressure on the chest wall to allow unrestricted chest recoil). Feedback devices are available for the rescuer to provide improved standards of chest compressions.

Mechanical CPR devices may also be used. The two most common types of mechanical CPR devices employed in clinical practice are the LUCAS-2 with a piston attached to an active compression-decompression cup (**Figure 24-3**) and the load-distributing band Autopulse (**Figure 24-4**). Defibrillator pads must be applied to the bare chest before application of the mechanical CPR devices. These devices allow provision of either 30:2 CPR or continuous chest compressions with interposed manual ventilations.

The critical rhythms associated with cardiac arrest are **VF** (**Figure 24-5**), pulseless **VT** (**Figure 24-6**), asystole (**Figure 24-7**), and pulseless electrical activity (**PEA**) (**Figure 24-8**).

Defibrillation may be done with either an automated external defibrillator (**AED**) or a manual defibrillator (see chapter 23). **Deliver shocks for VF or pulseless VT with minimal interruption of chest compressions only during actual shock delivery.** Make sure that the position of the defibrillator pads (**Figure 24-9**) does not interfere with monitoring leads.

After delivery of the first shock, resume CPR (**Figure 24-10**) immediately for up to about 2 minutes before reviewing the ECG monitor for a rhythm diagnosis. If a viable rhythm has returned, check for pulse and breathing. If breathing and pulse have returned, begin care for post–return of spontaneous circulation (**ROSC**) management. If breathing is absent, continue rescue breathing with a bag-valve mask at the rate of about 6 to 10 breaths per minute; if pulse is not present, continue CPR and move to the **Secondary ABCD Survey**.

SECONDARY ABCD SURVEY

Components of the Secondary ABCD Survey are listed in **Table 24-1**.

The Secondary ABCD Survey includes endotracheal intubation or the placement of another airway adjunct, assessment of ventilatory status, gaining intravenous access, identifying ECG rhythms, delivering drugs to enhance circulation, and addressing the reasons for the occurrence or persistence of cardiac arrest. While the secondary ABCDs are in progress, continue the basic resuscitative actions of the primary ABCDs. Usually, defibrillation pads placed carefully left of the apex and to the right of the sternum just below the right clavicle (Figure 24-9) can also act as monitoring leads. Otherwise, true monitoring leads may be placed at the front of the right and left shoulders and over the left iliac crest. Such placement does not interfere with defibrillation or cardiac pacing procedures. Further management is based on the cardiac rhythm.

VASCULAR ACCESS

Vascular access techniques are discussed in Chapter 31, "Vascular Access." A large peripheral vein allows a rapid rate of fluid administration, if needed. If unable to cannulate a peripheral vein, establish intraosseous access. Central venous lines take time to establish and, because of the length of the cannula, cannot deliver fluids as rapidly as a

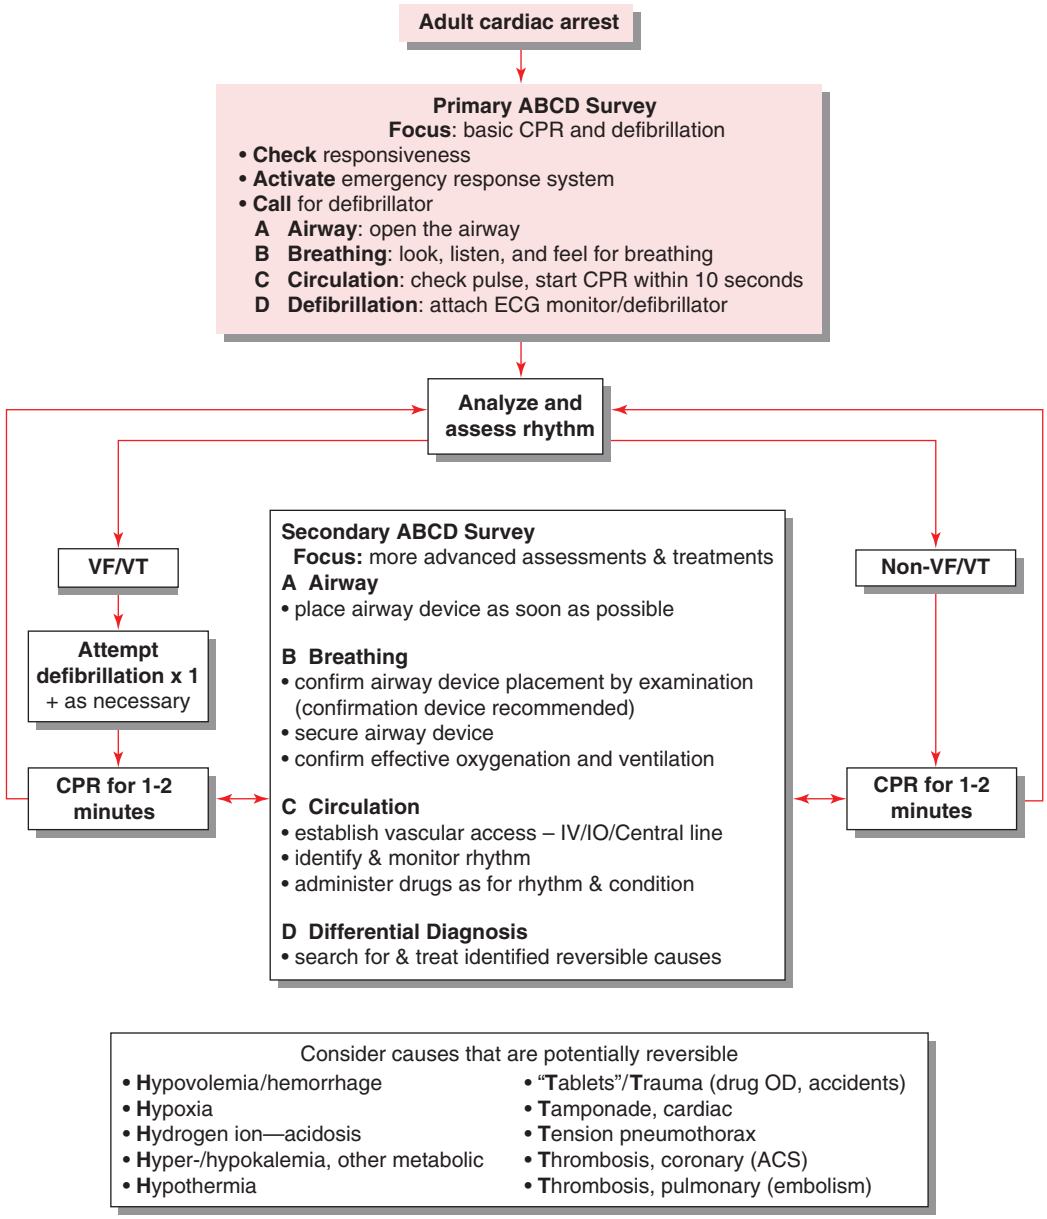

FIGURE 24-2. Universal ACLS Algorithm. ACS, acute coronary syndrome; OD, overdose. [Reproduced, with permission, from National Resuscitation Council, Singapore.]

peripheral line, and every bolus dose of drugs requires flushing with at least 20 mL of normal saline. Central lines are useful for central venous pressure monitoring to guide fluid resuscitation and circulatory management.

In cardiac arrest, circulation of blood grinds to a halt. With good-quality CPR, one can expect to generate up to about 30% of normal cardiac output, which is just about what is required to supply vital organs such as the heart, brain, and kidneys. The reduced circulation is associated with a slower circulation time. Therefore, drugs given during cardiac resuscitation are best administered via a proximal peripheral vein. Once drugs are given, flush the line with normal saline, and continue CPR for at least 30 to 60 seconds before repeat external defibrillation, so that the heart is optimally primed to respond.

The optimal infusion fluid is normal saline and not dextrose, Ringer's lactate, or sodium bicarbonate. However, unless hypovolemia is a contributing factor to cardiac arrest, fluid infusion should be slow, if at all necessary. Drug dosages are the same whether given by the intraosseous, IV, or central line routes. The endotracheal tube route is no longer recommended for drug administration because drug absorption is limited if the airway is filled with pulmonary edema fluid.

DRUGS USED IN RESUSCITATION TO ROSC FROM CARDIAC ARREST

Drugs available for cardiac resuscitation and cardiac dysrhythmia management are also described in chapters 19 and 20. This section will cover those drugs specifically used for resuscitation from cardiac arrest to ROSC. Drugs are an adjunct in the management of cardiac arrest patients. Good CPR, ventilation, and early defibrillation are the cornerstones of management of cardiac arrest. The effectiveness of standard resuscitative drugs on ROSC and survival to hospital discharge has not been well demonstrated.[9-11] However, consensus documents recommend the standard resuscitative drugs described below with the presumptive rationale that drugs help "restart" the heart and preserve coronary and cerebral circulation.

EPINEPHRINE

Epinephrine (adrenaline) is an endogenous catecholamine. It has an important role in cardiac arrest, although the evidence base for improved outcomes in humans is weak.[12] Epinephrine seems to improve short-term

TABLE 24-1 Components of the Secondary ABCD Survey

Component and Function	Detailed Components
A: Securing the Airway	Endotracheal intubation or other supraglottic airway, eg, Laryngeal Mask Airway
B: Breathing (Ventilation)	1. Ventilation with Bag-Valve Mask 2. Oxygen 3. Mechanical ventilation
C: Maintaining the Circulation	1. Continue CPR 2. Provide defibrillation and cardioversion to correct life threatening 'shockable' rhythms 3. Continuous ECG monitoring to monitor the circulation's rhythm and identify arrhythmias that need to be corrected 4. Gain vascular access through IV/IO line 5. Provide drugs to help maintain circulation 6. Consider use of ECMO
D: Differential diagnosis	1. Determine why the patient is not responding to the resuscitative efforts 2. Look for correctible causes of collapse and provide necessary interventions
Specialized Care after ROSC*	Therapeutic hypothermia, glycemic control, early goal directed therapy, percutaneous coronary interventions

* ROSC, return of spontaneous circulation

survival.[13] The primary beneficial effect appears to be peripheral vasoconstriction, which improves cerebral and coronary blood flow. Potential adverse effects include an increase in myocardial oxygen consumption and an increase in pulmonary shunting. The most common adverse reaction is tachycardia. Epinephrine may worsen myocardial ischemia and induce ventricular ectopy and VT. **Epinephrine is used mainly to treat cardiac arrest from VF or pulseless VT unresponsive to the initial shock, asystole, PEA, and profoundly symptomatic bradycardia.** The standard dose in cardiac arrest is 1.0 milligram diluted to 10 mL (10 mL of 1:10,000) given IV. Repeat if needed at 3- to 5-minute intervals. There is no maximum dose. Escalating doses at 2 to 5 milligrams IV every 3 to 5 minutes (high-dose epinephrine) have not resulted in increased long-term survival.[12] For IV infusion in patients with cardiogenic shock or symptomatic bradycardia, the dose is 1 milligram in 500 mL normal saline beginning at 2 to 10 micrograms/min, escalating as needed at 3- to 5-minute intervals. Do not add epinephrine to infusions that contain alkaline solutions because epinephrine has ineffective clinical activity in alkaline solutions.

AMIODARONE

Amiodarone is generally considered a Class III antiarrhythmic drug, but it possesses electrophysiologic characteristics of all four Vaughn-Williams classes. It causes coronary and peripheral artery vasodilation. It is more effective than lidocaine for improving short-term survival.[14] **Its main use in cardiac arrest is for persistent VT or VF after defibrillation and epinephrine.** It can also be used for hemodynamically stable VT, hemodynamically stable polymorphic VT, and hemodynamically stable wide-complex tachycardia of uncertain origin. Amiodarone is also used for the pharmacologic conversion of atrial fibrillation, control of rapid ventricular rate in preexcitation supraventricular dysrhythmias, and as an adjunct to electrical cardioversion of refractory paroxysmal supraventricular tachycardia/atrial tachycardia. For pulseless VT or VF, the dose is a bolus of 300 milligrams IV followed by a 20-mL flush with 5% dextrose in water or saline. Give another 150-milligram bolus if there is no response to the first dose. For stable ventricular and supraventricular dysrhythmias, administer amiodarone IV 150 milligrams over 10 to 15 minutes (not to exceed 30 milligrams/min), followed by a maintenance infusion of 1 milligram/min for 6 hours and then 0.5 milligrams/min for the next 18 hours. Infusions exceeding 2 hours should be administered in glass or polyolefin bottles because the drug precipitates in plastic tubing. Hypotension and bradycardia are the most common unwanted effects. These may be addressed by slowing the infusion rate, giving an IV fluid challenge, or using pressors or positive chronotropic agents. Occasionally, temporary pacing for refractory bradycardia from amiodarone may be required, especially if other measures are ineffective.

LIDOCAINE (LIGNOCAINE)

Lidocaine (lignocaine) (see also chapter 12, Approach to Shock) is a Class I antiarrhythmic drug. It reduces automaticity, suppresses ventricular ectopy, and is used for hemodynamically stable VT and refractory VF/pulseless VT. **Lidocaine is a second-choice drug after amiodarone or is used if amiodarone is not available.** In cardiac arrest, the dose is an IV bolus of 1 to 1.5 milligrams/kg body weight. Give a second bolus of 0.5 to 0.75 milligrams/kg if the rhythm persists. Upon restoration of spontaneous circulation, give lidocaine as an infusion at a rate of 1 to 4 milligrams/min. If dysrhythmia reappears during the infusion of lidocaine, give a bolus of 0.5 milligrams/kg and increase the infusion rate to 4 milligrams/min. Toxicity may occur with doses exceeding 3 milligrams/kg body weight bolus or in patients with liver disease, since the drug is hepatically metabolized. Symptoms include neurologic changes such as drowsiness, disorientation, reduced hearing ability, perioral paresthesia, muscle tremors, and seizures. Myocardial depression and circulatory depression are also features of toxicity, and these may be illustrated by widening QRS complexes and falling blood pressures. In patients with known impaired liver function or patients >70 years old, give the same recommended bolus doses, but decrease the normal infusion rate by 50%.

MAGNESIUM

Magnesium is a cofactor in numerous enzymatic reactions. It is essential for the function of the Na-K-ATPase pump. Magnesium deficiency may be associated with cardiac arrhythmias, sudden death, and precipitation of VF. Magnesium is used to treat hypomagnesemia, with or without dysrhythmias.

Magnesium is initial treatment for torsades de pointes and dysrhythmias secondary to hypomagnesemia, cardiac arrest from QT_c prolongation, or cardiac glycoside toxicity.[9,15] For patients in VF or pulseless VT due to the above conditions, give 1 to 2 grams in 10mL 5% dextrose in water IV over 1 minute. Magnesium provides no benefit for routine use in cardiac arrest. For patients with a pulse, the dose is 1 to 4 grams in 50 mL 5% dextrose in water over 60 minutes. Adverse reactions include flushing, sweating, mild bradycardia, hypotension, asystole with circulatory collapse (with too rapid administration), and respiratory depression. Hypermagnesemia may produce depressed reflexes, flaccid paralysis, diarrhea, respiratory depression, and circulatory collapse.

OTHER DRUGS IN CARDIAC ARREST

Atropine **Atropine** is a parasympatholytic agent that enhances sinus node automaticity and atrioventricular conduction by direct vagolytic action. **It is not recommended for PEA or for treatment of cardiac arrest.** It is indicated for symptomatic bradycardia. The dose is 0.5 or 0.6 milligrams IV (dose depends on formulation in country of use) and may be repeated at 5- to 10-minute intervals up to a maximum of 0.04 milligrams/kg body weight. Atropine may induce tachycardia or premature ventricular contractions and cause worsening of myocardial ischemia. Symptoms of overdosage include tachycardia, delirium, coma, flushed and hot skin, ataxia, and blurred vision. Administration of low doses less than 0.5 milligrams IV may produce paradoxical bradycardia and precipitate VF.

Calcium **Calcium is given during resuscitation only for cardiac arrest from hyperkalemia, hypocalcemia, or calcium channel blocker overdose.** Calcium is not recommended for routine administration for VF/pulseless VT or PEA.[9,16] The dose of calcium chloride is 0.2 mL/kg of 10% calcium chloride, given as a slow IV bolus.

Sodium Bicarbonate The use of sodium bicarbonate during cardiac arrest was advocated in the past to treat presumptive acidosis, because severe acidosis decreases myocardial contractility.[17] However, **routine use during cardiac arrest is no longer recommended** due to a number

of potential adverse effects. Sodium bicarbonate causes hypernatremia, hyperosmolality, and alkalosis (which in turn induces a left shift of the oxyhemoglobin dissociation curve), and IV sodium bicarbonate produces carbon dioxide, resulting in hypercarbia unless ventilation is increased. It does not appear to improve defibrillation success. **It may be given in cardiac arrest from hyperkalemia or cyclic antidepressant overdose.** It is also acceptable and possibly helpful for intubated patients with a long arrest interval until ROSC and with persistent severe metabolic acidosis. The dose is 1 to 1.5 mEq/kg IV bolus, followed by 0.75 mEq/kg every 10 to 15 minutes as needed. If continuous infusion of sodium bicarbonate is used, check pH to guide therapy.

VASOPRESSIN

Vasopressin, also called antidiuretic hormone, is a naturally occurring neurohypophysial peptide hormone synthesized in the hypothalamus and stored in the pituitary gland. It increases water absorption in the nephron and increases peripheral vascular resistance. Vasopressin levels elevate during cardiac arrest, and this observation led to investigation of its role in resuscitation. Vasopressin has a longer duration of action and, in laboratory studies, maintains coronary perfusion pressure, myocardial blood flow, and cerebral blood flow better than epinephrine. However, most studies do not show superiority of vasopressin over epinephrine.[12,16] Vasopressin as a first-line agent in cardiac arrest (40-milligram dose) does not improve long-term survival when compared to epinephrine,[18] although vasopressin might improve short-term survival in patients with prolonged cardiac arrest.[18] Combining vasopressin (40 milligrams) with epinephrine does not appear to improve outcomes.[12]

COMMON CARDIAC ARREST ALGORITHMS

The algorithmic approach to cardiac arrest management allows a structured decision-making process when managing cardiac arrest victims. The cardiac arrest rhythms discussed here are pulseless VT/VF, asystole, and PEA.

VENTRICULAR FIBRILLATION (VF)/PULSELESS VENTRICULAR TACHYCARDIA (VT)

Once VF or pulseless VT is diagnosed, prepare for electrical conversion while CPR is in progress. If ROSC does not occur after the first shock, move to the mega-VF approach (**Figure 24-11**). Continue CPR for 1 to 2 minutes followed by rhythm analysis, and if VF persists or recurs, deliver electrical shocks, usually biphasic, beginning usually at 150 J and escalating, if needed, to 360 J. For monophasic defibrillators, begin at 360 J. After delivery of shock, follow with CPR again for 1 to 2 minutes before rhythm analysis. Maintain good-quality CPR for optimal coronary and vital organ perfusion. Parallel to the CPR-analysis-shock-CPR-analysis-shock-CPR cycle, begin secondary ABCDs and give drugs that may help to lower defibrillation thresholds, such as epinephrine (adrenaline), amiodarone, and/or lidocaine (lignocaine). Any or all of these drugs may be administered in any combination and repeated at roughly 3- to 5-minute intervals. After administration of any of these drugs, provide at least 30 to 60 seconds of effective CPR to allow the injected drug to reach the central circulation before the next shock. Continue the resuscitation cycle for as long as the rhythm remains as VF or pulseless VT.

ASYSTOLE/PULSELESS ELECTRICAL ACTIVITY (PEA)

For asystole or PEA, (a condition in which cardiac contractions are absent in the presence of coordinated electrical activity), continue CPR and institute the secondary ABCDs. Give drugs to enhance the chances of ROSC (**Figure 24-12**). Epinephrine (adrenaline) 1.0 milligram as a bolus dose in 10 mL is the drug of choice. Vasopressin alone or in combination with epinephrine is no more effective than epinephrine alone. Repeat epinephrine as needed in 3- to 5-minute intervals. Consider other possible causes of asystole or PEA, and identify and correct them. It is currently assumed that narrow-complex PEA[19]

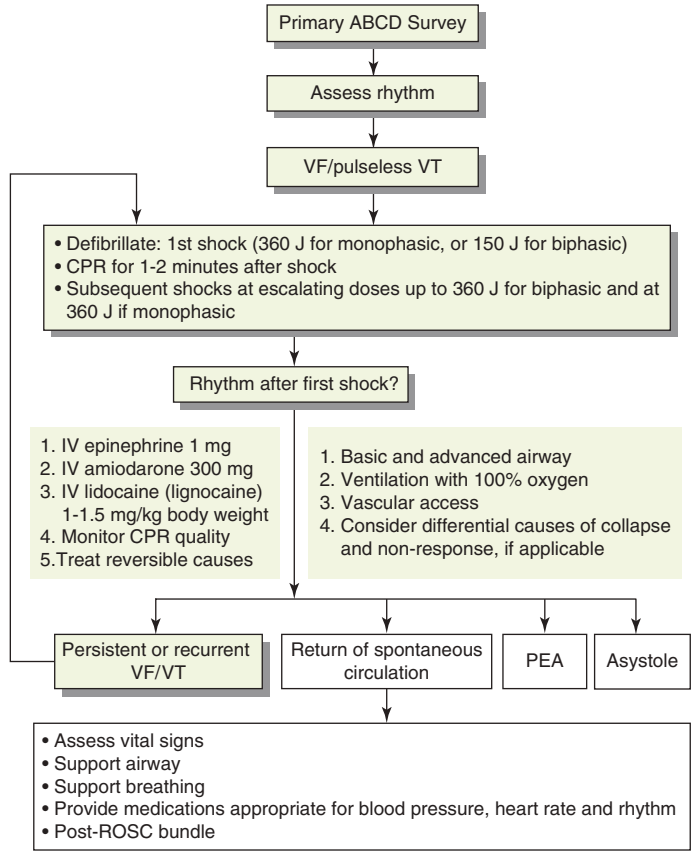

FIGURE 24-11. Management of VF/pulseless VT. [Reproduced, with permission, from National Resuscitation Council, Singapore.]

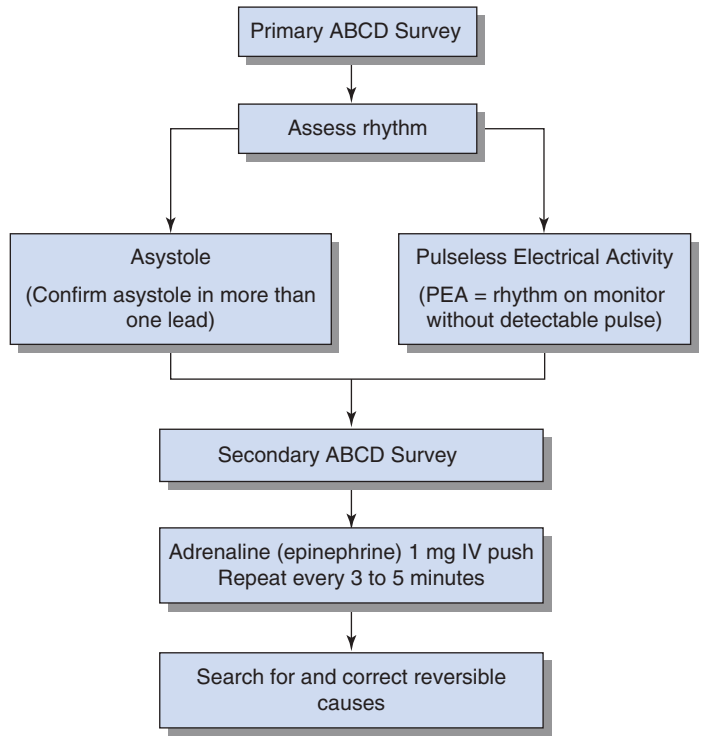

FIGURE 24-12. Asystole/PEA management algorithm. [Reproduced, with permission, from National Resuscitation Council, Singapore.]

could be the result of mechanical problems such as cardiac tamponade, pneumothorax, mechanical hyperinflation, pulmonary embolism, or myocardial rupture. Point-of-care US and assessment of the clinical scenario can direct specific treatment. Wide-complex PEA,[19] on the other hand, can result from a metabolic problem (ie, hyperkalemia), drug toxicity (ie, sodium channel blocker toxicity), or cardiac ischemia, and left ventricular failure and should be treated as appropriate. Survival is low if patients in asystole do not achieve ROSC in the field or convert to a shockable rhythm.[20-22]

DIFFERENTIAL DIAGNOSES OF CARDIAC ARREST

In every resuscitation, it is useful to identify important causes of cardiac arrest and reasons for lack of response to standard resuscitation algorithms. Causes can be grouped as the **5 H's—hypovolemia or hemorrhage, hypoxia, hydrogen ion (acidosis), hypo- or hyperkalemia, and hypothermia**—and the **5 T's—trauma + tablets (overdose), cardiac tamponade, coronary thrombosis, tension pneumothorax, and thrombosis (pulmonary embolism)**.

H: HYPOVOLEMIA OR HEMORRHAGE

History of fluid or blood loss may be available. Rectal examination can identify massive lower GI bleeding; nasogastric intubation can identify massive upper GI bleeding; and bedside FAST can diagnose massive intraperitoneal bleeding. Treat with fluids and blood products.

H: HYPOXIA

Hypoxia occurs with lack of oxygen and alveolar ventilation. Make sure that the airway adjunct is placed correctly. Check breath sounds at intervals to ensure that the endotracheal tube has not slipped out of the trachea or to identify pneumothorax. Verify the source of oxygen—an oxygen cylinder or the piped oxygen supply.

H: HYDROGEN ION (ACIDOSIS)

The acidosis of cardiac arrest is a combination of respiratory and metabolic acidosis. Respiratory acidosis is addressed by early endotracheal intubation and alveolar ventilation. Metabolic acidosis can be somewhat addressed by good-quality CPR. Sodium bicarbonate is administered for severe metabolic acidosis from prolonged or poor initial resuscitation, at a dose of 1 to 1.5 mEq/kg. Half the initial dose can be readministered after 10 to 15 minutes, depending on pH.

H: HYPER- OR HYPOKALEMIA, OTHER METABOLIC DISORDERS

Suspect hyperkalemia in patients on hemodialysis or peritoneal dialysis (look for presence of arteriovenous fistula or dialysis catheter). Other metabolic disorders are extremely difficult to confidently identify in cardiac arrest. If hyperkalemia is suspected, administer calcium chloride, sodium bicarbonate, insulin, and glucose. Treat hyperkalemia from suspected digitalis toxicity with IV magnesium sulfate or digoxin-specific Fab fragments (Digibind®).

H: HYPOTHERMIA

Treat hypothermia with gradual rewarming with blankets and warm IV fluids. If there is no recovery of consciousness in the hypothermic patient following ROSC, maintain a body core temperature of 33°C until further assessment and decisions can be made.

T: "TABLETS" (DRUG OVERDOSE)

Drug overdose is rarely identified as a cause of cardiac arrest during the resuscitation process. In the event of antidepressant overdose, administer IV sodium bicarbonate. Lipid emulsion infusion may be useful in cardiac arrest associated with cyclic antidepressants or local anesthetics.[24-28]

T: CARDIAC TAMPONADE

Cardiac tamponade is best identified during resuscitation by bedside transthoracic US. This requires brief interruption of chest compressions. Treatment of tamponade causing cardiac arrest is bedside pericardiocentesis.

T: TENSION PNEUMOTHORAX

Suspect tension pneumothorax during cardiac resuscitation if breath sounds are unequal on chest auscultation after verifying correct endotracheal tube placement. Treatment is immediate needle decompression.

T: CORONARY THROMBOSIS

Acute coronary thrombosis or acute myocardial infarction is one of the most common causes of cardiac arrest. Risk factors are a history of coronary artery disease and initial rhythm of VF/VT.[24-28] Cardiac catheterization after resuscitation is an underused procedure.[29] A 12-lead ECG in the immediate post–cardiac arrest state can identify an ST-elevation acute myocardial infarction and allow arrangements for immediate coronary angiography. Myocardial and neurologic function can improve after percutaneous coronary intervention following cardiac arrest.[30] Thus, after ROSC, especially in the face of post-ROSC ECG evidence of acute myocardial infarction, advocate for cardiac catheterization and percutaneous coronary revascularization if available and appropriate. A few case reports describe fibrinolysis during CPR with resultant ROSC and good neurologic outcome.[31] Reports are too few to determine whether thrombolysis together with CPR results in more severe bleeding than thrombolysis without CPR.[31]

T: THROMBOSIS (PULMONARY EMBOLISM)

Pulmonary embolism causing cardiac arrest requires fibrinolysis or embolectomy. However, the diagnosis is rarely made at time of collapse, and even then, most systems are not geared to make such prompt diagnosis and initiate the necessary procedures for embolectomy. Fibrinolytic agents could be considered during cardiac arrest from suspected pulmonary embolism on a case-by-case basis.[32] Factors suggestive of pulmonary embolism causing cardiac arrest include two of three signs/symptoms (prearrest respiratory distress, altered mental status, or shock); arrest witnessed by a physician or emergency medical technician; and PEA as the first or primary arrest rhythm.[33]

POST-ROSC COMPLICATIONS

After ROSC, many factors affect survival: anoxic brain injury, post–cardiac arrest myocardial dysfunction, the systemic reperfusion response, and the cause of cardiac arrest. Ischemic-reperfusion injury is discussed in chapter 26, Post-Cardiac Arrest Syndrome. Anoxic brain injury results in disturbance of cerebral microvascular hemostasis and manifests as coma, seizures, myoclonus, and varying degrees of neurocognitive dysfunction, including brain death. Post–cardiac arrest myocardial dysfunction results from myocardial stunning with cardiac hypokinesis and a low left ventricular ejection fraction. Clinical manifestations include tachycardia and elevated left ventricular end-diastolic pressures progressing to hypotension and reduced cardiac output. The systemic ischemia-reperfusion response consists of inflammation, endothelial activation, and disturbed vasoregulation with generalized activation of immunologic and coagulation pathways, causing increased risk of multiple organ failure and infection. Clinical manifestations of the systemic ischemia-reperfusion response include impaired oxygen delivery and utilization and increased susceptibility to infection.

OXYGENATION AND VENTILATION

Hyperoxia during the early phase of reperfusion after ROSC harms postischemic neurons and increases brain lipid peroxidation.[34,35] After ROSC, adjust the rate of ventilation and tidal volume to maintain arterial oxyhemoglobin saturation at 94% to 98%.[36] Hyperventilation is not recommended because it can increase intrathoracic pressures and

decrease venous return and cardiac output. In addition, hypocarbia resulting from hyperventilation decreases cerebral blood flow and aggravates anoxic brain damage. The suggested ventilator parameters during the post-ROSC phase[34-36] are as follows: Pa_{CO2} between 35 and 45 mm Hg (5 to 6 kPa); Sa_{O2} between 94% and 98%; tidal volume between 6 and 8 mL/kg ideal body weight; P_{ETCO2} between 35 and 40 mm Hg; and 10 to 12 ventilations per minute.

HEMODYNAMIC MANAGEMENT

Obtain 12-lead ECG after ROSC and repeat at 8 hours or as needed. Administer IV fluids and drugs to optimize blood pressure, cardiac output, and urine output. The target for blood pressure is a mean arterial pressure of 65 to 100 mm Hg, and the target for blood oxygenation is an S_{CVO2} of ≥70%.[37,38] Pharmaceutical agents to support the circulation include epinephrine, norepinephrine, dopamine, dobutamine, nitroglycerine, and esmolol. Obtain an echocardiogram at 24 hours after ROSC to detect regional wall motion abnormalities and determine ejection fractions.

TARGETED TEMPERATURE MANAGEMENT (THERAPEUTIC HYPOTHERMIA)

Brain cooling decreases cerebral oxygen demand, reduces cellular effects of reperfusion, and decreases the production of reactive oxide radicals. Targeted temperature management (cooling to 32 to 36°C; temperature goal is controversial) during the first 24 hours after ROSC improves survival and neurologic recovery[39-42] in patients who remain comatose soon after ROSC. Hyperpyrexia during the first 48 hours is usually associated with a lowered chance of optimal neurologic recovery.[43] See chapter 26, Post-Cardiac Arrest Syndrome, for detailed discussion.

GLYCEMIC CONTROL

Post-ROSC hyperglycemia is associated with increased mortality and worse neurologic outcomes.[44] Hypoglycemia, similarly, is also associated with poor outcomes in critically ill patients.[45] Maintain blood sugar levels between 100 and 180 milligrams/dL (6 and 10 mmol/L).

NEUROLOGIC ASSESSMENT

Features of brain injury after ROSC include coma, seizures, myoclonus, and various degrees of neurocognitive dysfunction ranging from memory deficits to a persistent vegetative state and finally brain death. Treat seizures promptly. The neurologic prognosis in the majority of comatose cardiac arrest survivors undergoing therapeutic hypothermia cannot be reliably predicted in the ED.

ECPR (ECMO) in Cardiac Arrest

Extracorporeal Membrane Oxygenation (ECMO), also known as Extracorporeal Life Support (ECLS) is a recent introduction in the management of cardiac arrest. Its use is well-documented in the neonatal and paediatric population,[1] and in adults, for refractory respiratory failure, and cardiogenic shock. Use in refractory cardiac arrest is also known as ECPR. ECPR is a bridging therapy to definitive treatments, such as percutaneous coronary interventions, cardiac bypass surgery, or heart transplant.

The ECMO equipment consists of a blood pump, a venous reservoir, an oxygenator for exchanging both oxygen and carbon dioxide, and a heat exchanger to warm the blood used. The whole system is monitored through pressure, oxygen saturation, and temperature monitors. Three types of ECMO circuits are available:

1. A veno-arterial ECMO (VA-ECMO) pumps blood from the venous side to the arterial side to facilitate gas exchange and provide hemodynamic support. The blood is pumped from the venous circulation through a cannula inserted in either the inferior vena cava or right atrium, through the oxygenator where gas exchange occurs, then warmed and returned to the patient through a cannula placed in either the aortic arch or femoral artery into the arterial circulation. This is the modality that is used to support cardiac arrest patients.
2. A veno-venous (VV) ECMO removes blood from the right atrium, passes it through the gas exchanger, and returns it across the tricuspid valve into the right ventricle. It does not provide hemodynamic support. This modality is used mainly for refractory respiratory failure.
3. An arterio-venous ECMO (AV-ECMO) makes use of the patient's own arterial pressure to pump the blood from the arterial to the venous side and facilitates gas exchange in the process. This does not require the use of a separate blood pump.

The ECMO circuit is initially primed with fresh blood, which is then pumped through the circuit. During maintenance of ECMO, haemodynamic parameters, urinary output, hematological indices, fluids, and electrolytes are monitored.

ECPR complications can be mechanical or medical, or both. Mechanical complications consist of clots in the circuit, mediastinal bleeding from tears to the great vessels, oxygenator failure and malfunction of the blood pump, oxygenator, heat exchanger and sensors. Medical complications include intracranial and systemic hemorrhage, initial cardiac stunning that may occur soon after initiation of ECMO, pneumothorax, acute kidney injury, gastrointestinal bleeding, sepsis, and metabolic derangement.

ECPR must also be accompanied by good post-cardiac arrest management, to include targeted temperature and hemodynamic management, and early coronary angiography for definitive treatment.[3] At the present time, survival rates are low, but can be improved with EMS and ED training, appropriate patient selection, and more widespread application of the technique.[2,3]

TABLE 1 General Indications and Contraindications for ECPR (ECMO in Cardiac Arrest)

Indications	Contraindications
Good pre-morbid status before cardiac arrest	Advanced age; advanced malignancy; poor baseline neurologic function; baseline inability to perform activities of daily living; pre-exisitng 'do not resuscitate' order
Intervention to be curative, not palliative	Suspect aortic dissection or severe aortic regurgitation; traumatic cardiac arrest
Reversible trigger event for cardiac arrest (dysrhythmia, STEMI, etc.)	Unwitnessed cardiac arrest and no bystander CPR Long prehospital transport time Prolonged cardiac arrest unless good perfusion and metabolic support is documented[2]

FIGURE 1. ECPR in the emergency department, Singapore General Hospital.

CHAPTER 25

Resuscitation in Pregnancy

Boyd Burns

INTRODUCTION AND EPIDEMIOLOGY

Cardiac arrest in pregnancy is rare, and resuscitation of a pregnant woman is typically an unexpected and chaotic event, which ideally involves multiple consultants from different specialties with different levels and types of skills. Emergency care and lifesaving procedures for resuscitation and cardiac arrest should not be delayed if specialists are not available. Contact the closest center providing neonatal and maternal services as soon as possible to facilitate rapid transport and continued care of the newly delivered infant and the mother.

The World Health Organization defines maternal deaths as deaths while pregnant or within 42 days of the end of pregnancy, related to or aggravated by pregnancy or pregnancy management, regardless of the duration or site of the pregnancy and irrespective of the cause of death.[1] Factors associated with pregnancy-related deaths in the United States include advanced maternal age, African American race, increasing live birth order, and lack of prenatal care.[2]

Management of emergencies during labor and delivery and diagnosis and management of pulmonary embolism and eclampsia are discussed in the chapters 101, "Emergency Delivery" and 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period."

PHYSIOLOGY OF PREGNANCY

Beginning early in pregnancy, virtually all major organ systems undergo changes (**Table 25-1**) that affect patient management.

CARDIOVASCULAR CHANGES

Uterine blood flow is not autoregulated but is directly proportional to the maternal mean arterial pressure and inversely proportional to the resistance of the uterine vasculature. Conditions that decrease uterine blood flow during pregnancy include maternal hypovolemia, hypotension, uterine vasoconstriction, tetanic uterine contractions and aortocaval compression.

As the uterus enlarges throughout pregnancy, compression of the pelvic and abdominal vasculature can occur, especially when the patient is supine. Compression of the inferior vena cava can decrease maternal venous return and reduce cardiac output from 10% to 30% (**Figure 25-1**).[4] This can contribute to supine hypotension syndrome, which is a constellation of findings including hypotension, tachycardia, dizziness, pallor, and nausea. It is reported to occur after 30 minutes in the supine position.[4] Therefore, place any patient in the third trimester of pregnancy in the full left lateral tilt position when in hemodynamic distress or exhibiting hypotension.[5] Left lateral tilt can be achieved by placing a roll under the patient's right hip, insertion of a Cardiff wedge, or full left lateral tilt of the patient while on a backboard (**Figure 25-2**).

TABLE 25-1 Physiologic Changes in Pregnancy Affecting Resuscitation

System	Parameters	Comment
Cardiovascular	Cardiac output	Increases 30%–50%
	Peripheral resistance	Decreases 20%
	Blood pressure	Decreases 10–15 mm Hg systolic in first half of pregnancy; then back to baseline
	Blood volume	100 cc/kg or 6–7 L
	Central venous pressure	May be increased up to 10 mm Hg
	Central venous oxygen saturation	Increases as high as 80%[3]
	Plasma volume	Increases 30%–50%
Hematologic	Fibrinogen, factors V, VII, VIII, X, von Willebrand factor	Increase, with heightened risk for venous thromboembolism in second half of pregnancy
Respiratory and pulmonary	Upper airway edema, hyperemia, and friability	Estrogen and volume effects; can result in difficult airway
	Diaphragm elevation	Higher thoracostomy tube insertion site during pregnancy
	Hemoglobin F has greater affinity for oxygen than maternal hemoglobin	Fetal oxygen maintained at expense of maternal oxygenation; maintain maternal oxygen saturation >95%
	Respiratory rate	No change
	Tidal volume, minute ventilation	Increase
Renal and urinary	Progesterone dilates renal collecting system; ureteral peristalsis decreases	Renal US may show mild hydronephrosis; increased risk for ascending infection
GI	Alkaline phosphatase rises from placental production; bile is more lithogenic	Increased risk of cholecystitis/cholelithiasis
	Decreased lower esophageal tone; decreased gastric emptying	Increased likelihood of aspiration of gastric contents
Uteroplacental unit	25% of blood flow directed to uteroplacental unit; no autoregulation of blood flow; enlarging uterus can compress vena cava and vessels below the diaphragm; supine hypotension syndrome can occur after 30 min of supine position	Place patient in left lateral tilt position during third trimester; replace volume adequately to account for increased blood and plasma volume in pregnancy; avoid femoral and lower extremity site for blood and volume delivery in second half of pregnancy

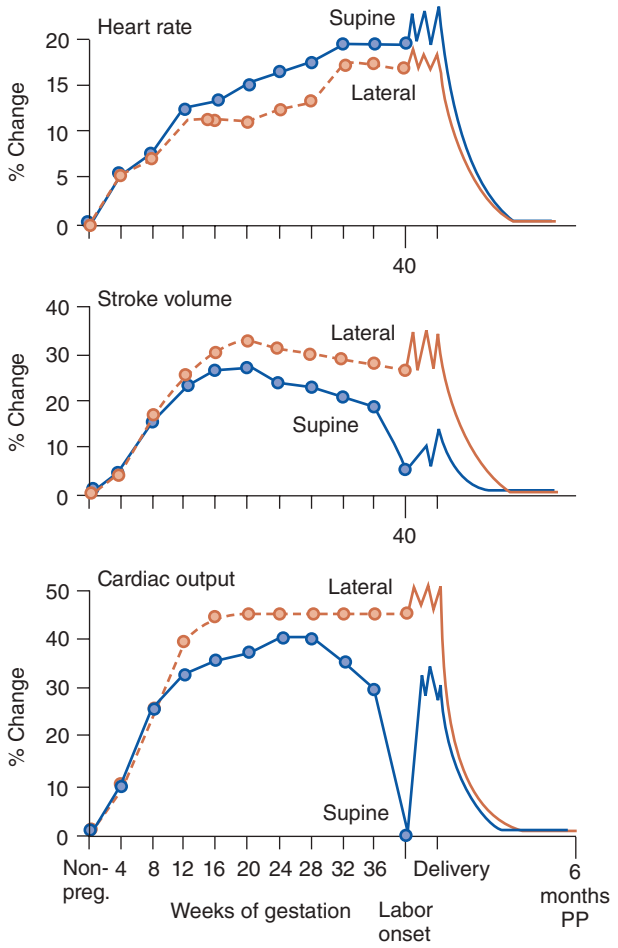

FIGURE 25-1. Changes in maternal heart rate, stroke volume, and cardiac output during pregnancy (preg.), with the gravida in the supine and lateral positions. PP = postpartum. [Reproduced with permission from Barclay ML: Critical physiologic alterations in pregnancy, in Pearlman MD, Tintinalli JE (eds): *Emergency Care of the Woman.* New York, The McGraw-Hill Companies, Inc., 1998, Chapter 2, Figure 2-3, p. 14. Copyright © 1998 by The McGraw-Hill Companies, Inc. All rights reserved.]

The Cardiff wedge provides a tilt of 27 degrees from the horizontal. Foam or hard wedges are better for maintaining the left lateral tilt position than are pillows or manual tilting.[6] Because compression of the abdominal vasculature can compromise intravascular delivery of medications through sites below the diaphragm, avoid femoral or saphenous venous sites for IV access during the resuscitation of a pregnant woman at >20 weeks of gestation. The negative effects of great vessel compression on uteroplacental blood flow increase in the presence of maternal hypotension and uterine contractions.

RESPIRATORY AND PULMONARY CHANGES

Respiratory changes occur early to help optimize fetal oxygenation. Progesterone drives an increase in resting minute ventilation and tidal volume. The respiratory rate, however, remains relatively unchanged, so **do not dismiss tachypnea as a normal part of pregnancy**. As pregnancy progresses, the diaphragm elevates approximately 4 cm with an increase of the transverse diameter of the thoracic cage by 2 cm.[7] Changes in pulmonary physiology and increased metabolic oxygen consumption can result in the rapid development of hypoxia during respiratory illnesses or as a result of respiratory arrest.

Because the fetal oxyhemoglobin dissociation curve is shifted to the left relative to the maternal oxyhemoglobin dissociation curve, the bond of fetal hemoglobin to oxygen is stronger than maternal hemoglobin, which results in preservation and optimization of fetal oxygen delivery at any given Po_2. Strive to maintain maternal pulse oximetry readings

FIGURE 25-2. Left lateral tilt position.

>95% to maintain a Pao_2 of >70 mm Hg to optimize maternal oxygenation and oxygen delivery to the placenta.[7]

The fetus exists in a physiologically acidemic state relative to the mother, which allows preferential oxygen transfer at the fetal tissue level.[8] Acidemia favors a rightward shift of the oxyhemoglobin dissociation curve, resulting in a greater amount of oxygen supplied to fetal tissues. Fetal cardiac output protects against brief periods of hypoxia, with increases in umbilical blood flow, placental gas exchange, and preferential redistribution to vital tissues.

RESUSCITATION IN PREGNANCY

The most common causes of pregnancy-related deaths in the United States are cardiovascular disease, cardiomyopathy, hemorrhage, infection/sepsis, hypertensive disorders of pregnancy, and thrombotic pulmonary embolism.[2,9,10] Major trauma is the greatest risk for nonobstetric cause of death. Motor vehicle collisions account for almost half of trauma, followed by falls and assaults.[11]

The best maternal care will provide the best fetal care, so follow general principles of resuscitation when treating pregnant women. **To accommodate the increase in blood and plasma volume that develops during pregnancy, make sure that the volume of resuscitative fluids increases by 50% above that required by the nonpregnant patient.** Place two large-bore IVs, and provide rapid infusions of isotonic saline. Volume must be adequately replaced before considering vasopressors, especially in pregnancy, because the uterine arteries are maximally dilated and blood flow is pressure dependent.

Select a vasopressor by the desired effects in the mother and the least harmful effects on the fetus (see Table 25-4). Because of variable effects of vasopressors on fetomaternal circulation, obtain critical care and obstetrical consultation if possible, before selecting vasopressors.

Studies of vasopressors in pregnancy focus on the treatment of hypotension with pseudoephedrine or ephedrine during spinal anesthesia for cesarean section or involve animal models, and data are difficult to

extrapolate to other human hypotensive situations. **Phenylephrine** (pregnancy risk factor C) is an α_1 selective agent without any β activity, so it raises blood pressure but decreases heart rate. It crosses the placenta and is excreted in breast milk but has a favorable fetal acid-base profile. **Ephedrine** (pregnancy risk factor C) is a mixed α and β stimulator. It crosses the placenta and can induce fetal acidosis.[12,13] The vasopressors norepinephrine, dopamine, and vasopressin are all pregnancy risk factor C with limited data available on use in pregnancy.

SEPSIS

Sepsis is a systemic inflammatory response to infection, leading to acute organ dysfunction. Currently there are no sepsis guidelines specifically for pregnant women, because this population has been excluded from early landmark sepsis studies. Pregnant women, when compared with nongravid women, are more likely to develop complications from serious infections. Maintain a high index of suspicion for sepsis in pregnant women, because signs and symptoms of sepsis may not be as apparent when compared to the nonpregnant population.[14] The clinical features of sepsis in pregnancy include fever or rigors, diarrhea or vomiting, rash, abdominal or pelvic pain, vaginal discharge, productive cough, or urinary symptoms.[15]

Septic shock in pregnancy is rare, occurring in a small number (0.002% to 0.01%) of deliveries and in only 0.3% to 0.6% of pregnant women (**Table 25-2**). However, sepsis as a cause of mortality can vary between 2.7% in developed countries to 11.6% in developing countries.[16] Common causes of sepsis are pyelonephritis, pneumonia, chorioamnionitis, and septic abortion.[17] Malaria, human immunodeficiency virus, and community-acquired pneumonia are causes of sepsis in developing countries.[18]

Pyelonephritis is the most common cause of septic shock in pregnancy.[17] Progesterone produces dilatation of the ureters, and mechanical compression of the urinary system by the enlarging uterus results in relative obstruction of the urinary tract. The most common causative agent is *Escherichia coli,* with *Klebsiella*, *Proteus*, and *Enterobacter* responsible for most other cases. Consider renal US to assess for renal/ureteral stones and to assess for renal complications.[19] Hospitalize pregnant women with pyelonephritis, because bacteremia is likely and the physiologic changes of pregnancy can rapidly cause hypoxia.[20,21] Begin empiric antibiotics. Treatment needs to consider local resistance patterns. In general, for mild to moderate disease, standard regimens are amoxicillin/clavulanate, ampicillin plus gentamicin, ceftriaxone, or cefepime. For severe disease with immunocompromise, consider ticarcillin/clavulanate or piperacillin/tazobactam.

Pneumonia in pregnancy can be particularly severe because a rapid decline in oxygen saturation can complicate the course whether or not sepsis is present.[20,21] Follow standard community-acquired pneumonia protocols for pneumonia treatment[22] (see chapter 65, "Pneumonia and Pulmonary Infiltrates" for further discussion). All antibiotics cross the placenta. Select pregnancy risk category B agents for treatment.

Malaria or HIV in developing countries

AIRWAY IN PREGNANCY

ANATOMIC CHANGES AFFECTING INTUBATION

Fluid retention causes edema within the structures of the upper airway,[23,24] and weight gain with adipose deposition can contribute to landmark distortion. Anticipate difficulty with mask ventilation, laryngoscopy, glottic visualization, and endotracheal intubation. Desaturation occurs quickly as a result of maternal increased oxygen consumption and decreased functional residual capacity.

During pregnancy, the incidence of **Mallampati Class III** airways increases (only the soft palate and base of the uvula are seen when the mouth is open and the tongue is protruding), making intubation more difficult (see Figure 29-8 in chapter titled "Intubation and Mechanical Ventilation"). Increased Mallampati scores correlate with gains in body weight,[25] and because obesity in pregnancy is more common than in the nonpregnant state, this contributes to the likelihood of a difficult airway.[26]

Mucosal engorgement and increased capillary friability make airway bleeding and swelling likely. Due to the engorgement and friability of the nasal mucosa, avoid blind nasotracheal intubation if possible. Pregnant women are likely to have full and intact dentition, and there may be little interdental distance in which to maneuver a laryngoscope. In addition, there are often redundant pharyngeal and palatal folds in the airways of obese gravid women. The rates of difficult intubation are reported to range from 1% to 6% and the incidence of failed intubation from 0.1% to 0.6%.[26,27] Decreased lower esophageal tone, increased intra-abdominal pressure, decreased gastric emptying, and a full stomach increase the likelihood of gastric aspiration.

INTUBATION

The most experienced physician should undertake the intubation with adjunctive airway equipment, smaller-sized endotracheal tubes, a gum elastic bougie, short laryngoscope handles, and stylets readily available. A video laryngoscope system facilitates first-pass success and direct visualization and decreases complications and prolonged hypoxia.[28-30]

Preoxygenate to 95% oxygen saturation to prevent hypoxia during intubation. Provide high-flow supplemental oxygenation by nasal cannula set to deliver 15 L/min during the procedure, even after paralysis, to continue oxygen delivery to the alveoli (passive apneic oxygenation).[31]

Place the patient in the supine position; manually displace the uterus to the left. Elevate the head and shoulders with a pillow or folded sheets to achieve the sniffing position. This maneuver is particularly important in obese patients.

For rapid-sequence induction, use standard doses of induction agents and paralytics (see chapter 29). The laryngeal mask airway was described as safe and effective in healthy selected patients undergoing elective cesarean section[32] and has been used as a rescue device after failed intubation.[33]

The determination of the initial ventilator settings should be the same as in the nonpregnant patient, with a P_{CO_2} goal of 28 to 35 mm Hg. Avoid respiratory alkalosis, as in animal models, this decreases uteroplacental flow.[34]

CARDIAC ARREST IN PREGNANCY

Pregnant women are typically younger than the traditional cardiac arrest patient but often have poor outcomes, with survival rates reported as low as 6.9%.[2,9,10] The causes of cardiac arrest in pregnancy are listed in **Table 25-3**.[35,36]

Cardiopulmonary arrest in pregnancy is broken down into two categories: before and after fetal viability. Typically, the onset of fetal viability varies between 22 and 26 weeks, with some institutional variation considering backup and available resources. By 20 weeks, the uterine fundus is palpable at the umbilicus; then from 20 to 32 weeks, the fundal height (in centimeters) approximates the gestational age (for singleton pregnancies). If the fundal height is at or below the umbilicus, resuscitative effort should focus on the mother with no modifications of CPR. If the uterus is palpable above the umbilicus, one person should provide

Perimortem Cesarean Section

Michael A. Bohrn
Jaylaine Ghoubrial

If maternal cardiac arrest occurs and the fetus is presumed to be of viable gestational age (**estimated beyond 24 weeks**), then perform a perimortem cesarean section. The prognosis of intact neonatal survival is best if delivery occurs <5 minutes after the maternal arrest.[1-3] If maternal arrest has exceeded5 minutes, still proceed with the perimortem cesarean section, because there is at least one case report of neonatal survival with good neurologic function after perimortem cesarean section at 30 minutes after maternal death.[4] Current Advanced Cardiovascular Life Support guidelines also recommend proceeding with cesarean delivery in this situation.[5]

Plan the procedure prior to the patient's arrival if advanced warning is available. Consider activation of a multidisciplinary code-type team, if this resource is available.[6] The chance of a neurologically intact neonate is increased with a more rapid delivery. Maternal pulses can return after delivery, once aortocaval compression is relieved.[7,8]

In an ideal setting, an emergency physician, nurses or technicians to assist with CPR, an obstetrician, a surgical assistant, and a neonatologist or pediatrician would be the team assembled to meet the patient immediately on arrival, but the reality is that the emergency physician and a nurse may be the only individuals present. **Shift focus from a typical cardiac arrest scenario to one that focuses both on maternal CPR and rapid delivery of the baby.** Once the baby is delivered, the resuscitation of the mother and baby can continue. The perimortem cesarean section should occur in the ED. Time to transport to the operating room only delays a potentially lifesaving procedure.

EQUIPMENT REQUIRED FOR EMERGENCY PERIMORTEM CESAREAN SECTION

- Scalpel
- Mayo scissors
- Bandage scissors (if available)
- Toothed forceps
- Needle holders
- 0 or 1 vicryl or chromic sutures
- 0 or 1 permanent suture
- Richardson retractors
- Bladder blade (may substitute another retractor if not available)
- IM oxytocin (Pitocin) administration: 10 units/mL oxytocin vials and a 10-mL syringe with IM needle
- *Or* IV oxytocin administration: 1 L of IV fluids with 20 units of oxytocin per liter
- Sponges and/or towel
- Wall or other suction (wall suction preferred as large amounts of amniotic fluid may need to be cleared)
- Clamps × 2
- Equipment for neonatal resuscitation

PROCEDURE FOR PERIMORTEM CESAREAN SECTION

MATERNAL CPR

Continue maternal CPR during the procedure. Remember personnel need to step away from the table if defibrillating the patient during the resuscitation. Keep the patient in left lateral tilt position if good compressions can be performed with the patient in that position; otherwise, keep the patient supine.

MATERNAL PREPARATION

Splash the abdomen with povidone-iodine or other antiseptic if it is readily available, but to avoid unnecessary delay, do not prep, drape, or give preoperative IV antibiotics. Place a Foley catheter only if it will not delay the delivery procedure. Draining the bladder will allow better visualization for the procedure and can decrease the risk of bladder injury.

STEPS FOR CESAREAN SECTION

1. Make a vertical incision with the scalpel from just below the umbilicus to the symphysis pubis (**Figure 25-1**). Some authors advocate a xiphoid to symphysis pubis incision (**Figure 25-2**), but umbilicus to symphysis pubis is typically adequate. The pigmented **linea nigra** is your guide for the midline. The incision should penetrate the skin, subcutaneous layer, and fascia (white layer).
2. Use your fingers to bluntly separate the rectus muscles laterally.
3. Sharply (using the scalpel) or bluntly (using your fingers) enter the peritoneum.
4. Once the uterus is exposed, have an assistant retract from above and place a bladder blade or other retractor inside the inferior aspect of the incision to aid with visualization.

   Make a vertical incision in the midline of the uterus (Figure 25-3). Continue incising with the scalpel to the level of the intrauterine cavity; the uterine muscle wall is thick. Enter the uterine cavity bluntly (using your fingers) or sharply and extend the incision with bandage scissors. **Keep the incision in the midline** of the uterus because the uterine vessels enter laterally. If an anterior placenta is encountered upon entry, go through the placenta and rapidly proceed with delivery of the baby. Expect some increased bleeding, but this is only temporary.
5. Rupture the amniotic sac with a sharp instrument if it has not occurred spontaneously. **Have wall suction ready to evacuate the fluid.**

FETAL DELIVERY

1. Place your hand into the uterine cavity between the symphysis pubis and the fetal vertex (or buttocks if breech) (**Figure 25-4**). Elevate the vertex (or buttocks) out of the pelvis, and then the physician or assistant should remove the bladder blade.

Once the head (or buttocks) is to the level of the uterine incision, have the assistant **apply steady pressure to the fundus** to assist in delivery of the baby's vertex (or buttocks) through the incision followed by shoulders and body.

In a **breech** presentation, deliver the buttocks first, followed by both legs, and then the body of the baby to the level of the shoulders. When one arm is delivered, rotate and deliver the contralateral arm, flex the head, and deliver the baby.

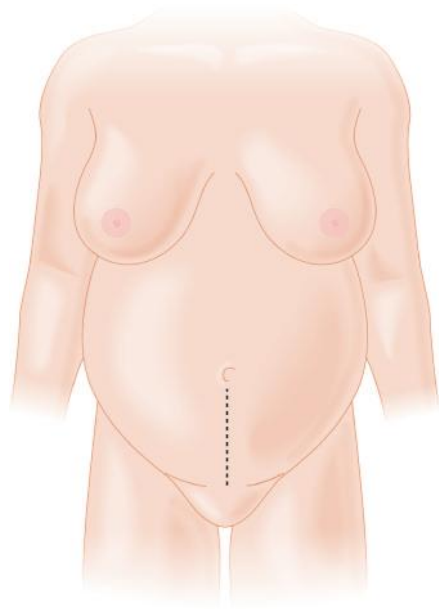

FIGURE 25-1. Midline vertical incision from umbilicus to symphysis pubis.

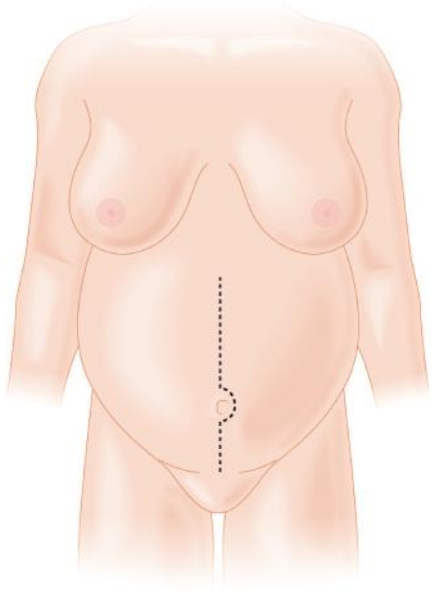

FIGURE 25-2. Midline vertical incision from xiphoid to symphysis pubis.

If a **footling breech** is encountered, gently grasp both feet and deliver to the level of the baby's shoulder and continue as a breech extraction as noted earlier.

2. Once the baby is delivered, **doubly clamp the cord, cut the cord between the clamps**, and take the baby to the providers who will be performing additional evaluation and resuscitation (if additional providers are available). There is some debate about delayed clamping of the umbilical cord. Delaying clamping for longer than 60 seconds (or beyond when cord pulsations cease) may provide the benefit of increased hemoglobin and iron stores in the newborn.[9] However, this is primarily based on studies of healthy babies, so **do not delay cord clamping if the baby requires immediate resuscitation**. If no additional providers are present, quickly determine the emergency physician's greatest benefit for resuscitation and proceed accordingly (i.e., lead/aid ongoing resuscitation of the mother or proceed to lead/aid resuscitation of the newborn baby).

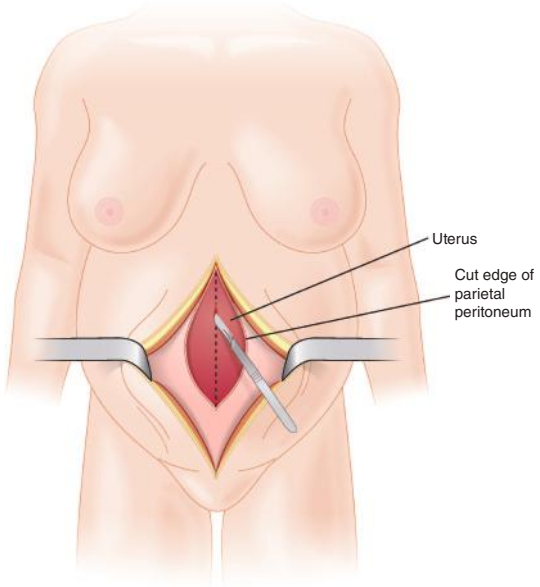

FIGURE 25-3. Uterine midline vertical incision.

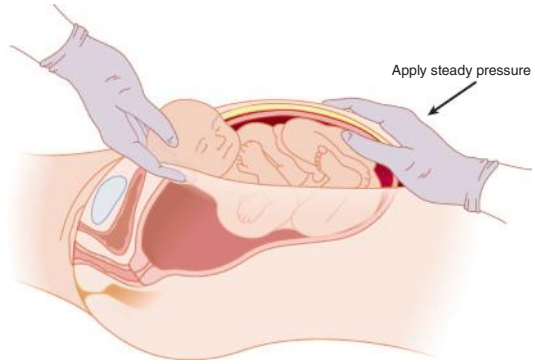

FIGURE 25-4. Delivering the fetus.

PLACENTAL DELIVERY AND UTERINE CARE

1. **Manually remove the placenta** and begin an infusion of 20 units of oxytocin (Pitocin) in 1 L NS wide open or 10 units of oxytocin (Pitocin) IM to help the uterus contract and decrease bleeding. **Uterine massage** will also aid in uterine contraction and decrease blood loss. The average estimated blood loss for a cesarean section is 1000 mL.

2A. **If an obstetrician or surgeon is available** to complete the closure, once the placenta is delivered, clean out the uterine cavity with sponges until it is completely cleared. Temporarily pack the uterus and abdomen with moistened laparotomy sponges until the obstetrician or surgeon arrives.

2B. **If a surgeon or obstetrician is not available,** then exteriorize the uterus and clean out the uterine cavity with sponges until it is completely cleared.

3. Close the uterus with one or two layers with a locked running stitch of number 0 or 1 vicryl or chromic suture on a large needle. Close the fascia with number 0 or 1 permanent suture in a running fashion.

4. Finally, close the skin with staples or suture.

Informed consent for perimortem cesarean section is not necessary because it is part of resuscitation. Perimortem cesarean section during cardiac arrest fulfills the criteria for absence of malfeasance and beneficence for the mother and the fetus, and as yet, there has not been a physician charged with criminal or civil malfeasance for the procedure.

manual left lateral displacement of the uterus while another is performing CPR.[5,36]

Make preparations for completion of perimortem cesarean section if time from arrest is short and the fetus is of survivable gestational age. The following factors are associated with an increased chance of fetal survival after maternal cardiac arrest: gestational age >28 weeks or fetal weight >1 kg, short interval between maternal death and delivery, cause of maternal death not related to chronic hypoxia, healthy fetal status before maternal death, availability of neonatal intensive care facilities, and quality of maternal resuscitation.[37]

DEFIBRILLATION AND VASOACTIVE MEDICATIONS

Treat pregnant women in cardiac arrest according to current Advanced Cardiovascular Life Support guidelines (**Table 25-4**). Perform defibrillation at recommended adult doses. Despite an increase in plasma volume and glomerular filtration rate, there is no evidence that the standard doses of Advanced Cardiovascular Life Support medications should be altered. Place IV sites above the diaphragm secondary to aortocaval compression.

POST–CARDIAC ARREST HYPOTHERMIA

Case reports describe successful use of post–cardiac arrest hypothermia during pregnancy. The 2010 American Heart Association guidelines, Cardiac Arrest in Special Situations, recommend hypothermia in early pregnancy without emergency cesarean section (with fetal heart monitoring). Hypothermia can be used on a case-by-case basis based on the current recommendations for the nonpregnant patient.[38-40]

REFERENCES

The complete reference list is available online at www.TintinalliEM.com.

TABLE 25-4 Medications Used during Resuscitation—Considerations in Pregnancy

Drug	Indications	Pregnancy Risk Category
Epinephrine	Potentially beneficial in all forms of cardiac arrest	Category C. Teratogenic in animals in large doses; may induce uteroplacental vasoconstriction and fetal anoxia.
Lidocaine	Ventricular ectopy, tachycardia, and fibrillation	Category B. Use during pregnancy is not well studied; crosses the placenta, but in therapeutic doses has no teratogenic effect on the fetus; may cause fetal bradycardia.
Atropine	Symptomatic bradycardia	Category B. Crosses placenta but results in no fetal abnormalities; can cause fetal tachycardia.
Sodium bicarbonate	Cardiac arrest unresponsive to other measures; documented preexisting metabolic acidosis	Category C. No studies of risk. Use for hyperkalemia and selected toxic overdoses.
Dopamine	Hemodynamically significant hypotension in the absence of hypovolemia	Category C. No teratogenic effects in animals, but sufficient studies in humans are lacking; use only when clearly indicated.
Dobutamine	Short-term inotropic support of patients with depressed myocardial contractility	Category B. Not teratogenic in animal studies.
Norepinephrine	Vasopressor for septic shock after adequate volume replacement	Category C. No animal reproductive studies done. Crosses the placenta.
Amiodarone	Ventricular fibrillation, tachycardia, and supraventricular tachycardia	**Category D. Do not use in pregnancy;** serious fetal adverse effects of congenital goiter and hypothyroidism.
Adenosine	Supraventricular tachycardia	Class C. Multiple case reports of the safe use of adenosine to treat maternal and fetal supraventricular tachycardia.
Magnesium sulfate	Torsades de pointes	Class B. This drug is commonly used in pregnancy for toxemia and tocolysis with no reports of congenital defects; neonatal neurologic depression may occur with respiratory depression, muscle weakness, and loss of reflexes.
Ephedrine	Hypotension related to spinal anesthesia or unresponsive to fluids	Class C. Multiple reports of use during anesthesia-related hypotension in pregnancy. Maintains uterine blood flow. May cause dose-dependent increase in fetal acidosis, tachycardia, and abnormal variability in fetal heart rate (indicative of fetal stress), or an increase in metabolic activity.
Phenylephrine	Hypotension related to spinal anesthesia or unresponsive to fluids	Class C. Superior to ephedrine for management of hypotension after spinal anesthesia with a decrease in fetal acidosis.[12]
Vasopressin	Cardiac arrest	Class C. There are no controlled data in human pregnancy. Current data suggest no benefit over epinephrine in cardiac arrest.

CHAPTER 26

Post-Cardiac Arrest Syndrome

Benjamin S. Abella
Bentley J. Bobrow

INTRODUCTION AND EPIDEMIOLOGY

Sudden cardiac arrest represents one of the most time-sensitive diseases in the practice of emergency medicine, requiring prompt recognition and rapid delivery of resuscitative care, including high-quality CPR, early defibrillation when appropriate, and appropriate airway management.[1] Even with these interventions, aggregate survival to hospital discharge is less than 20% in most communities and hospital systems.[2,3] Among survivors, neurologic injury is common (present in up to 50% of survivors) and widely varied, ranging from subtle memory deficits to persistent vegetative state.[4,5] This chapter focuses on the pathophysiology of ischemia-reperfusion injury and the provision of targeted temperature management, also called therapeutic hypothermia.[6]

PATHOPHYSIOLOGY OF ISCHEMIA-REPERFUSION INJURY

The brain is exquisitely sensitive to ischemia, such that disruption of blood flow for several minutes is sufficient to initiate a set of injury mechanisms that may lead to irreversible disabilities.[7,8] The complete loss of blood flow, followed by the abrupt return of spontaneous circulation (**ROSC**), rapidly leads to a complex pathophysiologic process known as ischemia-reperfusion injury, also known specifically in the sudden cardiac arrest setting as postresuscitation syndrome.[8,9]

When blood flow is abruptly stopped and then restored, a number of overlapping mechanisms lead to clinical injury (**Figure 26-1**).

CELLULAR RESPONSES TO ROSC

At the cellular level, mitochondrial integrity and function become damaged, with release of crucial enzymatic machinery such as cytochrome c and disruption of oxidative phosphorylation.[9,10] Mitochondrial injury is implicated in the increased concentration of oxygen free radicals and downstream activation of programmed cell death pathways.[10,11] At the humoral level, reperfusion triggers a broad array of immune activation, including increased blood levels of cytokines including interleukin-6 and tumor necrosis factor alpha.[12] In addition, aberrant neutrophil and platelet activation can occur. These immune phenomena have led Adrie et al[13] to describe the postresuscitation condition as a "sepsis-like syndrome," in which inflammation plays a crucial role in injury. Immune activation, in turn, can lead to additional production of oxygen free radicals such as superoxide and hydrogen peroxide. These molecules, produced in small quantities during normal cellular function, are usually converted to oxygen and water by the enzymes catalase and superoxide dismutase. However, enzyme systems become overwhelmed with the dramatic increase of free radical species generated during postresuscitation syndrome. Different tissues exhibit varying sensitivity to ischemia-reperfusion processes, with brain tissue and vascular endothelium appearing to be particularly vulnerable.[8,9]

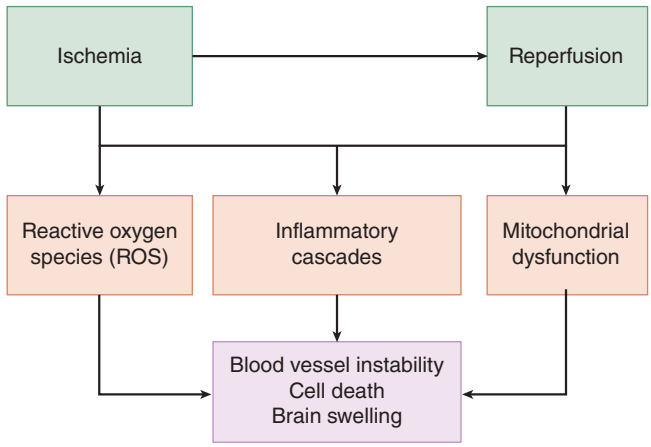

FIGURE 26-1. Schematic of postarrest pathophysiology, also called ischemia-reperfusion injury. The concepts shown here represent processes that occur at the subcellular, cellular, tissue, and organismal levels. The kinetics of these processes following cardiac arrest and the extent to which they affect clinical outcomes are still unclear.

ORGAN SYSTEM EFFECTS OF ROSC

The biochemical and cellular phenomena described earlier lead to diverse clinical manifestations of injury in the minutes to hours following resuscitation. Inflammatory changes and immune cellular activation can lead to vascular leak and a drop in peripheral vascular resistance, with concomitant loss of fluid from the intravascular compartment and hypotension.[14] Cellular injury in the brain, combined with endothelial damage, can trigger cerebral edema, a common and dangerous component of postresuscitation syndrome.[15] Cerebral edema and increased intracranial pressure can cause cerebral herniation and serve as the cause of death, often in the initial 72 hours following resuscitation. Myocardial stunning is clinically evident on echocardiography as global hypokinesis and markedly reduced ejection fraction.[16,17] Myocardial depression is usually transient and typically resolves over the first few days following resuscitation with appropriate hemodynamic support.[17,18] Postresuscitation infection may be related to bacterial translocation into the bloodstream from loss of intestinal tissue integrity.[19] Adrenal injury from ischemia may cause adrenal insufficiency as a further cause of clinical deterioration.[20]

CLINICAL FEATURES AFTER ROSC

Following initial resuscitation, the clinical condition of patients varies considerably. Some patients with prompt recovery after only brief periods of CPR can be awake and responsive; however, most patients are initially comatose or markedly obtunded following resuscitation. Neurologic assessment is highly limited in most cases, as in the course of clinical resuscitation care, patients are intubated and sedated and/or pharmacologically paralyzed. Patients may be hypotensive or hypertensive, depending on factors such as myocardial stunning, degree of vascular leak, and preexisting hypertensive disease. Patients are most frequently tachycardic following resuscitation; bradycardia may reflect underlying myocardial ischemia and damage to the conduction system.

Physical examination is limited in the immediate postresuscitation period as well. Most patients exhibit absent or abnormal papillary responses and absent gag reflex or doll's eyes responses. **Clinical neurologic reflexes are not predictive of cardiac arrest outcomes.**[21] **The bedside neurologic examination should not influence decisions for continued care in the hours following successful resuscitation.** Focus the physical examination after resuscitation on identifying clues to determine the possible cause of cardiac arrest, such as the presence or absence of asymmetric lower extremity edema that might suggest thromboembolic disease, absent or decreased lung sounds that might implicate pneumothorax, or jugular venous distension and muted heart sounds that might suggest cardiac tamponade. An ECG should be obtained and if ST segment elevation consistent with an acute myocardial infarction is present, coronary reperfusion with percutaneous coronary intervention is recommended.

DIAGNOSIS OF ANOXIC BRAIN INJURY AFTER ROSC

Neuroprognostication after sudden cardiac arrest is a crucial issue for healthcare providers in the critical care setting but persists as a challenging and inexact process. A variety of radiographic, biochemical, and neurophysiologic tools are available to assess brain injury following

sudden cardiac arrest, but most are poorly validated and require additional research to determine clinical utility.

In the ED, perform head CT in survivors as soon as feasible. Head CT can identify subarachnoid hemorrhage[21,22] or epidural and subdural hematomas. The degree of cerebral edema can also be assessed by head CT.[22-24] Because cerebral edema often peaks several days after resuscitation, swelling that is radiographically apparent on initial CT is a worrisome sign. Brain MRI is generally neither practical nor useful during initial ED management.[25]

Marked elevations of nerve-specific enolase or S100 calcium-binding protein B are often associated with a poor neurologic prognosis,[26] and a nerve-specific enolase level >33 micrograms/L has been used as a cut-off with very high sensitivity for severe brain injury and poor prognosis. The biomarker glial fibrillary acidic protein is under current investigation.[27] At present, biomarker measurement is not part of standard emergency medicine practice.

Many protocols for postarrest care involve the early institution of continuous electroencephalogram monitoring to assess for electrical convulsive activity, which is present in up to 25% of patients after resuscitation.[28] The presence of seizures generally augurs a poor prognosis, but not all patients with electrical seizure activity sustain severe long-term injury. Bispectral index monitoring, a simple approach to electrical brain monitoring relative to electroencephalography, can be useful to predict neurologic outcome.[29,30] Measurement of somatosensory evoked potentials, a bedside test of neuronal connectivity and function, can be performed several days following cardiac arrest and may also be useful to predict outcome.[31]

TABLE 26-2 Suggested Inclusion and Exclusion Criteria for Postarrest Targeted Temperature Management[40A]

Inclusion criteria	Pulse ROSC and GCS motor score <6 No other reason for coma No DNR or DNI status Adult (age >17 years)*
Exclusion criteria	Awake/alert after cardiac arrest Arrest of traumatic etiology Arrest associated with significant bleeding Cerebral Performance Score 4–5 before arrest† Pregnancy* DNR/DNI status
Not an exclusion criterion	Patient on warfarin or heparin Arrest rhythm was nonshockable Long QT syndrome

Note the inclusion of a category of clinical items that would NOT preclude the use of therapeutic hypothermia. These represent issues commonly asked about by practitioners but should not represent exclusion criteria.

*Criteria that are controversial and may vary from hospital to hospital.

†See Cerebral Performance Scores in **Table 26-1**.

Abbreviations: DNI = do not intubate; DNR = do not resuscitate; GCS = Glasgow Coma Scale; ROSC = return of spontaneous circulation.

TARGETED TEMPERATURE MANAGEMENT (OR THERAPEUTIC HYPOTHERMIA)

The key ED intervention for postresuscitation syndrome is the prompt delivery of systemic cooling therapy, also called therapeutic hypothermia or targeted temperature management. Cooling of resuscitated adult cardiac arrest patients to a core body temperature of 32 to 36°C (89.6 to 96.8°F) for 24 hours following arrest and ROSC can dramatically improve survival and neurologic outcomes.[32-34] The ideal temperature is not clear. Neurologic outcome after ROSC can be assessed by the Cerebral Performance Score (**Table 26-1**),[35] where a score of 4 or 5 predicts poor quality of life with a sensitivity of 55.6% (95% confidence interval 42-67%) and specificity of 96.8% (95% confidence interval 94-98%). A European study[33] demonstrated that therapeutic hypothermia instituted for 24 hours following cardiac arrest and ROSC resulted in a Cerebral Performance Score of 1 or 2 in 55% of hypothermia-treated patients, whereas only 39% of patients in the control group achieved a score of 1 or 2. Six-month mortality was 41% in the hypothermia group and 55% in controls. The trial only enrolled out-of-hospital cardiac arrest patients with ventricular fibrillation/ventricular tachycardia (VF/VT) as an initial rhythm; no definitive trial has been performed for patients with either pulseless electrical activity (PEA) or asystole as the initial arrest rhythm. However, a body of clinical evidence suggests that therapeutic hypothermia also improves outcomes for patients with PEA or asystole.[36-39]

INCLUSION AND EXCLUSION CRITERIA FOR THERAPEUTIC HYPOTHERMIA

Patients who are awake and appropriately alert following ROSC are excluded from consideration (**Table 26-2**). Patients with very poor neurologic status before arrest and resuscitation are often not considered for therapeutic hypothermia, as treatment can at best only restore patients to their prearrest clinical state. Other inclusion and exclusion criteria are less well defined. For example, many hospital protocols for postarrest care exclude pregnant patients; however, several case reports have demonstrated good outcomes for postarrest pregnant patients.[41,42] Because coagulopathy and bleeding can result from lowering of core body temperature, patients with clinically significant bleeding at the time of arrest or who have arrested from penetrating trauma are generally excluded from therapeutic hypothermia. Anticoagulation is not considered a contraindication. Therapeutic hypothermia may benefit patients resuscitated from hanging-related asphyxial arrest.[43]

TABLE 26-1 Cerebral Performance Score[40]

Score	Description
1	Awake and alert; can work
2	Awake and alert; cannot work but can perform independent daily activities
3	Conscious but dependent on others
4	Coma or vegetative state
5	Brain death

PRACTICAL CONSIDERATIONS

The technique requires the coordination of care between the ED, critical care units, and cardiology intensive care units. A standing hospital protocol is a crucial step for hospital systems. Sample protocols are available on the Internet.[44] Protocols should delineate processes for hypothermia induction, maintenance, and rewarming, as well as adjunctive pharmacologic interventions (sedation, paralysis) and monitoring. Incorporation of these protocols into electronic order sets for postarrest care encourages uniformity of treatment. An overview of the time course of treatment is shown in **Figure 26-2**.

Cooling and Supportive Care **Table 26-3** outlines elements of cooling and supportive care. To lower core body temperature to 32 to 36°C (89.6 to 96.8°F), apply commercially available clinical cooling systems (both surface-wrap or catheter-based cooling solutions exist), or apply chilled saline or ice packs to the axillae and groin. The aim is to reach goal temperature within several hours of resuscitation, so a combination of these approaches is often employed.

Maintain hypothermia for 12 to 24 hours following lowering of core temperature. It is difficult to maintain a steady temperature with chilled saline or ice packs alone.[45,52,53] Commercial cooling devices take input from temperature probes to modify cooling power and carefully hold core temperature steady. During hypothermia maintenance, check serum electrolytes frequently (every 4 h) as hypokalemia can result from

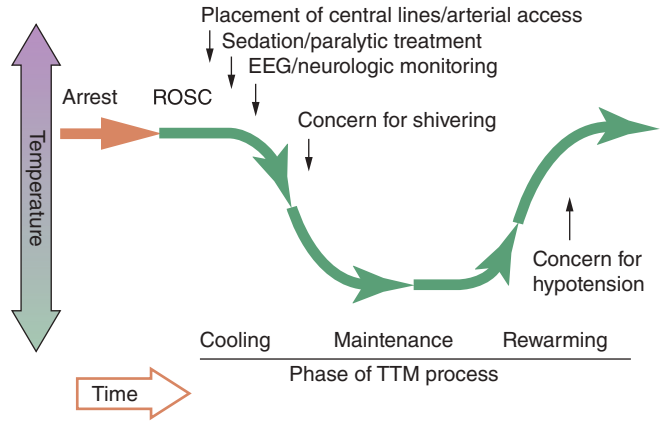

FIGURE 26-2. Timeline of postarrest therapeutic hypothermia induction, maintenance, and rewarming. Relevant clinical actions are shown in relation to these three phases of the treatment process. For further protocol details, consult the protocol repository at the University of Pennsylvania Internet resource site.[45] EEG = electroencephalographic; ROCS = return of spontaneous circulation; TTM = targeted temperature management.

cold-mediated diuresis.[53,54] Monitor hemodynamic parameters carefully to maintain a mean arterial pressure sufficient to enable cerebral perfusion (often a mean arterial pressure >60 mm Hg [>8kPa] is considered minimum).[55] After the maintenance phase, rewarm over 12 to 24 hours. More rapid rewarming can induce hypotension from vasodilation as well as electrolyte shifts.

Complications A number of possible adverse effects have been associated with temperature-targeted hypothermia (**Table 26-4**). Bradycardia is very common and often pronounced (heart rate <50 beats/min is common) with induction, but usually is of little clinical consequence and requires no treatment.[32] Tachydysrhythmias, atrial fibrillation, and nonsustained ventricular tachycardia are uncommon unless core body temperature is <32°C (89.6°F). QT_c prolongation has been observed, so continuous cardiac monitoring and interval electrocardiograms are necessary.[56]

Shivering can impede the lowering of body temperature. A variety of treatment approaches to shivering exist, the most definitive being neuromuscular blockade. Bleeding can be exacerbated by lowered core temperature but occurs in <5% of cases.[32,57] Hypokalemia and hypomagnesemia can result from intracellular shifts and diuresis mediated by lowered core temperature.

TABLE 26-3 Components of Cooling and Supportive Care

Lower core body temperature to 32–36°C (89.6–96.8°F) as soon as possible but within 4–6 h after ROSC[46]
Surface cooling:
Chilled saline or ice packs to the axillae, neck, and groin
Cooling blankets, vests, and leg wraps[47]
Cooling helmet [48,49]
Intravascular cooling[50]
IV 30 mL/kg normal saline at 4°C over 30 min[51]
Intubation and mechanical ventilation
Obtain electrocardiogram and provide continuous cardiac monitoring, pulse oximetry, and capnometry
Sedation and neuromuscular blockade
Central venous and arterial access
Continuous core temperature monitoring; use bladder catheter, central venous catheter, or esophageal probe
Maintain mean arterial pressure >60 mm Hg
Check electrolytes every 4 h
Maintain hypothermia for 12–24 h
Do not let core temperature drop to <32°C (89.6°F); avoid fever

TABLE 26-4 Potential Adverse Effects of Targeted Temperature Management (Therapeutic Hypothermia)

More Common	Less Common
Bradycardia	Nonsustained ventricular tachycardia
Prolongation of QT interval	Significant bleeding
Coagulopathy with PTT prolongation	Skin injury/ulceration from surface cooling
Hypokalemia during cooling	
Hyperkalemia during rewarming	
Shivering	

Abbreviation: PTT = partial thromboplastin time.

SPECIAL CONSIDERATIONS FOR TARGETED TEMPERATURE MANAGEMENT (THERAPEUTIC HYPOTHERMIA)

Children The indications for therapeutic hypothermia after cardiac arrest in children are not well established. Although hypothermia improves outcomes after neonatal hypoxic ischemic encephalopathy, no supporting randomized trial evidence exists for its use after pediatric sudden cardiac arrest.[58] Regardless, some hospitals use hypothermia protocols for resuscitated children.

Prehospital Application Therapeutic hypothermia could have maximal benefit when begun immediately after ROSC.[59,60] Although effective hospital-based interventions exist, they may be used infrequently due to multiple barriers such as lack of knowledge, experience, resources, and infrastructure.[61] These barriers and the safety and relative ease of inducing hypothermia in the prehospital setting have led some EMS systems to implement protocols directed at induction of cooling prior to hospital arrival.[62-64] Although this strategy has logical validity, the impact of prehospital hypothermia induction on outcomes is not well established.[65-67]

CHAPTER 27

Ethical Issues of Resuscitation

Catherine A. Marco

GENERAL PRINCIPLES OF MEDICAL ETHICS

The study of ethics is an effort to *understand and examine the moral life.*[1] The Hippocratic Oath is revered as one of the oldest codes of medical ethics. More recently, the American Medical Association Code of Ethics (earliest version in 1847)[2,3] and the American College of Emergency Physicians Code of Ethics (1997 and 2008)[4,5] have provided guidance to emergency physicians in the application of ethical principles to clinical practice. Most ethical codes share common tenets such as *beneficence* (doing good); *nonmaleficence* (*primum non nocere,* or "do no harm"); respect for patient *autonomy*, *confidentiality*, *and honesty*; *distributive justice*; and *respect for the law.* Ethical dilemmas arise when there is a potential conflict between two principles or values. Physicians resolve these dilemmas by gathering additional information; conducting meetings with other healthcare professionals, patients, and families; and applying an informed judgment in individual situations. In some circumstances, physicians may seek the involvement of the institutional ethics committee or the judicial system.

CARDIAC RESUSCITATION AND OUTCOMES

There are approximately 300,000 sudden deaths in the United States annually.[6] The outcome of resuscitative efforts for victims of cardiac arrest is uniformly poor but varies depending on a variety of factors, including

TABLE 27-1 Proposed Prehospital Termination of Resuscitation Criteria

Unwitnessed arrest
No shock delivered
No bystander CPR
No return of spontaneous circulation in response to advanced cardiac life support protocols
Initial rhythm of asystole or pulseless electrical activity

time elapsed since arrest (down time), presenting rhythm, bystander CPR, and response to prehospital advanced cardiac life support protocols.

Physicians should consider the patient's potential outcome including quality of life when initiating a resuscitation effort. Patients who receive early advanced cardiac life support have improved outcomes.[7,8] Patients presenting with ventricular fibrillation or ventricular tachycardia have higher survival rates than patients with asystole or pulseless electrical activity.[9,10] Many studies of cardiac arrest victims have estimated survival to hospital discharge to be between 0% and 13%.[6,8-19] Advanced resuscitative techniques, such as therapeutic hypothermia and advanced cardiac life support protocols, have improved the survival rate for patients with cardiac arrest.[9]

Based on such data, several authors have proposed criteria for withholding resuscitative efforts for patients with a low likelihood of successful resuscitation. Several validated decision rules incorporate related factors predictive of dismal outcome[20-29] (**Table 27-1**).

RISKS AND BENEFITS OF RESUSCITATIVE EFFORTS

When considering offering or withholding resuscitative efforts, the physician must take into account the risks and benefits of resuscitation. The primary goals of resuscitative efforts are to restore the patient's circulation and, ideally, normal function. Another less tangible benefit may be providing additional time for survivors to accept the distressing news of imminent death of their loved one.

Resuscitative measures are frequently undertaken in clinical situations where physiologic survival with meaningful neurologic function is very unlikely. Patients may be left with significant anoxic brain injury, persistent vegetative state, or dementia with poor quality of life.

Substantial resources are consumed in resuscitative efforts, and clinicians are taken away from other patients (a violation of distributive justice). Another benefit in limiting resuscitative efforts is the freeing of time and resources for family counseling and communication.

FUTILITY AND NONBENEFICIAL INTERVENTIONS

The term *futility* is subject to interpretation.[30] Healthcare professionals may determine futile interventions to be those that carry an absolute impossibility of successful outcome, a low likelihood of return to spontaneous circulation, a low likelihood of survival to discharge from the hospital, or a low likelihood of restoration of meaningful quality of life. *Futility* can be defined as "any effort to achieve a result that is possible, but that reasoning or experience suggests is highly improbable and that cannot be systematically produced."[31] There is no consensus among physicians about the meaning of the term. It is probably more accurate to use terminology such as *nonbeneficial*, *ineffectual*, or *low likelihood of success* when discussing resuscitation with patients or families.

Many ethicists agree that physicians are not required to provide treatments that they estimate will provide little or no benefit to the patient.[32,33] The American Medical Association Council on Ethical and Judicial Affairs stated that CPR may be withheld, even if requested by the patient, "when efforts to resuscitate a patient are judged by the treating physician to be futile."[34] Dilemmas regarding nonbeneficial interventions often arise due to inadequate or ineffective communication between the physician, patient, and family. This is of particular concern in emergency medicine, in which previous relationships with patients and family rarely exist and time is often inadequate to establish effective relationships. Thus, initial efforts should be directed to improve communication, education, and joint decision making.

TABLE 27-2 Ethical Issues at the End of Life: The American College of Emergency Physicians Policy

The American College of Emergency Physicians believes that:
Emergency physicians play an important role in providing care at the end of life.
Helping patients and their families achieve greater control over the dying process will improve end-of-life care.
Advance care planning can help patients formulate and express individual wishes for end-of-life care and communicate those wishes to their healthcare providers by means of advance directives (including state-approved advance directives, do not attempt resuscitation [DNAR] orders, living wills, and durable powers of attorney for health care).
To enhance end-of-life care in the ED, the American College of Emergency Physicians believes that emergency physicians should:
Respect the dying patient's needs for care, comfort, and compassion.
Communicate promptly and appropriately with patients and their families about end-of-life care choices, avoiding medical jargon.
Elicit the patient's goals for care before initiating treatment, recognizing that end-of-life care includes a broad range of therapeutic and palliative options.
Respect the wishes of dying patients including those expressed in advance directives. Assist surrogates who make care choices for patients who lack decision-making capacity, based on the patient's own preferences, values, and goals.
Encourage the presence of family and friends at the patient's bedside near the end of life, if desired by the patient.
Protect the privacy of patients and families near the end of life.
Promote liaisons with individuals and organizations in order to help patients and families honor end-of-life cultural and religious traditions.
Develop skill at communicating sensitive information, including poor prognoses and the death of a loved one.
Comply with institutional policies regarding recovery of organs for transplantation.
Obtain informed consent from surrogates for postmortem procedures.

The American College of Emergency Physicians states that "physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient" (**Table 27-2**). Emergency physicians' judgments should be unbiased, based on available scientific evidence, mindful of societal and professional standards, and sensitive to differences of opinion regarding the value of medical intervention in various situations.[35]

Ultimately, the decision regarding CPR and its likelihood of benefit to the patient and decisions to provide, limit, or withhold resuscitative efforts are to be made by the emergency physician in the context of well-accepted research results, patient and family wishes, and professional judgment. Individual bias regarding quality of life or other related issues should be avoided. There are many situations in which dying can be accepted as a natural process, even in an emergency setting.

ADVANCE DIRECTIVES

An **advance directive** is any proactive document stating the patient's wishes in various situations should the patient be unable to do so. The **living will** is a document suitable for terminally ill individuals, and the treating physician should accept the provisions. Many advance directives state that no life support should be applied in situations in which meaningful recovery is improbable. **Durable power of attorney** specifies a surrogate decision maker in the event that the patient no longer has the capacity to make medical decisions. The U.S. Federal Patient Self-Determination Act mandates that the opportunity to sign an advance directive is provided for all patients admitted to a hospital.

Despite widespread advocacy and legal mandates for the increased use of advance directives, only a minority of patients have completed an advance directive, and an even smaller minority arrive in the ED with the necessary documentation.[36] Advance directives and code status are especially important in emergency care medical decision making.[32,37,38]

FAMILY PRESENCE DURING RESUSCITATION

Family presence during resuscitation may serve to improve understanding and relieve family member guilt or disappointment and may be a helpful part of the grieving process.[39-45] Physicians should be sensitive to the possibility that this option may be difficult for certain family members or staff.[46] If family members are invited to be present, provide a liaison to assist with communication and education about procedures and other medical issues.[42]

PROCEDURES ON RECENTLY DECEASED PATIENTS

The practices of teaching and performing procedures on recently deceased patients are controversial. The most important benefit of these practices is the opportunity for hands-on practice for students, house staff, and even experienced physicians.[47] However, some consider performing procedures without informed consent to be disrespectful, deceptive, or unethical.[48] Obtaining consent from families or surrogates is recommended before such practice.[49,50]

RESUSCITATION RESEARCH

Research on resuscitation techniques and pharmaceuticals has been problematic due to the frequent inability to obtain informed consent and the constraints of the decision-making process. Ordinarily, the informed consent procedure for human subject research is designed to ensure protection and autonomy of the subject. However, this process is time-consuming and requires decisional capacity in the subject. Because of these difficulties, the U.S. Food and Drug Administration issued guidelines under which resuscitation research may be performed, with a **waiver of informed consent** under certain conditions.[51] When designing such research protocols, relevant factors include the patient's wishes (if known), expected safety of the study protocol, expected benefit of the therapeutic intervention, overall predicted benefit to society by improved knowledge regarding resuscitation, related animal data, feasibility of surrogate consent, local institutional review board opinion, and local general public opinion, if available. Waiver of consent is available through application with the Food and Drug Administration with local institutional review board approval.

COMMUNICATION AND COUNSELING FOR SURVIVORS

Counseling should be available for families and friends of those patients who have died in the ED. See chapter 300, "Death Notification and Advance Directives": Delivering Effective Death Notifications in the Emergency Department, for detailed discussion on communication strategies. **Table 27-3** provides a summary of practical advice for resuscitation scenarios.

TABLE 27-3 Practical Advice for Resuscitation Scenarios

Assess patient wishes (advance directive, prior communications).
Communicate with family and loved ones throughout resuscitative efforts.
Allow family to be present during resuscitative efforts, if appropriate.
Assess likely outcome, based on scientific evidence.
Weigh risks and benefits of resuscitation, in conjunction with family and primary care provider, if available.
Enroll in research trials, with surrogate consent, or using U.S. Food and Drug Administration waiver of consent rule, as appropriate.
Consider teaching procedures, with consent of patient or surrogate.
Use a multidisciplinary approach to family communications.
Provide spiritual, psychosocial, and educational support to family and loved ones throughout and after termination of resuscitative effort.

CHAPTER 28

Noninvasive Airway Management

Jestin N. Carlson
Henry E. Wang

INTRODUCTION

Airway management is a critical need in many acutely ill and injured patients. Optimal strategies seek to assist with airway patency, oxygen delivery, and carbon dioxide excretion. Commonly, many classify airway management techniques into two categories: noninvasive (passive oxygenation, bag-valve mask ventilation, supraglottic airways, and noninvasive positive-pressure ventilation) and invasive (endotracheal intubation, cricothyroidotomy, transcutaneous needle jet ventilation, and tracheostomy). This chapter discusses noninvasive airway management strategies. Detailed discussion of invasive airway management strategies is found in the chapters 29, Intubation and Mechanical Ventilation and chapter 111, Intubation and Ventilation in Infants and Children.

ASSESSMENT OF THE AIRWAY AND VENTILATORY EFFORT

The decision to initiate airway support must often be made rapidly based on the patient's clinical condition. Laboratory testing or other studies should not delay the decision to initiate airway management strategies.

First, assess every patient for airway obstruction, which can be functional (e.g., unconscious patient) or mechanical (e.g., foreign body). The ability to spontaneously swallow and speak provides a basic indication of airway patency, and the absence is a potential sign of obstruction. Other potential signs of airway obstruction include anxiety, wheezing or stridor, and coughing. Many conditions can cause airway obstruction (**Table 28-1**).

Some obstructions, such as foreign bodies or masses, are subglottic, or below the vocal cords.

Laryngospasm is obstructive closure of the glottis by constriction of laryngeal muscles. Laryngospasm may result from stimulation of the upper airway receptors on the tongue, palate, and oropharynx. Other causes include chemical irritation, secretions, blood, water, and vomitus in the upper airway and traction on the pelvic/abdominal viscera. Laryngospasm can persist after the causative stimulus has departed.

TABLE 28-1 Causes of Upper Airway Obstruction

Congenital/Genetic	Infectious	Medical	Trauma/Tumor
Large tonsils	Tonsillitis	Cystic fibrosis	Laryngeal trauma
Macroglossia	Peritonsillar abscess	Angioedema	Hematoma/masses
Micrognathia	Pretracheal abscess	Laryngospasm	Smoke inhalation
Neck masses	Epiglottitis	Inflammatory	Thermal injuries
Large adenoids	Laryngitis/respiratory syncytial virus Ludwig angina Retropharyngeal abscess	Airway muscle relaxation	Foreign body/hemorrhage

SIGNS AND SYMPTOMS OF RESPIRATORY FAILURE

Patients with hypoventilation (inadequate carbon dioxide excretion) and hypoxia (inadequate alveolar oxygen content) can present with a variety of symptoms including weakness, fatigue, chest pain, or shortness of breath. Inadequate oxygenation and ventilation can lead to altered mentation, including anxiety, confusion, obtundation, or coma. Patients with respiratory distress can present with audible wheezing, stridor, or a silent chest. A subjective gauge of respiratory distress is the patient's respiratory effort or "work of breathing."[1] Dyspnea, tachypnea, hyperpnea, or hypopnea, accessory muscle use, and cyanosis are signs of increased work of breathing.

TYPES OF RESPIRATORY FAILURE

There are two types of respiratory failure. **Type 1 respiratory failure** is characterized by hypoxia *without* hypercapnia. Type 1 respiratory failure may be the result of conditions that affect oxygenation but not necessarily ventilation (e.g., pneumonia, pulmonary embolism). Patients with type 1 respiratory failure require assistance with oxygenation. Treatment of type 1 failure focuses on optimizing oxygenation. **Type 2 respiratory failure** is characterized by hypoxia *with* hypercapnia. Type 2 respiratory failure is often the result of conditions that affect ventilation (e.g., chronic obstructive pulmonary disease). Treatment of type 2 failure requires not only optimizing oxygenation but also supporting ventilation.

PREPARATION FOR AIRWAY MANAGEMENT

AIRWAY EQUIPMENT

Having key equipment at the bedside is a fundamental requirement for optimal airway management. **Table 28-2** provides a model list of equipment.

PREDICTING THE DIFFICULT AIRWAY

Anticipating challenges with airway management is best done before any attempts to intervene. **Table 28-3** lists some factors that may complicate noninvasive airway management.

TABLE 28-2 Sample List of Equipment for Noninvasive Airway Management

Oxygen source and tubing
Tongue blade
Bag-valve mask device
Clear facemasks—various sizes and shapes
Oropharyngeal airways—small, medium, large
Nasopharyngeal airways—small, medium, large
Suction catheter
Suction source
Pulse oximetry
End tidal carbon dioxide detector
Laryngoscope blades and handles
Syringes
Magill forceps
Water-soluble lubricant or anesthetic jelly
CPAP/BiPAP mask and machine
Supraglottic airways: laryngeal mask airway, intubating laryngeal mask airway, Shiley™ esophageal tracheal airway (Covidien, Boulder, CO), King LT® (King Systems, Noblesville, IN)
Backup equipment in the case of unsuccessful NIPPV*†

*See chapter 29, "Intubation and Mechanical Ventilation."

†See chapter 30, "Surgical Airways."

Abbreviations: BiPAP = bilevel positive airway pressure; CPAP = continuous positive airway pressure; NIPPV = noninvasive positive-pressure ventilation.

TABLE 28-3 Predictors of Difficult Noninvasive Airway Management Techniques[2]

BVM ventilation			
	M	Mask seal	Beard, trauma, or other situations that may cause BVM to not seal
	O	Obesity or Obstruction	
	A	Age	Age >55 years
	N	No teeth	
	S	Stiff lungs or chest wall	
Supraglottic airway			
	R	Restricted mouth opening	
	O	Obesity or Obstruction	
	D	Disrupted or Distorted airway	
	S	Stiff lungs or cervical spine	

Abbreviation: BVM: bag-valve mask ventilation.

OXYGENATION

Provide supplemental oxygen to all critically ill patients requiring airway management. The method of oxygenation used depends on the patient's clinical condition and oxygen requirement (**Table 28-4**). Even if the patient is apneic, providing supplemental oxygenation with nasal cannulae can extend the time to hypoxia and hypoxemia, allowing providers additional time to prepare for or attempt airway maneuvers.[3]

PATIENT POSITIONING

The first step in airway management is to optimize patient positioning to facilitate airway patency and subsequent airway management efforts.

Upper airway obstruction occurs in the unconscious patient as the intrinsic muscles of the neck and upper airway relax, causing the epiglottis to obstruct the laryngeal inlet. Although the tongue displaces posteriorly during anesthesia in supine patients, it may not always occlude the pharynx.[4]

The first relief step in upper airway obstructions is extension of the neck with anterior displacement of the mandible. This maneuver moves the hyoid bone anteriorly and, in turn, lifts the epiglottis away from the laryngeal inlet. Forward flexion of the neck in addition to extension ("sniffing" position) may also help to relieve upper airway obstructions and requires less neck extension. This can be accomplished by placing a *folded* towel (not rolled) or foam rubber device underneath the patient's occiput. Neither maneuver should be attempted in patients when there is concern for cervical spine injury.

Oropharyngeal (Oral) Airway An oropharyngeal or oral airway (**Figure 28-1**) is a curved, rigid instrument used to prevent the base of the tongue from occluding the hypopharynx. Use only in a comatose or deeply obtunded patient without a gag reflex. Properly sized oral airways should reach from the corner of the mouth to the angle of the mandible. Place an oral airway with the concave portion of the airway cephalad and rotated 180 degrees after passing the tongue. Alternatively, the concaved portion can be oriented horizontally and rotated 90 degrees, following the curvature of the tongue, after insertion.

Nasopharyngeal (Nasal) Airway A nasopharyngeal or nasal airway (**Figure 28-2**) is made of pliable material and is placed into the nostril, displacing the soft palate and posterior tongue. Nasal airways are helpful

TABLE 28-4 Oxygen delivery methods

	O_2 Flow	FiO_2 Delivered
Nasal cannulae	2–5 L/min	20%–40%
Simple face mask	6–10 L/min	40%–60%
Non-rebreather mask	10–15 L/min	Near 100%

Abbreviation: FiO_2 = inhaled fraction of oxygen.

FIGURE 28-1. An oral airway.

FIGURE 28-3. Bag-valve mask.

in patients with an intact gag reflex absent any midface trauma. Properly sized nasal airways should reach from the corner of the mouth to the angle of the mandible. After lubrication, insert the nasopharyngeal airway in the most patent nostril and horizontal to the palate with the bevel oriented toward the nasal septum.

Bag-Valve Mask Bag-valve masks (BVMs) (**Figure 28-3**) contain a self-inflating insufflation bag coupled with a facemask and a valve to prevent re-inhalation of exhaled air. Effective BVM ventilation requires a good seal and a patent airway. Although typically used with supplemental oxygen, the BVM can aid even when used with room air. Most BVM systems deliver approximately 75% oxygen. A demand valve attached to the reservoir port of the ventilation bag may help to a deliver higher concentration of oxygen.[5] Adequate oxygenation and ventilation with a BVM require a good face–mask seal, which may be difficult in patients with facial trauma, facial hair, or anatomic anomalies or in those who are edentulous.

BVM ventilation is performed using one- or two-person techniques. Two-person techniques deliver greater tidal volumes than one-person techniques and are preferred if possible.[6]

With the one-person approach, the rescuer uses one hand to grasp and seal the mask and the other hand to squeeze the BVM reservoir bag. A common mask-sealing technique is to grasp the mask with the thumb and index finger in a "C" shape while placing the third, fourth and fifth digits in an "E" shape to lift the mandible. During mask ventilation, be careful to keep the fingers *on* the mandible, not compressing the soft tissue beneath (and hence compressing the airway) (**Figure 28-4A**).

In the two-operator approach, one rescuer seals the facemask using both hands, while the other squeezes the reservoir bag. The rescuer sealing the mask may use the same "E-C" approach but with both hands applied to the mask (**Figure 28-4B**). In an alternate modified two-handed technique, the practitioner places the thenar eminence and thumb of each hand on the mask while the remaining digits grasp the mandible (**Figure 28-4C**). Both two-handed techniques provide similar tidal volumes.[6]

FIGURE 28-2. A nasal airway.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NIPPV) provides positive-pressure airway support through a face or nasal mask without the use of an endotracheal tube or other airway device. NIPPV is an initial noninvasive airway management strategy. In adults, NIPPV includes continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP).

NIPPV helps to augment spontaneous respirations. Ideal patients for NIPPV are cooperative, have protective airway reflexes, and have intact ventilatory efforts. NIPPV is not appropriate in patients who have absent or agonal respiratory effort, impaired or absent gag reflex, altered mental status, severe maxillofacial trauma, potential basilar skull fracture, life-threatening epistaxis, or bullous lung disease. Use NIPPV with caution in hypotensive patients because any volume depletion can be worsened from the positive pressure, triggering more hypotension (**Table 28-5**).

NIPPV reduces work of breathing through multiple mechanisms.[7,8] NIPPV improves pulmonary compliance and recruits and stabilizes collapsed alveoli, improving alveoli aeration and ventilation-perfusion mismatches.[1] NIPPV increases both intrathoracic and hydrostatic pressure, shifting pulmonary edema into the vasculature. Increased intrathoracic pressure can also decrease venous return, transmural pressure, and afterload, leading to improved cardiac function. NIPPV also increases tidal volume and minute ventilation, leading to increased Pao_2 and reduction in $Paco_2$. NIPPV reduces work of breathing by 60% and dyspnea scores by 29% to 67%, while improving inspiratory muscle endurance by 14% to 95% over spontaneous respirations.[1] The ability of NIPPV to improve pulmonary function such as forced expiratory volume and forced vital capacity is unclear.[9-11]

CPAP delivers a constant positive pressure throughout the respiratory cycle. **BiPAP** provides different levels of positive airway pressure during inspiration (inspiratory positive airway pressure [IPAP]) and expiration (expiratory positive airway pressure [EPAP]). Although the terms EPAP and positive end-expiratory pressure are often used interchangeably, positive end-expiratory pressure is specific to the end of the respiratory cycle whereas EPAP refers to the pressure administered via the BiPAP machine during the entire expiratory phase. Both CPAP and BiPAP can be used in a variety of patient populations with limited data directly comparing the two methods.

Be aware that different NIPPV devices exist with differing operating mechanisms. Many standard ventilators can provide NIPPV, although in these devices, the inspiratory and expiratory pressures are additive. For example, if the IPAP is set at 5 cm H_2O and the IPAP is set at 15 cm H_2O, the total delivered IPAP may be 20 cm H_2O (5 + 15). There are standalone NIPPV units that can provide both CPAP and BiPAP, allowing for independent setting of inspiratory and expiratory pressures. For example, if the IPAP is set at 5 cm H_2O and the IPAP is set at 15 cm H_2O, the total delivered IPAP will be 15 cm H_2O. Specialized adapters that connect directly to oxygen tanks and wall-mounted oxygen units may provide CPAP for a brief period of time. These devices have a limited range of settings and should be used on a temporary basis.

B

C

FIGURE 28-4. **A.** One-person bag-valve mask ventilation. **B.** Two-handed mask seal. **C.** Modified two-handed mask seal.

TABLE 28-5 Advantages and Adverse Effects of Noninvasive Positive Pressure Ventilation

Advantages	Disadvantages
Reduces work of breathing	Air trapping
Improves pulmonary compliance	Increased intrathoracic pressure leading to decreased venous return, afterload, and cardiac output, and hypotension
Recruits atelectatic alveoli	Pulmonary barotrauma leading to pneumothorax
Less sedation	Respiratory alkalosis
Shorter hospital stay	Abdominal compartment syndrome
Decreased rate of intubation without risks of endotracheal intubation	

INITIATING AND TITRATING NIPPV

Select the mask for NIPPV to create a tight seal while preserving patient comfort. Base the initial settings on the patient's condition and type of respiratory failure. Typical starting settings for CPAP are 5 to 15 cm H_2O. Typical starting setting for BiPAP include "spontaneous" mode with IPAP set to 8 to 10 cm H_2O and EPAP set to 3 to 5 cm H_2O. Be cautious when using NIPPV at pressures >15 cm H_2O because this may increase the intrathoracic pressure, leading to barotrauma along with decreased venous return, decreased preload and afterload, and eventually decreased cardiac output.

NIPPV requires frequent assessment for work of breathing, heart rate, respiratory rate, oxygen saturation, and blood pressure. Arterial blood gas analysis can aid in titrating NIPPV but is not mandatory. EPAP can help open and stabilize collapsed alveoli and reverse hypoxemia. In patients in whom ventilation is an issue, adjust the IPAP settings to help decrease the work of breathing and improve ventilation.

If the patient is not tolerating NIPPV, the first potential cause is an air leak. NIPPV is a flow-limited, pressure support system, and therefore, leaks prevent the machine from reaching the preprogrammed flow rate for a set pressure. As a result, the inspiratory time may be prolonged, making each breath cycle less comfortable for the patient. Potential solutions for air leaks include programming the machine to limit the inspiratory time or selecting alternative modes of ventilation including proportional assist ventilation.[1] Proportional assist ventilation is a form of synchronized ventilatory support where the NIPPV machine generates pressure in proportion to the patient's instantaneous effort such that as the patient generates a greater inspiratory effort, the machine generates greater IPAP. This allows the machine to adjust to air leaks that may impair ventilation and oxygenation with other modes (CPAP and BiPAP). Although proportional assist ventilation has not been shown to improve clinical outcomes, it is better tolerated by some patients.[12]

If the patient is not improving with NIPPV, consider endotracheal intubation and ventilation.

NIPPV Applications The most common use of NIPPV is for **cardiogenic pulmonary edema** where NIPPV may reduce rates of endotracheal intubation, hospital length of stay, and mortality.[13-20] In patients with **chronic obstructive pulmonary disease,** NIPPV is helpful in those with respiratory acidosis.[21] NIPPV may similarly benefit patients with moderate to severe **asthma** exacerbations, although data on effectiveness are limited.[22] Because of the bronchospastic nature of chronic obstructive pulmonary disease and asthma, be vigilant for air trapping and subsequent barotrauma when using NIPPV.

NIPPV may reduce the rate of intubation and in-hospital death in patients with **pneumonia**.[23-25] Exercise caution in this patient group because hypovolemia may coexist, with resultant NIPPV-induced hypotension.

There are reports of NIPPV use in **blunt chest wall trauma,** including **flail chest,** although it does not yet clearly decrease mortality or hospital length of stay.[26-28] NIPPV is also reported in burn patients. Do not use NIPPV in patients with suspected or confirmed high esophageal or tracheal injuries, maxillofacial or basilar skull fractures, or severe facial burns.[29,30]

Prehospital NIPPV Prehospital NIPPV in patients with cardiogenic pulmonary edema and chronic obstructive pulmonary disease decreases the rate of subsequent intubation and mortality.[31-34] When such patients arrive in the ED, assess the response to NIPPV and determine whether to discontinue NIPPV, adjust the NIPPV settings, or change to invasive airway strategies.

NIPPV Complications Complications of NIPPV include difficulty with mask seal, patient discomfort, aspiration (rare), air trapping, pulmonary barotrauma including pneumothorax, and increased intrathoracic pressure leading to decreased cardiac output and hypotension. Monitor patients carefully to determine NIPPV effectiveness and to identify the need to further secure the airway with intubation. Aspiration risk can be minimized by proper patient selection[35]; make sure patients have a gag reflex and do not have altered mental status. Gastric distension and increased intragastric pressure can lead to *abdominal compartment syndrome*, resulting in oliguria, hypoxia, hypercarbia, high peak inspiratory pressures, and even renal failure. A nasogastric tube can decompress the stomach and relieve this syndrome.[36] Although complications are uncommon, evaluate patients frequently to identify any of these complications early.

Occasionally, patients develop anxiety and agitation during NIPPV treatment due to the claustrophobic feeling of the mask or the discomfort of positive-pressure ventilation. Anxiety and agitation can increase the work of breathing and result in NIPPV asynchrony. Although often relieved with encouragement, verbal support, or hand restraints, anxiety and agitation may require the administration of sedatives or anxiolytics. There are no systematic studies of sedation during NIPPV, and sedation practices are typically based on physician preference.[35,37] Avoid agents or doses that cause excess sedation or respiratory depression. Dexmedetomidine, a centrally acting α_2 agent, can provide sedation without decreasing respiratory drive, but its expense and availability limit general use.[38] Benzodiazepines and opiates are commonly used but can be difficult to titrate and may cause respiratory depression.[35,37,38] Haloperidol in low doses may accomplish anxiolysis with less respiratory depression than opiates or benzodiazepines.[37]

SUPRAGLOTTIC AIRWAYS

Supraglottic airways (SGAs) are devices placed in the oropharynx, allowing for oxygenation and ventilation without the use of an endotracheal tube. SGAs are the initial bridge to endotracheal intubation or a rescue device after failed intubation efforts. Although SGAs provide adequate oxygenation and ventilation for short periods of time, they are not used for prolonged ventilation. SGA should not be the initial airway management strategy in any patient needing high inspiratory pressures (e.g., chronic obstructive pulmonary disease) given the seal issues and leak that occur.[39] Although these devices are often used during cardiac arrest care, an animal study suggests that the large cuffs of these devices can impair carotid blood flow during cardiac arrest.[40]

SGAs are most often placed in apneic, unconscious patients; their large cuffs can cause gagging and discomfort in awake patients. Another option is use after deploying a rapid sequence induction medication regimen.41 Providers must confirm proper position of any SGA with end-tidal carbon dioxide and then secure it with tape or commercial holders.[42,43] A number of SGAs are commercially available (**Figure 28-5A–C**).

SHILEY™ ESOPHAGEAL TRACHEAL AIRWAY

The Shiley™ esophageal tracheal airway (Covidien, Boulder, CO; Figure 28-5A) is a plastic double-lumen tube that is inserted blindly. It has a proximal low-pressure cuff that seals the pharyngeal area and a

A

B

C

FIGURE 28-5. Esophageal airways. **A.** Shiley™ esophageal tracheal airway (Copyright ©2014 Covidien. All rights reserved. Used with permission of Covidien, Boulder, CO.). **B.** King LT. **C.** Laryngeal Mask Airway.

distal cuff that seals the esophagus. After placement, the proximal balloon is inflated with 80 cc of air while the distal balloon is inflated with 10 cc of air. During insertion, the device may rest in the esophagus or trachea. To determine the location of the device, first ventilate through the longer blue port; this allows oxygen to be delivered through fenestrations between the proximal and distal balloons. If chest rise is absent, the ETC is in the trachea; switch to ventilation to the shorter, clear/white port. The standard Shiley™ esophageal tracheal airway is sized for patients 5 feet, 6 inches or taller. The Shiley™ is used for patients 4 feet to 5 feet, 6 inches tall. Complication with the Shiley™ include hypoxia (from ventilating the incorrect port), esophageal perforation, and aspiration pneumonitis.[44]

KING LARYNGEAL TUBE (KING LT™)

The King LT™ (King Systems, Noblesville, IN) (Figure 28-5B) is similar to an ETC but has a *single* lumen. A proximal cuff seals the posterior oropharynx while a distal cuff occludes the esophagus. The King LT is placed blindly into the oropharynx until the lip aligns with the device lip line. The balloon is then inflated to a pressure of 60 cm H_2O. After placement, the provider may need to withdraw the King LT slightly to allow it to fully occlude the oropharynx. The King LT is placed in the esophagus >95% of the time, allowing ventilation of the trachea through the multiple fenestrations between the proximal pharyngeal and distal esophageal cuffs.[45] Complications with the King LT are similar to the Shiley™ but also include tongue engorgement whereby the proximal balloon can impair venous drainage of the tongue.[46] Removing the King LT will relieve this condition. The King LT is available in several sizes depending on the patient's height: 4 to 5 feet, size 3 (yellow); 5 to 6 feet, size 4 (red); and >6 feet, size 5 (purple).

LARYNGEAL MASK AIRWAY (LMA™)

The Laryngeal Mask Airway (LMA™; Teleflex, Research Triangle Park, NC; Figure 28-5C) is another SGA placed blindly through the mouth; it occludes the structures around the larynx. The LMA consists of a single cuff inflated with generally 20 to 30 mL of air. To insert the LMA, place a gloved index finger into the oropharynx to guide the device into the oropharynx and position the cuff around the larynx. The LMA is an alternative when the endotracheal tube fails, especially when the vocal cords cannot be visualized, and is successfully placed 88% to 100% of the time.[47,48] There are various models, including an intubating LMA, which allows an endotracheal tube to be passed through the lumen. This permits conversion from an SGA to an endotracheal tube without visualizing the glottis. Complications of the LMA include partial or complete airway obstruction and aspiration of gastric contents, although animal data suggest the LMA may prevent aspiration.[49] The LMA is available in several sizes based on the patient's estimated body weight: 50 to 70 kg, size 4; 70 to 100 kg, size 5; and >100 kg, size 6.

OTHER SUPRAGLOTTIC AIRWAYS

Other SGAs are available including the i-gel® (Intersurgical Inc., Liverpool, NY) and CobraPLA™ (Engineered Medical Systems, Indianapolis, IN). These have not been well studied for emergency care. The i-gel has a soft, gel-like cuff that seals the perilaryngeal structures without inflation. This limits tissue compression that may be caused by devices with large cuffs. Lubricate the gel-like cuff prior to insertion. The device is advanced into the poster pharynx until resistance is met and the lips align with the lip line on the i-gel. The i-gel is available in various sizes for patients from 2 to >90 kg.

The CobraPLA is a cuffed SGA that is inserted blindly similarly to the King LT. The potential advantage of the CobraPLA is that providers can pass an endotracheal tube through the lumen of the device, easing conversion to an endotracheal tube. Like all SGAs, neither of these is used for long-term ventilation or in conditions that may require elevated peak airway pressures, and neither has proven to prevent aspiration. The CobraPLA is available in various sizes for patients from 2.5 to >130 kg.

Converting a Supraglottic Airway to an Endotracheal Tube In general, SGAs may have a higher risk of aspiration than endotracheal tubes, and the large cuffs may cause hypopharyngeal mucosal damage. Thus, although SGAs may play an essential role during emergent airway management, endotracheal tubes are better suited for long-term ventilation. **SGAs do not need to be *immediately* changed to an endotracheal tube.** The urgency for conversion depends on the condition of the patient, the adequacy of oxygenation and ventilation through the SGA, and the reasons for SGA insertion. Strategies for converting an SGA to endotracheal tube include:

- **Remove the supraglottic device and perform direct laryngoscopy.** Determine why the SGA was initially inserted. If the SGA was placed because of intubation difficulty, removing the SGA and attempting direct laryngoscopy is risky, and alternative techniques should be strongly considered. When attempting direct visualization, use airway adjuncts (gum elastic bougie, video laryngoscopy, etc.) to help make laryngoscopy efforts successful.
- **Convert the SGA with a gum elastic bougie (King LT only).** To exchange the SGA over a gum elastic bougie, insert the gum elastic bougie blindly though the King LT into the trachea and then remove the King LT, leaving the gum elastic bougie in place. Then pass a standard endotracheal tube over the bougie. This is a "blind" exchange, meaning that the operator does not visualize the glottis during the conversion. This maneuver is not possible with the Shiley™ or standard LMA.
- **Convert the SGA with a fiberoptic bronchoscope (King LT or LMA).** To convert using a fiberoptic bronchoscope, one must use a special intubating catheter (Aintree; Cook Medical, Inc., Bloomington, IN), which is similar to a bougie but is hollow, allowing placement over a fiberoptic bronchoscope. First, place the catheter over the fiberoptic scope, and then direct the scope into the trachea. Next, remove the fiberoptic scope and SGA, leaving the catheter in the trachea. Finally, direct a standard endotracheal tube over the catheter into the trachea. This technique allows for visualization of the glottis but requires expertise in the use of a fiberoptic bronchoscope. This technique is not possible with the Shiley™.
- **Leave the SGA in place and perform a surgical airway (cricothyroidotomy or tracheostomy).** Providers may elect to convert directly to a surgical airway in cases where an SGA was placed due to difficulties with intubation and if the patient requires prolonged mechanical ventilation. This can be done either in the operating room or in the ED if needed depending on the patient's condition, available resources, and skills of the provider.

CHAPTER 29

Intubation and Mechanical Ventilation

Robert J. Vissers
Daniel F. Danzl

INTRODUCTION

The goals of emergency airway management are maintaining airway patency, assuring oxygenation and ventilation, and preventing aspiration. Tracheal intubation can achieve these goals. Sedation or paralysis after intubation can facilitate diagnostic testing. Extraglottic devices are discussed in detail in the chapter 28, "Noninvasive Airway Management."

Rapid-sequence intubation (RSI) is the sequential administration of an induction agent and neuromuscular blocking agent to facilitate endotracheal intubation. It is the method of choice for emergency airway

management.[1] RSI allows the highest intubation success rate in properly selected emergency airway cases and is superior to sedation alone. Not all patients targeted for intubation are best managed with RSI; patients deeply comatose and those in cardiac or respiratory arrest will not likely have a response to laryngoscopy and may be intubated without pharmacologic assistance.

Whenever performing endotracheal intubation, anticipate airway difficulties and be facile with alternative airway techniques: bag-mask ventilation, rescue airway devices, and surgical access to the airway.[2] In addition, if bag-mask ventilation or rescue device deployment is not likely to succeed or if anatomic alterations exist that will not improve with RSI (edema, mass, bony disruption), do not extinguish intrinsic airway protection and respirations with paralysis.

Develop and discuss an intubation plan, and communicate responsibilities of the care team. Make sure medications are prepared. Have equipment for the difficult or failed airway available. Review proper patient positioning. Discuss the plan for postintubation hypoxia, hypotension, sedation, and ventilation. The use of a checklist may facilitate decision making and error prevention.[3]

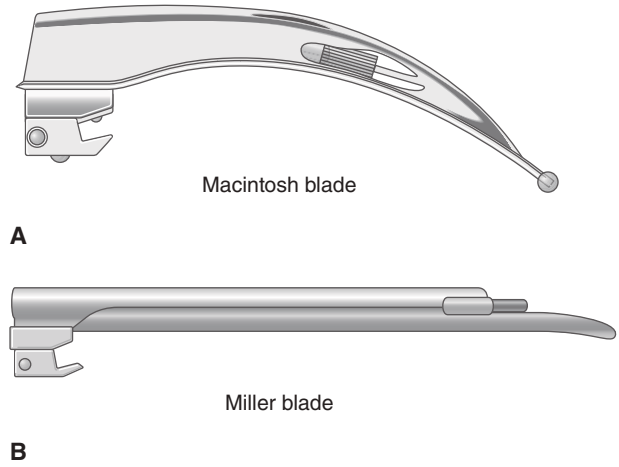

FIGURE 29-1. **A.** Curved or Macintosh blade. **B.** Straight or Miller blade.

OROTRACHEAL INTUBATION

PREPARATION

Clinical assessment, pulse oximetry, capnography, and the expected course of the patient all collectively guide decisions regarding the need for tracheal intubation. See the "Difficult Airway" section below for detailed discussion of airway assessment.

EQUIPMENT

Table 29-1 lists all equipment needed at the bedside before beginning intubation.

Rescue devices and a surgical airway option ideally are placed in a designated difficult airway cart in the ED and include pediatric sizes (see chapter 111, "Intubation and Ventilation in Infants and Children".)

When preparing for intubation, select the appropriate-size endotracheal tube (ETT) and an additional tube (0.5 to 1.0 mm smaller in diameter), and check the cuffs for air leaks with a 10-mL syringe. ETTs with high-volume, low-pressure cuffs are preferred. The approximate sizes for ETTs are 8.0- to 8.5-mm inner diameter for an average adult male and 7.5- to 8.0-mm inner diameter for an adult female. The second hole at the end of the tube above the bevel is called the **Murphy eye**. This hole permits some uninterrupted airflow if the tip is occluded. A stylet can aid emergent intubations, especially when using video laryngoscopy. Test the light on the laryngoscope after attaching the appropriate-size blade.

TABLE 29-1 Equipment Needed for Airway Management

Oxygen source and tubing
Ambu bag
Mask with valve, various sizes and shapes
Oropharyngeal airways—small, medium, large
Nasopharyngeal airways—small, medium, large
Suction catheter
Suction source
Pulse oximetry
Carbon dioxide detector
Endotracheal tubes—various sizes
Laryngoscope blades and handles
Syringes
Magill forceps
Stylets, assorted
Tongue blade
Intubating stylet (gum elastic bougie)
Water-soluble lubricant or anesthetic jelly
Alternative or rescue devices: video laryngoscopes, laryngeal mask airway, intubating laryngeal mask airway, Combitube® (Sheridan Catheter Corp., Argyle, NY), King LT® (King Systems, Noblesville, IN)
Surgical cricothyroidotomy kit
Medications for topical airway anesthesia, sedation, and rapid-sequence intubation

Laryngoscopes have straight or curved blades. The straight **Miller blade** physically lifts the epiglottis to visualize the larynx. The curved **Macintosh blade** tip is placed in the vallecula to indirectly lift the epiglottis off the larynx (**Figure 29-1**). The curved blade may cause less trauma and is less likely to stimulate an airway reflex when used properly, because it does not directly touch the larynx. It also allows more room for adequate visualization during tube placement and is helpful in the obese patient. The straight blade is mechanically easier to insert in many patients who do not have large central incisors. In adults, the curved Macintosh #3 is popular, and #4 is more useful in large patients. The straight Miller #2 and #3 are popular for the same purposes.

There are a variety of other straight and curved blades available; however, the Miller or Macintosh blades are most commonly used in direct laryngoscopy. Video laryngoscopes often use blades that have a much more acute angle to the blade because of the indirect visualization. **Video laryngoscopy** is an alternative to traditional direct laryngoscopy and preferred in some clinical scenarios including morbid obesity, difficult airway, or limited neck mobility.[4]

PROCEDURE

Preoxygenation Begin preoxygenation as soon as possible, even for patients with no apparent hypoxia/hypoxemia. Preoxygenation optimizes blood oxygen content and also displaces nitrogen in the alveoli, creating a potential reservoir of oxygen that may prevent hypoxia and hypoxemia during the first minutes of apnea. Even with adequate preoxygenation, hypoxia develops more quickly in children, pregnant women, and obese patients and in hyperdynamic states. **To preoxygenate, administer 100% oxygen for 3 minutes, using a non-rebreather mask supplied with 15 L/min of oxygen. Nasal cannulas alone do not provide optimal preoxygenation.** Non-rebreather masks typically deliver 60% to 70% oxygen. A bag-mask ventilator, appropriately applied, can deliver 90% to 97% oxygen. This requires a tight seal, with either active bagging or enough inspiratory pressure from the patient to open the one-way valve. There are a number of bag-mask devices that vary in their oxygen delivery; use a bag-valve mask device with one-way inspiratory and expiratory valves.

In patients who have arterial oxygen saturations that remain below 95% despite supplemental oxygen, a short period of noninvasive positive-pressure ventilation may improve the oxygen reservoir. This strategy is particularly effective in obese patients.[5] Elevating the head of the patient 20 to 30 degrees improves preoxygenation. Finally, providing high-flow

nasal cannula oxygen (≥15 L/min) or the Optiflow™ oxygen delivery system (which allows even higher flow) throughout the apneic phase of RSI prolongs the period of safe apnea during paralysis and is wise in all patients undergoing emergent RSI.[5]

Patient Positioning Flex the lower neck and extend the atlanto-occipital joint (sniffing position) to align the oropharyngeal–laryngeal axis for a direct view of the larynx. Padding under the shoulders, not the neck, also improves visualization. For most airway maneuvers, the best position occurs when **the ear is horizontally aligned with the sternal notch**. Inadequate equipment preparation and poor patient positioning are common failure triggers; take the time to do these right before using the laryngoscope. Reposition the patient if initial attempts at viewing the larynx fail.

Sellick Maneuver The **Sellick or cricoid maneuver** (application of direct pressure on the cricoid ring in the unconscious or paralyzed patient) can impair bag-mask ventilation, worsen the laryngoscopic view, and hamper insertion of the tube.[6] Some practitioners still use it to prevent aspiration of gastric contents, although it may trigger vomiting. If the Sellick maneuver is used, apply *cricoid* (not thyroid) pressure and release if visualization does not improve. Aspiration occurs due to low esophageal sphincter tone, depressed protective laryngeal airway reflexes, or stimulation in the patient with upper airway fluids or stomach contents (**Table 29-2**).

Endotracheal Tube Insertion with Direct Laryngoscopy Instructions for ETT insertion are summarized in **Table 29-3**.

Suction at the bedside is critical. The Yankauer catheter is the most common device used, but any large-diameter suction system and tubing that allows for the removal of particulate matter or large clots is acceptable.

ETT insertion without clear cord visualization commonly leads to espohageal placement. Some techniques can help avoid esophageal placement: (1) retracting the right side of the mouth laterally by an assistant aids visualization; (2) using backward-upward-rightward pressure on the thyroid cartilage enhances visualization of the anterior glottis (**BURP maneuver**); and (3) bimanual laryngoscopy, where the intubator manipulates the larynx with the right hand until ideal visualization and then an assistant maintains this position, improves visualization of the vocal cords.[6] To avoid error, make sure you see the cuff of the ETT pass completely through the cords. Finally, abort the attempt if you cannot visualize the larynx.

The endotracheal introducer, also known as the "**gum elastic bougie**"[7] (**Figure 29-2**), may aid and is typically 70 cm in length and made of plastic. The angled tip facilitates insertion when the glottis cannot be fully visualized, although it is not helpful when no visualization exists. Once correctly inserted, you may feel the bougie tip moving over the tracheal rings. Thread the ETT over the introducer into the trachea and then remove the introducer. Never force the tube through the vocal cords, which can avulse the arytenoid cartilages or lacerate the vocal cords.

Most difficulties in passing the tube are a result of the failure to maintain the best possible laryngoscopic view, selecting too large a tube, applying cricoid pressure, or the formation of an undesirable curve on a semi-rigid stylet that is inserted into the ETT. A stylet angle of <35 degrees is more likely to pass through the glottis. Switching to a smaller tube, altering the curve of the stylet, or rotating the tube 90 degrees to align the bevel with the glottic opening are other techniques for eventual success. Do not apply cricoid pressure when inserting the ETT.

Advance the tube until the cuff disappears below the cords. Inflate the cuff with 5 to 7 cc of air. To avoid ischemia of the tracheal mucosa while limiting aspiration and maintaining a seal, target a cuff pressure of 25 to 40 cm H_2O. There is poor correlation between volume of air and tracheal cuff pressure, and if there is concern about cuff pressure, a manometer can be used to measure cuff pressure.

Tracheobronchial Suction After ETT insertion, use a well-lubricated, soft, curved-tip catheter to suction the tracheobronchial tree. Straight catheters usually will pass into the right mainstem bronchus. If a curved-tip

TABLE 29-3 Instructions for Endotracheal Tube Insertion

Step	Comments
1. Hold laryngoscope in left hand.	Holding the laryngoscope at the base, where the blade inserts to the handle, aids proper use and lift; do not hold further up the handle.
2. Use right hand to:	Remove dentures and any obscuring blood, secretions, or vomitus suctioned before insertion of the ETT.
Insert the ETT	Use a properly sized, semi-rigid, malleable, blunt-tipped, metal or plastic stylet to assist with tube placement. The tip of the stylet must not extend beyond the end of the ETT or exit the Murphy eye.
Operate suction catheter.	
Manipulate larynx externally to enhance the visualization.	
3. Insert blade into the right corner of the patient's mouth.	The flange of the curved Macintosh blade will push the tongue toward the left side of the oropharynx.
	If the blade is inserted directly down the middle, the tongue can force the line of sight posteriorly, impairing the view.
4. Visualize arytenoids.	—
5. Lift epiglottis.	Lift the epiglottis directly with the straight blade or indirectly with the curved blade.
6. Expose larynx.	Pull laryngoscope handle in the direction that it points (i.e., 90 degrees to the blade).
	Cocking the handle back, especially with the straight blade, risks fracturing central incisors and is ineffective at revealing the cords.
7. Advance blade incrementally.	Look for the arytenoid cartilages to avoid overly deep insertion of the blade, which is a common error. BURP maneuver may improve visualization.
8. Advance ETT.	Visualize tube *and* cuff passing through vocal cords.
	Correct tube placement is a minimum of 2 cm above the carina (approximately 23 cm in men and 21 cm in women).
	The base of the pilot tube (a tube with the adapter to inflate the cuff) is usually at the level of the teeth.
9. Check ETT placement.	Listen for bilateral breath sounds and the absence of epigastric sounds.
	Confirm placement with colorimetric carbon dioxide detector or capnography.
10. Inflate balloon.	Use 5–7 cc of air. Ask the technician to check cuff pressure to avoid tracheal injury from pressure (target 25–40 cm H_2O).
11. Secure ETT.	Do not impede cervical venous return with umbilical tape or a fixator; circumferential securing devices can cause skin breakdown if too tight or in place too long.
	Use a modified clove-hitch knot or a commercial fixator to avoid kinking the pilot tube.

Abbreviations: BURP = backward-upward-rightward pressure; ETT = endotracheal tube.

catheter is available, turn the head to the right and rotate the catheter to facilitate passage into the left bronchus. The suction catheter should be no larger than half the diameter of the ETT to prevent pulmonic collapse from insufficient ventilation during suctioning. Insert the catheter without suctioning and then slowly remove it while rotating and suctioning over 10 to 15 seconds.

Complications of suctioning include hypoxia/hypoxemia, cardiac dysrhythmias, hypotension, pulmonic collapse, and direct mucosal injury. Intracranial pressure may increase during suctioning due to coughing.

Confirm Endotracheal Tube Location **"When in doubt, take it out."**

Mainstem bronchial or esophageal intubation results in hypoxia or hypoxemia and hypercarbia. There is no clinically reliable substitute for directly visualizing the tube passing through the vocal cords. Other clinical assessments, including chest and epigastric auscultation, tube condensation, or symmetric chest wall expansion, are not infallible. "Breath sounds" from the stomach can be transmitted through the chest after gastric insufflation. You should confirm intratracheal tube positioning with an objective measure.

The two basic categories of confirmatory adjuncts either assess expired (end-tidal) carbon dioxide ($ETCO_2$) or assess misplacement by esophageal detection. Both have advantages provided that the operator knows the limits of each approach.

Capnometers and capnographs measure carbon dioxide in the expired air. The most commonly used capnometric devices in the ED are colorimetric, with a pH-sensitive purple filter paper. Hydrogen ions are formed by contact with carbon dioxide, resulting in color changes that vary with the concentration of carbon dioxide. For example, with the Nellcor Easy Cap II (Nellcor, Boulder, CO), the paper turns yellow after exposure to 2% to 5% $ETCO_2$, which is equivalent to 15 to 38 mm Hg partial pressure of carbon dioxide (PCO_2). No color change occurs (the filter paper remains purple) if the $ETCO_2$ is <0.5%, equivalent to <4 mm Hg PCO_2. Colorimetric capnometers are useful for assessing proper ETT placement but are not accurate enough for precise $ETCO_2$ determinations and cannot exclude bronchial mainstem intubation.

Capnography displays real-time characteristic carbon dioxide waveforms. A persistent positive capnograph formation after clear and direct visualization of tube placement approaches certainty about tube placement. Rarely, a misplaced hypopharyngeal glottic tube tip may result in normal oximetry and capnography in a spontaneously breathing patient. This error is recognized by noting inadequate depth of tube insertion, inadequate ventilatory volumes, or incorrect tube placement on chest x-ray.

Table 29-4 notes conditions associated with false colorimetric or capnographic carbon dioxide readings.

Esophageal detection devices help determine initial tube location and do not depend on adequate cardiac output and pulmonary perfusion—an asset in the cardiac arrest patient. When the ETT is in the esophagus, the soft, noncartilaginous walls will collapse, and air cannot be easily aspirated with an esophageal detector. Esophageal detection devices use a syringe aspiration or a compressible bulb technique. The device is attached to the ETT adapter after intubation but before ventilation. The syringe is then rapidly retracted or the bulb is compressed. Taking advantage of the anatomic differences between the rigid cartilage of the trachea and the collapsible esophagus, syringe aspiration or bulb refilling is rapid when in the trachea. If the ETT tube is in the esophagus, the vacuum causes the esophagus to collapse around the tube, creating resistance to aspiration or preventing the bulb from refilling.

TABLE 29-4 Conditions Associated with False Colorimetric or False Capnographic Carbon Dioxide Readings

False-Negative Reading	Comments
Low pulmonary perfusion—cardiac arrest, inadequate chest compressions during CPR, massive pulmonary embolism	—
Massive obesity	—
Tube obstruction	Secretions, blood, foreign bodies
False-Positive Reading	**Comments**
Recent ingestion of carbonated beverage	Will not persist beyond 6 breaths
Heated humidifier, nebulizer, or endotracheal epinephrine	Transient

After intubation, obtain a chest x-ray to identify mainstem bronchus intubation and to locate the ETT tip. A chest x-ray does not reliably distinguish ETT placement in the trachea from the esophagus.

COMPLICATIONS OF ENDOTRACHEAL INTUBATION

Adverse events include unrecognized esophageal intubation, aspiration, oxygen desaturation, hypotension, dysrhythmia, and cardiac arrest. In the ED, first-attempt success is achieved 80% to 95% of the time.[1,8,9] Higher first-attempt success is associated with more experienced clinicians, trained emergency physicians, the use of RSI, the use of video laryngoscopy, and the absence of predictors of airway difficulty.[4,10] Multiple intubation attempts are associated with increased adverse events; this is why it is important to employ an intubation strategy most likely to lead to first-pass success.[9,11]

Immediate complications include unrecognized esophageal intubation or mainstem bronchus intubation. *Never assume correct positioning and patency after intubation if deterioration is seen.* **Tube displacement can occur during patient movement or if the tube is not properly secured.** Repeated suctioning helps prevent secretions from obstructing the tube or bronchus. Cuff displacement or overinflation obstructs or damages the airway. If tracheal ball-valve obstruction is suspected, deflate the cuff.

If the **ETT cuff leaks** after the intubation, check the inflation valve. A simple remedy for a leaking inflation valve is to attach a three-way stopcock to the valve, re-inflate the cuff, and turn off the stopcock. If the tube needs to be replaced, use a tube changer. Commercially available tube changers are semi-rigid catheters with 15-mm adaptors or connectors to permit ventilation during the tube exchange. Insert the changer into the ETT, withdraw the ETT, and then insert a new ETT over the catheter and reconfirm placement.

Although uncommon, soft tissue injury related to emergent endotracheal intubation does occur. Arytenoid cartilage avulsion or displacement, usually on the right, will prevent the patient from phonating properly after extubation. Other complications include intubation of the pyriform sinus, pharyngeal-esophageal perforation, and development of stenosis. Subglottic stenosis usually occurs in patients with poorly secured tubes who are combative or mechanically ventilated for extended intervals.

RAPID-SEQUENCE INTUBATION

RSI is the simultaneous administration of an induction and a neuromuscular blocking agent to facilitate tracheal intubation and is preferred for emergency intubation (**Table 29-5**).

TABLE 29-5 Rapid-Sequence Intubation Steps

1. Set up IV access, cardiac monitor, oximetry, and capnography/capnometry.
2. Plan procedure incorporating assessment of physiologic status and airway difficulty.
3. Prepare equipment, suction, and potential rescue devices.
4. Preoxygenate and denitrogenate.
5. Consider pretreatment agents based on underlying conditions.*
6. Induce with sedative agent.
7. Give neuromuscular blocking agent immediately after induction.
8. Bag-mask ventilate only if hypoxic; otherwise, provide high flow oxygen during apneic phase. Cricoid pressure during laryngoscopy only, if needed.
9. Intubate trachea after muscle relaxation has been achieved.
10. Confirm placement and secure tube.
11. Provide postintubation sedation and low tidal volume (6 cc/kg start) management.

*It is unclear if pretreatment improves outcome.[12]

Bag-mask ventilation may increase gastric distention and is best deferred in the well-oxygenated patient before laryngoscopy. Once the patient is adequately sedated and paralyzed, perform laryngoscopy and tracheal intubation. Contraindications to RSI are relative and primarily occur when the anticipated airway difficulties suggest that paralysis may lead to a "cannot intubate, cannot ventilate" predicament or when not needed or unlikely to aid (massive edema or fixed anatomic hindrances). Always be prepared for failure and have two alternatives ready, often including rescue airways.

PRETREATMENT AGENTS

Pretreatment agents attenuate adverse physiologic responses to laryngoscopy and intubation; however, data do not show a clear outcome benefit from pretreatment agents.[12,13] Adverse effects from laryngoscopy include a reflex sympathetic response that causes increases in heart rate and blood pressure; this may be harmful in patients with elevated intracranial pressure, myocardial ischemia, and aortic dissection. In children, the vagal response predominates and can result in bradycardia, even in the absence of succinylcholine. Patients without cerebral autoregulation can experience a centrally mediated increase in intracranial pressure. Laryngeal stimulation also can have respiratory effects, including laryngospasm, cough, and bronchospasm. Constraints on time, usually from worsening clinical status, often preclude pretreatment; if pretreatment agents are used, administer them 3 to 5 minutes before initiation of RSI (**Table 29-6**). Finally, the duration and nimbleness of laryngoscopy are the biggest factors in physiologic perturbations; quick and with minimal extraneous movement are best.

Fentanyl can attenuate the reflex sympathetic response to airway manipulation. It may aid in patients in whom a rise in blood pressure and heart rate could be detrimental, such as patients with elevated intracranial pressure and certain cardiovascular conditions (i.e., aortic dissection, ischemic heart disease, and aneurysms). Fentanyl is less likely to produce hypotension in the suggested dose (3 micrograms/kg IV) than other agents with similar effects and has a rapid onset of action. Adverse reactions, such as respiratory depression and chest rigidity, are rare when fentanyl is given in lower RSI doses (3 micrograms/kg IV) and over 30 to 60 seconds.

Pretreatment with atropine limits but does not universally prevent bradycardia in children. It is recommended for symptomatic bradycardia, and not as a routine agent.[13] **Pretreatment with a small dose of a nondepolarizing neuromuscular blocking agent, such as vecuronium or rocuronium in one tenth of full dose, is no longer recommended to alter side effects.**

TABLE 29-6 Pretreatment Agents Considered in Rapid-Sequence Intubation

Agent	Dose	Indications	Precautions
Lidocaine	1.5 milligrams/kg IV/ topically	Elevated ICP	Lack of evidence-based studies on effectiveness in ICP[12]
		Bronchospasm	No evidence of improved outcome and may not be better than inhaled albuterol
		Asthma	
Fentanyl	3 micrograms/kg IV	Elevated ICP	Respiratory depression
		Cardiac ischemia	Hypotension
		Aortic dissection	Chest wall rigidity
Atropine	0.02 milligram/kg IV	Children <5 y with bradycardia	Minimal dose 0.10 milligram
		Children <10 y receiving succinylcholine and with bradycardia	Recommend giving in response to bradycardia, not as routine agent[13]
	0.01 milligram/kg IV	Bradycardia from repeat succinylcholine in adults	

Abbreviation: ICP = intracranial pressure.

INDUCTION AGENTS

There is no single agent of choice for achieving adequate sedation during RSI in the ED. All of the commonly used agents offer advantages and risks in specific clinical conditions (**Table 29-7**).

Etomidate Etomidate, a nonbarbiturate hypnotic, is a popular agent for ED RSI. It protects from myocardial and cerebral ischemia, causes minimal histamine release, has little hemodynamic depression in most patients, and has short duration of action. Myoclonus, nausea, and vomiting can occur in awake patients, but clinically important effects are rare. Etomidate is not an analgesic, and it does not blunt the sympathetic response to intubation. There is no evidence that a single dose of etomidate given in the ED for RSI worsens patient outcomes through cortisol inhibition, even in septic shock, although this can be measured and is key to recognize after use.[14]

Propofol Propofol is a highly lipophilic, rapid-acting sedative that is effective for emergent RSI. Propofol has a more rapid onset of action than etomidate and a shorter duration of action. It has anticonvulsant and antiemetic properties, and it may lower intracranial pressure without triggering histamine release. Propofol can cause hypotension through myocardial depression and vasodilation; for this reason, avoid it in trauma patients and any patient with hypovolemia or hypotension. Trismus and dystonic reactions are rare side effects of propofol.

Ketamine Ketamine, a phencyclidine derivative, is a dissociative induction agent that provides analgesia and amnesia. Ketamine preserves the respiratory drive, an ideal feature for sedation during awake intubation. It causes an increase in blood pressure and heart rate through catecholamine

TABLE 29-7 Preferred Rapid-Sequence Intubation Induction Agents

Agent	Dose	Onset	Duration	Benefits	Caveats
Etomidate	0.3–0.5 milligram/kg IV	<1 min	10–20 min	↓ ICP	Myoclonic jerking or seizures and vomiting in awake patients
				↓ Intraocular pressure	No analgesia
				Neutral BP	↓ Cortisol
Propofol	0.5–1.5 milligrams/kg IV	20–40 s	8–15 min	Antiemetic	Apnea
				Anticonvulsant	↓ BP
				↓ ICP	No analgesia
Ketamine	1–2 milligrams/ kg IV	1 min	10–20 min	Bronchodilator	↑ Secretions
				"Dissociative" amnesia	↑ BP
				Analgesia	Emergence phenomenon

Abbreviations: BP = blood pressure; ICP = intracranial pressure.

release, which is useful in hypovolemic or hypotensive patients. Ketamine causes direct smooth muscle relaxation and bronchodilation and is often used in those with refractory status asthmaticus.

Ketamine does not cause consistent increased intracranial pressure in sedated and ventilated patients, and some studies suggest that the drug has possible cerebroprotective effects.[15] Despite previous theoretic concerns about γ-aminobutyric acid–altering effects that could worsen CNS function, ketamine is a good option in patients with head injury and hypotension. Ketamine is not a preferred agent for the elderly or for patients with a potential for cardiac ischemia, because of the potential for associated tachycardia and hypertension.

Other Agents **Barbiturates** commonly cause hypotension from myocardial depression and venous dilatation; they have been largely replaced with etomidate or propofol. Benzodiazepines may be used when other agents are contraindicated or unavailable, with **midazolam** being the common choice.

PARALYTIC AGENTS

Depolarizing and nondepolarizing neuromuscular blocking agents facilitate RSI (**Table 29-8**). Depolarizing neuromuscular blocking agents have high affinity for cholinergic receptors of the motor end plate and are resistant to acetylcholinesterase. Depolarizing blockade is not antagonized and may be enhanced by anticholinesterase agents. Succinylcholine is the common depolarizing agent.

Nondepolarizing neuromuscular blocking agents compete with acetylcholine for the cholinergic receptors and usually can be antagonized by anticholinesterase agents. **Rocuronium** and **vecuronium** are nondepolarizing agents used in the emergency setting; rocuronium is the most common alternative to succinylcholine in RSI due to its shorter duration of action and its ability to achieve intubating conditions closest to those of succinylcholine (**Table 29-9**).[16] Vecuronium has a longer time of onset, even with the high-dose approaches, making it a less favorable choice in RSI; it is primarily used for ongoing paralysis after intubation.

In the ED, neuromuscular blockade can facilitate tracheal intubation, improve mechanical ventilation, and help control intracranial hypertension. Paralysis improves oxygenation and decreases peak airway pressures in a variety of disorders, including refractory pulmonary edema and respiratory distress syndrome. Neuromuscular blockade limits assessments of neurologic status, and long-term use increases critical illness polyneuropathy and posttraumatic stress disorder. Neuromuscular blockers are neither anxiolytics nor analgesics, so agents targeting these are needed. **Maintain sedation during initial paralysis to avoid patient awareness;** later, some patients can be managed with less or little sedation, but this is not ideal in the emergent setting.

Depolarizing Agent: Succinylcholine Succinylcholine is the most commonly used agent for neuromuscular blockade in ED RSI. Succinylcholine is two joined acetylcholine molecules and is rapidly hydrolyzed by plasma cholinesterase. It has a rapid onset after IV dosing and a shorter duration of action than do the nondepolarizing agents. After brief fasciculation, complete relaxation occurs at 60 seconds, with maximal paralysis at 2 to 3 minutes.[17] Effective respirations resume in 8 to 12 minutes. IM succinylcholine (4 milligrams/kg) will act more slowly and last longer; however, this is best reserved for the rare setting where paralysis is required absent IV access.

TABLE 29-8 Succinylcholine Complications and Contraindications

Clinically important hyperkalemia in patients with:
Burns >5 d old
Denervation injury >5 d old
Significant crush injuries >5 d old
Severe infection >5 d old
Preexisting myopathies
Preexisting hyperkalemia
Fasciculations
Transient increased intragastric, intraocular, and intracranial pressure (? impact)
Masseter spasm alone or with malignant hyperthermia
Bradycardia
Prolonged apnea with pseudocholinesterase deficiency or myasthenia gravis

TABLE 29-9 Paralytic Agents in RSI

Agent	Adult Intubating IV Dose	Onset	Duration	Comments
Rocuronium (intermediate/long)	1 milligram/kg	1–3 min	30–45 min	Tachycardia. Longer duration of action and onset compared to succinylcholine. Most common alternative to succinylcholine in RSI.[15]
Vecuronium (intermediate/long)	0.08–0.15 milligram/kg	2–4 min	25–40 min	Prolonged recovery time in obese or elderly, or if there is hepatorenal dysfunction.
	0.15–0.28 milligram/kg (high-dose protocol)		60–120 min	
Succinylcholine	1.5 milligrams/kg	45–60 s	5–9 min	Provides optimal intubating conditions most quickly. There are several rare but important contraindications (see Table 29-8).

Succinylcholine provides excellent intubation conditions and is the preferred agent for RSI in the ED.[16] In the event of a failed airway, mask ventilation may be required for up to 12 minutes, until the return of spontaneous ventilation. Give the induction agent immediately before succinylcholine to avoid awareness and enhance intubating conditions.

Serum potassium will transiently rise an average of 0.5 mEq/L with succinylcholine, usually without any clinical impact (Table 29-9). A clinically significant or exaggerated hyperkalemic response can occur 5 or more days after a burn, denervation, or crush injury. The exaggerated hyperkalemic response is due to acetylcholine receptor upregulation at the neuromuscular junction, which requires time to occur and thus is not an immediate factor. Patients with preexisting myopathies are at particular risk for a life-threatening hyperkalemic response. **Do not use succinylcholine in patients with suspected preexisting significant hyperkalemia (especially renal failure), myopathies, or myasthenia gravis.**

Other succinylcholine complications are rare. Genetically susceptible individuals may develop malignant hyperthermia after succinylcholine (or after a volatile inhaled anesthetic). Suspect malignant hyperthermia if unexplained rapid fever with muscle rigidity, acidosis, or hyperkalemia occurs after succinylcholine, and treat with IV dantrolene sodium (2.5 milligrams/kg) and temperature control. Patients with acquired or genetic atypical or low plasma cholinesterase may have prolonged paralysis. Cocaine is metabolized by plasma cholinesterase, which reduces the amount of enzyme available for succinylcholine metabolism. **If known plasma cholinesterase deficiency is suspected, use a nondepolarizing agent (usually rocuronium) instead of succinylcholine.**

Nondepolarizing Agents: **Rocuronium** is an intermediate-duration nondepolarizing agent that is an excellent alternative to succinylcholine for RSI.[16] By increasing the dose of rocuronium to 0.9 to 1.2 milligrams/kg, the onset of action approximates that of succinylcholine, but the duration of action is prolonged. There are fewer side effects and contraindications with rocuronium than with vecuronium (Table 29-8).

Vecuronium bromide is an intermediate- to long-acting nondepolarizing agent (Table 29-8). Vecuronium has no cardiac effects. Hypersensitivity reactions are rare, doses are only minimally cumulative, and excretion is biliary. Despite the lack of histamine release, hypotension may occur through other mechanisms that include sympathetic ganglia block and less venous return from altered absent muscle tone and positive-pressure ventilation.

Sugammadex is a reversal agent that encapsulates the molecules of the nondepolarizing agent that are circulating in plasma. It reverses

blockade from rocuronium or vecuronium within minutes. It is not yet approved by the Food and Drug Administration in the United States but is available in Europe. The dose is 2 to 4 milligrams/kg, depending on the intensity of neuromuscular paralysis.[18] Neostigmine, a cholinesterase inhibitor, has cardiac and cholinergic side effects that make its use undesirable, and reversal is not effective anyway until there is evidence of some spontaneous recovery.

VIDEO LARYNGOSCOPY

Video laryngoscopes use an integrated monitor, antifogging mechanisms, and a high-resolution camera to indirectly visualize the glottis. ETT advancement and position are viewed through the video screen. All of the other elements of preparation, preoxygenation, and confirmation of intubation are unchanged.

Video laryngoscopy is either a rescue technique for failed direct intubation or the primary technique for routine and difficult airways. Video laryngoscopy improves glottic visualization and first-pass and overall intubation success rates compared to direct laryngoscopy in the emergency setting.[4,19] It may require a longer first attempt to intubation interval. Success rates as a rescue device in patients who have failed direct laryngoscopy are reported as greater than 90%.[20] Video laryngoscopy is useful in those with potentially difficult airways, notably obese patients and those with limited neck mobility.[21] Avoid video approaches and use direct laryngoscopy if the camera could be obscured by blood or emesis.

Although the video laryngoscope handle has the familiarity of the traditional laryngoscope, the operator performs the intubation watching a video screen rather than looking into the oropharynx. The angle of the blade and transmission to the monitor creates a magnified view and provides views that cannot be obtained through direct laryngoscopy. The device can be used in patients with limited oral opening and with the neck in neutral position. These are advantages in patients with difficult airways or restricted cervical spine mobility. These devices also allow shared visualization and video recording useful for quality review, education, and training.

The two most studied video laryngoscopes are the **GlideScope Video Laryngoscope®** (Verathon, Bothell, WA) and the **C-MAC Video Laryngoscope®** (Karl Storz, Tuttlingen, Germany). Both devices offer a sharp-angled blade that is best used with malleable stylets or rigid stylets designed specifically for this purpose. Blades similar in shape to Macintosh and Miller blades, pediatric sizes, and disposable blades are available. Comparative studies between devices are limited, and no significant difference in success has been clearly demonstrated.

The technique for both blades differs from traditional laryngoscopy, in that a midline insertion is preferred and a tongue sweep is not needed. Once past the teeth, the operator identifies the midline by finding the uvula. The blade is then slowly advanced down the tongue until the epiglottis is seen. The ideal view is usually obtained by insertion into the vallecula, much like a Macintosh blade. The handle is then gently tilted forward until visualization of the glottis opening is obtained.

FIBEROPTIC LARYNGOSCOPY

The flexible fiberoptic laryngoscope is a valuable adjunct when anatomic limitations prevent visualization of the vocal cords.[21] Clinical examples include conditions that prevent opening or movement of the mandible, massive tongue swelling from angioedema, upper airway infections, congenital anatomic abnormalities, and cervical spine immobility. Flexible fiberoptic scopes allow visualization of the posterior pharynx, glottis, and laryngeal structures (**Figure 29-3**).

Use of a fiberoptic scope requires instruction, facility, and practice, often initially in the simulation lab. Fiberoptic scopes allow airway assessment in select patients before attempting intubation. If equipment or expertise is not available in the ED, consult an expert with fiberoptic skills and tools.

Contraindications to fiberoptic intubation are relative. The procedure requires time to set up and usually a compliant, spontaneously breathing patient. Patients needing an immediate airway, with near-complete obstruction, with large bleeding or vomitus, and who cannot be ventilated to maintain saturation, are poor candidates.

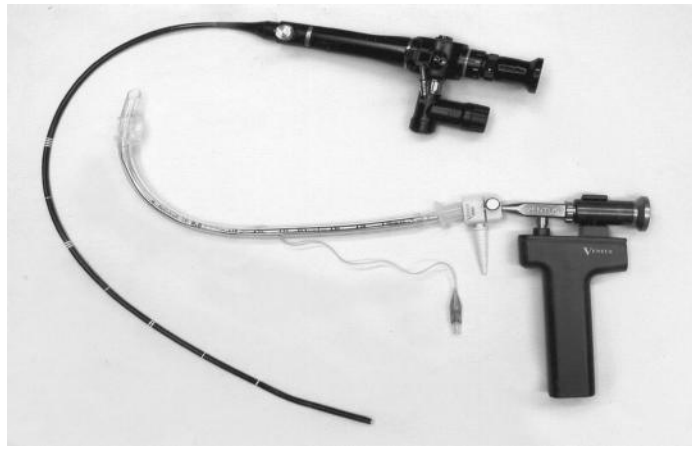

FIGURE 29-3. A fiberoptic laryngoscope and a Shikani endoscope [Clarus Medical LLC, Minneapolis, MN].

Topical anesthesia is essential to fiberoptic intubation success. Use atomized or nebulized topical anesthetics, such as lidocaine or tetracaine. An antisialagogue, such as glycopyrrolate, 0.01 milligram/kg, reduces secretions and enhances topical anesthesia but should be given 20 minutes prior for best effect. Sedation is often required because most patients are spontaneously breathing and aware. If using the nasal route, instill a topical vasoconstrictor such as phenylephrine or oxymetazoline. Nasal viscous lidocaine followed by a nasal airway allows topical anesthesia and enhanced passage of the scope through the airway, although remember to remove the nasal tube prior to the passage of an ETT.

The nasal route allows easier midline airway positioning, and the optic tip enters the glottis at a less acute angle. Oral obstruction, such as tongue or posterior pharyngeal swelling, is a common indication for nasal fiberoptic intubation. If using the oral route, tongue extrusion and anterior mandibular displacement help. Fiberoptic equipment is more frequently damaged transorally, so use a bite block. In the emergent setting, the nasal approach is preferred to the oral route in an upright, awake patient.

To begin the procedure, focus the eyepiece and lubricate the flexible shaft. Immerse the lens at the tip of the laryngoscope in warm water or apply antifogging solution. Newer flexible scopes use video technology, not fiberoptics, and interface directly with video laryngoscope monitors.

Continuously monitor pulse oximetry, and reduce the gag reflex with topical anesthetic. After attaching the oxygen tubing to the suction port, intermittent insufflation of oxygen at 10 to 15 L/min will keep the optic tip clear.

The adapter initially is removed from an ETT. If possible, use a tube that is at least 7.5 mm in inner diameter; slip the lubricated tube over the shaft up to the handle. The distal end of the fiberoptic laryngoscope must extend beyond the end of the ETT. Hold the laryngoscope in the left hand to control tip deflection while advancing it through the cords. The laryngoscope will function as a stylet for the tube. After the laryngoscope is in the trachea, the ETT is advanced, and the laryngoscope is removed.

Another option is to insert a warmed nasotracheal tube into the nasopharynx, stopping just proximal to the posterior pharynx. Dilating with lubricated nasopharyngeal airways before placement can be helpful. Then insert the scope through the ETT, and direct the fiberoptic tip into the glottis. This technique provides the assurance that the tube can be passed and allows the scope to bypass the secretion-laden anterior nares. Advancing the scope through the cords is the greatest technical challenge and requires good glottic anesthesia. Spraying 4% lidocaine through the working channel when the scope is over the glottic opening provides further suppression of the gag or cough reflex. Once the scope is through the cords, the tube is gently passed over the scope in a Seldinger technique. Resistance at the cords is best overcome with tube rotation rather than forceful insertion.

BLIND NASOTRACHEAL INTUBATION

Blind nasotracheal intubation is helpful in situations in which laryngoscopy may be difficult, RSI is contraindicated, and flexible fiberoptics are not available to facilitate nasal intubation. This technique is particularly useful in patients in whom oral intubation is impossible due to obstruction, such as severe angioedema, or with limited oral opening, such as fracture or recent surgery. Severely dyspneic patients with congestive heart failure, chronic obstructive pulmonary disease, or asthma who are awake often cannot remain supine but may tolerate nasotracheal intubation in the sitting position. This technique is now rarely used given the other options available; do not try this in an emergency without prior practice or unless a physician with prior experience is at hand to direct you in the procedure to avoid failure.

To minimize epistaxis, spray both nares with a topical vasoconstrictor anesthetic. Select a cuffed ETT 0.5 to 1.0 mm smaller than optimal for oral intubation. Verify the integrity of the cuff and the tube adapter to ensure a snug fit. Use universal precautions. Insert a nasal airway, first in one nare and then in the other, to determine which is more patent. Select the nare for intubation that is the largest and easiest to maneuver.

Have an assistant immobilize the patient's head and maintain it in a neutral or slightly extended position ("sniffing position"). The intubator stands at the side of the patient, with one hand on the tube and with the thumb and index finger of the other hand straddling the larynx. Advance the lubricated tube along the nasal floor on the more patent side. Facing the bevel against the septum helps minimize abrasions of the Kiesselbach plexus. Steady, gentle pressure or slow rotation of the tube usually bypasses small obstructions. Pass the tube *straight back toward the occiput* (not upward), and then advance it while rotating it medially 15 to 30 degrees until maximal airflow is heard through the tube. Then, gently, but swiftly, advance the tube at the *initiation (upswing) of inspiration*. Entrance into the larynx may initiate a cough, and most expired air should exit through the tube even though the cuff is uninflated. **If the patient can speak, the trachea was not intubated; remove the tube.**

You may palpate or externally see the tube enter the trachea toward the carina. The normal distance from the external nares to the carina is 32 cm in the adult male and 27 to 28 cm in the adult female. Therefore, **the optimal initial depth of tube placement for nasotracheal intubation in adults at the nares exit is 28 cm in men and 26 cm in women**. Confirm the tube placement as with oral intubation, and suction the tube before initiating positive-pressure ventilation.

If nasotracheal intubation is unsuccessful, carefully inspect the neck to identify tube malposition. Most commonly, the tube is in the pyriform fossa on the same side as the nostril used. A lateral neck bulge may be seen or palpated. Withdraw the tube into the retropharynx until breath sounds are heard. Then redirect the tube while manually displacing the larynx toward the side of the previous bulge. If there is no contraindication, flexing and rotating the neck to the ipsilateral side while the tube is rotated medially often is effective. If the tube hangs up on the vocal cords, shrill, turbulent air noises will be heard. The tube can be rotated slightly to realign the bevel with the cords.

The risk of inadvertent intracranial passage of a nasotracheal tube is extremely low. Severe traumatic nasal or pharyngeal hemorrhages are relative contraindications to nasotracheal intubation.

Serious complications of nasotracheal intubation are rare. The most common complication is epistaxis from inadequate topical vasoconstriction, excessive tube size, poor technique, or anatomic defects. Excessive force can damage the nasal septum or turbinates. Retropharyngeal lacerations, abscesses, and nasal necrosis are reported. Once the patient is stabilized, the nasotracheal tube can be electively replaced with an oral tube. If left in place for more than 48 hours, virtually all patients will have evidence of sinus blockage on imaging and many develop clinical infection.

DIFFICULT AIRWAY

The difficult airway is one in which mask ventilation or tracheal intubation fails or is likely to fail. Approximately 1% to 3% of attempts at tracheal intubation fail with standard techniques. *Difficult mask ventilation* is the inability to maintain oxygen saturation above 90% despite optimal positioning and airway adjuncts. *A failed airway* is defined as three unsuccessful attempts at intubation by an experienced operator or failure to maintain oxygenation.[22] The key to difficult airway management is expecting it to happen, preparing with a plan and expertise, and placing the appropriate airway equipment ready in one location at the bedside (**Table 29-10**).

TABLE 29-10 Suggested Difficult-Airway Cart Equipment

Endotracheal tubes: assorted sizes, designs, tip control, fiberoptic
Laryngoscope blades: alternate sizes and designs, fiberoptic (extra bulbs)
Laryngoscope handles: extra batteries
Stylets: Eschmann bougie, semi-rigid, hollow, light wand
Syringes, fixators, and Magill forceps
4% lidocaine, viscous lidocaine
1% phenylephrine (Neo-Synephrine), oxymetazoline
Suction catheters
Rescue devices:
Laryngeal mask airways
Combitube® (Sheridan Catheter Corp., Argyle, NY)
King LT® (King Systems, Noblesville, IN)
A surgical airway option:
Transtracheal jet ventilation equipment
Cricothyrotomy equipment
Tracheostomy tubes
Video laryngoscopy
Diagnostic flexible nasopharyngoscope
Intubating flexible scope

Before any attempt at intubation, assess potential difficulties for bag-valve mask ventilation and laryngoscopy. The presence of two of the following factors increases the likelihood of difficult bag-valve mask ventilation: facial hair, obesity, edentulous patient, advanced age, and snoring. An inability to adequately ventilate with a bag-valve mask is usually solved by better positioning, jaw thrust, a tighter seal with two-person bagging, and the use of oral and nasal airways.[23] A lubricant may improve the seal in a bearded patient; dentures left in place facilitate bag-valve mask ventilation, but remove dentures before any intubation attempt. External features associated with difficult intubation include obesity, a short neck, small or large chin, buckteeth, high arched palate, and any airway deformity due to trauma, tumor, or inflammation.

Most studies of airway difficulty use a grading system identified through laryngoscopic view. Such methods are not practical in the ED. A simple, systematic, and rapid evaluation of the airway is used to predict a potentially poor laryngoscopic view before RSI and neuromuscular blockade.[22,24] The mandibular opening in an adult should be at least 4 cm, or **two to three fingerbreadths**. The ability of the mandible to accommodate the tongue can be estimated by the distance between the mentum and the hyoid bone, which should be **three to four fingerbreadths**. A small mandible is more likely to have a tongue obstruction impairing visualization during laryngoscopy. An unusually large mandible also may impair visualization by elongating the oral axis. A high, anterior larynx is possible if the space between the mandible and top of the thyroid cartilage is narrower than two fingerbreadths. The degree to which the tongue obstructs the visualization of the posterior pharynx on mouth opening has some correlation with the visualization of the glottis. Assess this with the **Mallampati criteria**, with classes III and IV being associated with poor visualization and higher failure rates (up to 5% and 20%, respectively; **Figure 29-4**). The *Mallampati approach is limited in that it requires an upright patient who can open his/her mouth spontaneously*; attempting this in a supine patient or with a tongue depressor will not accurately predict laryngoscopic views.

Neck immobility interferes with the ability to align the visual axes by preventing the desired "sniffing position." Neck immobility can occur

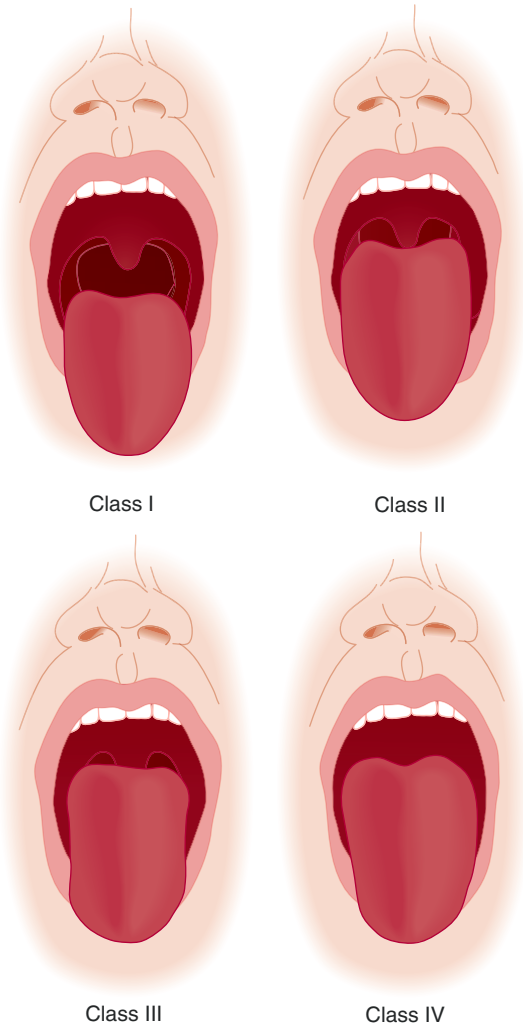

FIGURE 29-4. Classification of tongue size relative to the size of the oral cavity as described by Mallampati and colleagues. Class I: Faucial pillars, soft palate, and uvula can be visualized. Class II: Faucial pillars and soft palate can be visualized, but the uvula is masked by the base of the tongue. Class III: Only the base of the uvula can be visualized. Class IV: None of the three structures can be visualized.

from a cervical collar or structural changes that include fracture, dislocation, or arthritis. If there is no suspicion of cervical injury, assess atlanto-occipital extension; if unimpeded, laryngoscopy will likely be easier.

Airway obstruction presents another challenge to airway management. If evidence of obstruction is present, consider the location of the obstruction, whether it is fixed (e.g., tumor) or mobile (e.g., epiglottis), and how rapidly it is progressing. The location may determine which approach or rescue device can be used. Oral airway obstruction from angioedema of the tongue may limit the physician to nasal techniques or a surgical airway (see chapter 30, "Surgical Airways"). Bag-valve mask ventilation is more likely to be successful in mobile as opposed to fixed obstruction. The speed of progression determines whether the patient can await alternative management elsewhere.

MECHANICAL VENTILATORY SUPPORT

Ventilators are pressure or volume cycled. Volume-cycled ventilators are used routinely in EDs. Decisions with regard to mechanical ventilatory support in the ED include the rate, mode, fraction of inspired oxygen, minute ventilation, and use of positive end-expiratory pressure.

There are three common ventilator methods for providing the tidal volume: continuous mechanical ventilation, assist-control, and synchronized intermittent mandatory ventilation. Continuous mechanical ventilation is most commonly used in the operating room for heavily sedated or paralyzed apneic patients. The **assist-control mode** is preferred initially for patients in respiratory distress, allowing inspiration triggered by either the intrinsic effort or an elapsed time interval. The ventilator provides a "controlled" breath at a predetermined tidal volume during the selected time cycle or sooner if triggered by the patient's effort. In the **synchronized intermittent mode**, a predetermined number of ventilator-generated tidal volumes exists, and ventilation is synchronized to patient effort. If the intrinsic respiratory rate is below the set rate, synchronized intermittent mode acts like the assist-control mode. However, if the patient is breathing above the set respiratory rate, the efforts are not assisted; this increases the work of breathing, making synchronized intermittent mode undesirable in the ED. Initial ventilator settings and goals can be found in **Table 29-11**. Obtain an arterial blood gas after initiation of mechanical ventilation to ensure proper ventilation.

TABLE 29-11 Initial Ventilator Settings and Goals

Ventilator Parameters	Ventilator Settings
Mode	Assist-control
FIO_2	Begin with 100% oxygen
Tidal volume	6 mL/kg (ideal body weight) to start
Respiratory rate	12 breaths/min
Inspiratory flow rate	60 L/min
Inspiratory:expiratory ratio	1:2 or 1:3 ratio
Positive end-expiratory pressure	Begin with 5 cm H_2O, titrate to 10 cm H_2O
Ventilation goals	PaO_2: 60–90 mm Hg $PaCO_2$: 40 mm Hg pH: 7.35–7.45 FIO_2 of 40%–60% Inspiratory peak pressure <35 cm H_2O

Abbreviations: FIO_2 = fraction of inspired oxygen; $PaCO_2$ = partial pressure of arterial carbon dioxide; PaO_2 = partial pressure of arterial oxygen.

Adjust initial mechanical ventilation based on responses to oximetry, capnography, and plateau pressures.[25] Minimize plateau pressures and tidal volumes to reduce the risk of lung injury. Tidal volumes of 6 cc/kg are best for lung protection. In some cases, such as obstructive airway disease, hypercapnia is tolerated to achieve lower plateau pressures. Positive end-expiratory pressure, starting at 5 cm H_2O and titrating to 10 cm H_2O if tolerated, can prevent alveolar collapse and improve oxygenation. Unless a contraindication exists, elevate the head of the bed 30 degrees to prevent aspiration and ventilator-associated pneumonia and improve lung recruitment. A prone position aids to improve lung segment recruitment, although this is not often started in the ED and is usually deployed after paralysis and the other measures fail. When possible, titrate oxygen to less than 60% to prevent oxygen toxicity.

Maintain patient sedation and analgesia initially during mechanical ventilation, particularly if the patient is paralyzed.[26] This is usually best achieved with an initial bolus followed by an IV infusion titrated to need. Intermittent boluses are reserved for anticipated short-term mechanical ventilation (**Table 29-12**). The goal is the optimal sedation (not deeper or longer than needed) for comfort and to allow recovery; targeting clinical assessments of sedation, blood pressure, and heart rate are common. The goals include amnesia, pain control, and the ability to ventilate without neuromuscular blockade if possible. Later, sedation withdrawal is an option based on response and can limit postextubation cognitive changes.

EXTUBATION

This maneuver is not common in the ED but may be required in settings of rapid recovery or after prolonged ED care. Before extubation, assess respiratory sufficiency by determining inspiratory capacity—it should be at least 15 mL/kg. Ideally, there should be no intercostal or suprasternal reactions, and the patient hand grip should be firm.

TABLE 29-12 Sedation During Mechanical Ventilation

Drug	Initial Bolus	Starting Infusion	Comments
Fentanyl	1-2 micrograms/kg IV	0.5–1 microgram/kg/h	Often combined with midazolam
Remifentanil	1.5 micrograms/kg IV	0.5–1 microgram/kg/h	Ultra-short-acting
Midazolam	0.05 milligram/kg IV	0.025 milligram/kg/h	Often combined with fentanyl
Propofol	0.5 milligram/kg IV	20-50 micrograms/kg/min	Can cause hypotension
Ketamine	0.5–1 milligram/kg IV	0.5 milligram/kg/h	May provide bronchodilation; sympathetic stimulation

After suctioning secretions and ensuring ongoing adequate oxygenation, explain the procedure to the patient. Positive-pressure ventilation with a mask will help while the cuff is deflated. *Remove the tube at the end of a deep inspiration.* Continue giving oxygen by mask to prevent secretory reaccumulation.

Observe closely for stridor after extubation. Postextubation laryngospasm is treated initially with positive-pressure oxygen or using a high-flow oxygen (including an Optiflow™) delivery system. If necessary, nebulized racemic epinephrine (0.5 mL of 2.25% epinephrine in 4 mL of saline) helps when stridor suggests laryngospasm or upper airway edema secondary to tube placement and removal.

CHAPTER 30

Surgical Airways

Michael D. Smith
Donald M. Yealy

INTRODUCTION

Establishing an airway by means of a surgical approach—incision or percutaneous insertion—is a challenging procedure deployed at high-risk and high-stress moments when basic airway maneuvers have failed. **The key is preparation and practice, which means having all equipment ready and available** (often in a common cart to ensure consistency) **and prior practice** in laboratory settings if not recently performed in clinical care. Knowing what options are available and then choosing one and implementing it before respiratory collapse will improve the outcome. The success rates depend largely on the preparedness of the ED and the training of the staff.[1,2]

Surgical cricothyrotomy refers to incision of the cricothyroid membrane under direct visualization and insertion of a tracheostomy tube either directly through the incision or by using the Seldinger technique. **Needle cricothyrotomy** is a dated term referring to insertion of a 12- to 16-gauge needle catheter into the trachea and connected to either a bag-valve device or wall oxygen. **We do not recommend needle cricothyrotomy. Percutaneous transtracheal jet ventilation** uses a 12- to 16-gauge catheter inserted into the cricothyroid membrane and connected to a high-pressure (35 to 50 psi) oxygen source for both oxygenation and ventilation.

PATIENT SELECTION

The primary indication for surgical airway placement is a "can't intubate, can't ventilate" scenario. Most emergency surgical airways follow a failed attempt to establish an oral endotracheal airway. Cricothyrotomy or jet ventilation can be used before laryngoscopy and direct glottic intubation if the latter is likely to fail because of anatomic impingement or any other cause that impedes visualization, notable blood, secretions, swelling, or foreign matter. *It is not necessary to try to intubate once before moving to cricothyrotomy*; this often simply enhances the risk of harm.

TABLE 30-1 Clinical Manifestations Associated with Acute Airway Obstruction

Etiology	Manifestation
Vascular	Hematoma External hemorrhage Hypotension Hemoptysis
Laryngotracheal	Stridor Subcutaneous air (massive) Hoarseness Dysphonia Hemoptysis
Pharyngeal and/or hypopharyngeal	Subcutaneous air Hematemesis Dysphagia Sucking wound

Difficulty in establishing an airway may be due to anatomy (short, obese neck), a disease state (epiglottitis, laryngeal edema, paralyzed vocal cords, or retropharyngeal abscess), trauma from distortion of the neck by hematoma (cervical fracture or major vessel injury), aspiration of blood (facial trauma), or loss of supporting structures (mandibular fractures). Assess for these factors before any laryngoscopic attempts, have a surgical airway plan in mind, and have equipment ready at the bedside to manage impending or actual respiratory failure.

In a patient with a failed intubation attempt, the best course of action is to use bag-valve mask ventilation to restore or maintain gas exchange while regrouping. If bag mask ventilation is successful, try another attempt at laryngoscopy with a different operator and approach, rather than performing immediate cricothyrotomy. Clinical signs and symptoms of airway obstruction—one common reason to choose a surgical airway—are listed in **Table 30-1**.

PATIENT AGE

Most children do not require advanced airway management, especially a surgical airway. In children under 12 years, the larynx is more easily damaged by cricothyrotomy, and placement is challenged by compressible structures and less distinction between cartilages. Late airway complications, especially stenosis, occur more often in children.[3] **For children under 12 years old, especially those under 8 years, tracheotomy is preferred**; the difficulty is that few emergency physicians have experience performing this successfully, making it an unavailable practical option. Alternatively, a 14- to 16-gauge catheter inserted percutaneously through the cricothyroid membrane to either oxygenate (temporizing for minutes, done by connecting the catheter to high-flow wall oxygen) or jet ventilate (connecting to 0.5 psi/kg compressed gas source, using a 1:3 second insufflation/expiration ratio) is an option while awaiting tracheotomy. Neither technique is well studied, although jet ventilation offers wider capabilities but requires specific equipment ready in advance. Again, the key to success is advance thought, planning, and equipment preparation coupled with training for this specific event. Needle/jet approaches are discussed in more detail later.

INJURIES REQUIRING OPEN OR PERCUTANEOUS CRICOTHYROTOMY

Penetrating trauma to the neck affecting a major artery (carotid, vertebral, or thyroid) may create an expanding hematoma and obstruct the

FIGURE 30-1. Tracheostomy tube with obturator. [Photo used with permission of David Effron, MD.]

airway. If free blood spills into the oro- or hypopharynx, direct visualization for intubation is often not possible. Placing a cuffed tracheostomy tube after cricothyrotomy is the best option to restore gas exchange and limit aspiration. Difficulty in establishing an airway occurs in approximately 10% of patients with penetrating cervical trauma.[4]

Blunt trauma to the neck or face may cause hemorrhage of the soft tissues or injury to the trachea/larynx, including rupture. **If the trachea or larynx is disrupted, *do not* attempt cricothyrotomy**; in this rare setting, an emergency tracheostomy is needed. In blunt facial trauma, the principal cause of death is airway obstruction from bleeding (often from fractures) or soft tissue swelling; a surgical airway can prevent death and harm if deployed quickly and with skill.

TYPE OF EMERGENCY AIRWAY AND TUBE SELECTION

Cricothyrotomy is preferred over percutaneous approaches (except for children <12 years old). The most skilled provider should perform this procedure to optimize success and limit harm.

Although any large-bore tube is adequate, we suggest using a **tracheostomy tube** because it has an obturator to ease insertion, is shorter and easier to suction, and secures well by using the flanges on each side and a cloth ribbon around the neck or suturing to nearby skin (**Figure 30-1**). When an endotracheal tube is placed during cricothyrotomy, the tube is difficult to secure and may be advanced too deeply; it also may be inadvertently directed cephalad (the wrong way) when placed through the cricothyrotomy incision. To avoid this, many use a gum elastic bougie to ensure tracheal placement and the correct tube direction.[5] If a standard endotracheal tube is used and then designated for change to a tracheostomy tube, use the Seldinger (change over a guide device) technique. Use a suction catheter with the suction vent cut off at one end as an obturator for endotracheal tube removal and tracheostomy tube insertion.

The diameter of the tube inserted is crucial. A common choice for an adult is a **6-mm tracheostomy or 6- to 7-mm endotracheal tube**. **Do not choose a larger (≥7 mm) tube or one smaller than 4 mm.** Larger tubes are difficult to insert in the narrow space between the cricoid and thyroid cartilages. If airway pressures are high with the small-diameter tube or ventilation is inadequate, consider changing to a larger diameter tube. Ventilation problems may occur when a smaller tube is used (3-mm internal diameter or less.) Any tube with a 4- or 5-mm internal diameter will allow adequate volume ventilation in most patients, although at 4 mm there is limited area for suctioning and aggressive minute ventilation; for that reason, select a 4- to 5-mm size only if a 6-mm tube is unavailable or cannot be placed.

SURGICAL CRICOTHYROTOMY

ANATOMY

The cricothyroid membrane is located between the thyroid and cricoid cartilages (**Figure 30-2A**). Both structures are easily palpated but are not directly seen because they are covered with the pretracheal fascia. In men, the thyroid cartilage is prominent and creates the "Adam's apple"; in women and children, the thyroid and cricoid cartilages can be hard to distinguish from each other.

The cricothyroid membrane is found approximately one-third the distance from the manubrium to the chin in the midline in patients with normal habitus (**Figure 30-2B**). In a patient with a short, obese neck, the membrane may be hidden at the level of the manubrium. In a patient with a thin, long neck, it may be midway between the chin and the manubrium. The thyroid gland overlies the trachea; both structures are difficult to palpate. One easy way to find the cricoid membrane is to slowly palpate the trachea as you move up toward the head from the sternal notch; when your fingers "fall off" after a firm structure, you have palpated the thyroid cartilage. Next, slowly palpate downward toward the feet, and the first "soft spot" after that thyroid cartilage is the cricoid membrane.

The vascular structure potentially injured during the course of a properly performed cricothyrotomy is a thyroid artery, a branch of the aorta running up to the thyroid gland in the midline. This vessel infrequently reaches the level of the cricothyroid membrane. A carotid injury is potential when landmarks are not seen or not adhered to or when technique is poor; this can be catastrophic and requires immediate direct pressure to avoid harm.

EQUIPMENT

The equipment needed to perform a surgical cricothyrotomy is listed in **Table 30-2**.

PATIENT PREPARATION AND POSITIONING

Place the patient supine, with the neck slightly hyperextended if no cervical trauma is present (neutral if there is suspected trauma) so neck structures can be palpated and identified. If time permits, apply antiseptic solution to the skin. Ventilate with a bag-valve mask connected to 100% oxygen while preparing.

PROCEDURE

The procedure for performing a surgical cricothyrotomy is summarized in **Table 30-3**.

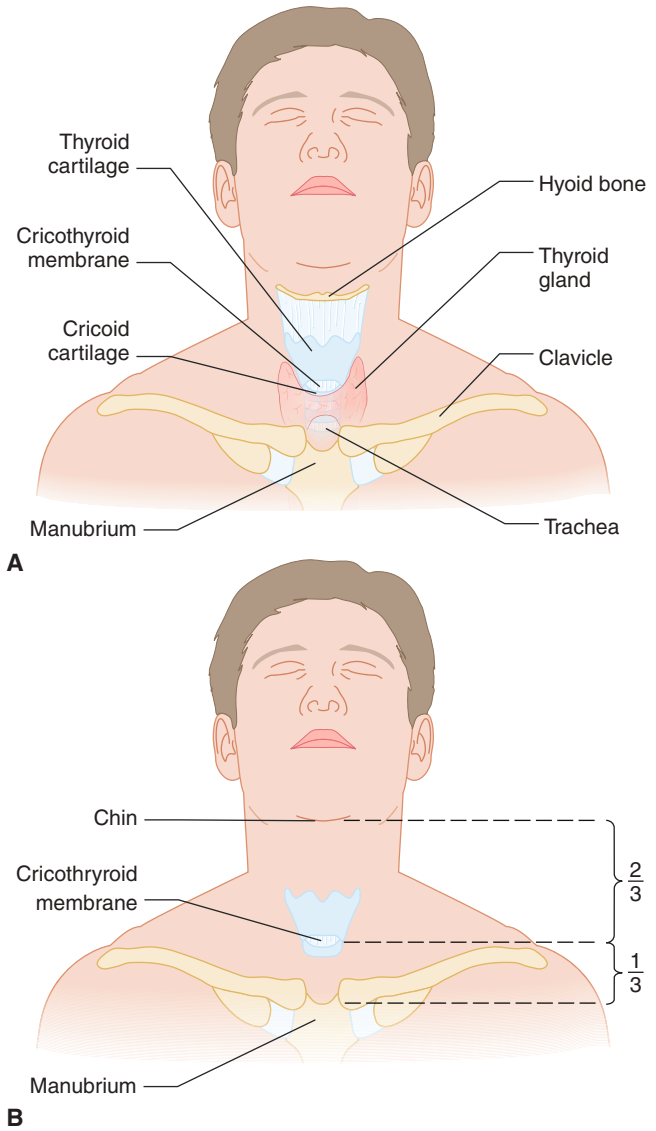

FIGURE 30-2. **A.** Neck anatomy. **B.** Location of the cricothyroid membrane.

SURGICAL CRICOTHYROTOMY USING SELDINGER TECHNIQUE

This method uses the Seldinger technique (**Figure 30-8**). Make a small vertical incision through the skin at the cricothyroid membrane. Insert the needle and aspirate air to make sure the needle is in the trachea. Next, pass the guide wire through the needle, directing the guide wire caudally. Place a tracheostomy tube over the dilator, and make a "nick"

TABLE 30-2 Equipment Needed to Perform a Surgical Cricothyrotomy

Personal protective equipment
Scalpel with a #10 (preferable because of its greater width) or #11 blade
A 6-mm endotracheal tube or tracheostomy tube (latter preferred), plus a smaller one available
Tape to secure the tube in place
Cloth ribbon and sutures to secure tracheostomy tube in place
Bag-valve mask device and oxygen source
Gum elastic bougie for guiding tube
Suction devices

TABLE 30-3 Performing a Surgical Cricothyrotomy

Step	Comment
1. Stand to one side of the patient at the level of the neck.	Right-handed practitioner—stand on the patient's right side. Left-handed practitioner—stand on the patient's left side.
2. Locate the cricothyroid membrane.	Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring), or use "fall off and return" approach noted earlier. Roll the index finger one finger breadth above to locate the membrane between the cricoid and thyroid cartilages (**Figure 30-3**).
3. Using the thumb and middle finger of the nondominant hand, stabilize the two cartilages.	—
4. Use the scalpel to make a vertical incision in the midline between the two cartilages, extending if needed.	Incise through the skin and subcutaneous tissues. The structures are superficial, so do not incise deep to avoid damage to the cricoid or thyroid cartilage or vascular structures (**Figure 30-4**). The membrane is felt, not directly seen, after incision.
5. With the scalpel blade positioned horizontally, perforate the cricothyroid membrane so that the blade goes in approximately half its length.	The horizontal orientation is in anatomic alignment with the membranes to avoid vascular injury (**Figure 30-5**). **Once the membrane is perforated, do not leave it empty**; slide forceps or dilator around the blade or place a bougie before removing the scalpel.
6. Widen the incision opening.	A dilator or mosquito or Kelly clamp may be used (**Figure 30-6**).
7. Place the tube in the opening.	Although instinct may guide you to direct the tracheostomy tube posterior, remember that the trachea is superficial and the tube should follow the tracheal axis (**Figure 30-7**).
8. Connect to a bag-valve mask device for ventilation. Check for breath sounds with ventilation.	If no ventilation is heard bilaterally, pull the tube out and reinsert it. Recheck for breath sounds to ensure that the endotracheal tube is correctly positioned after any manipulation. When inserting a standard endotracheal tube, listen for asymmetry of breath sounds. If breath sounds are absent on the left side, then the tube has been inserted down the right mainstem bronchus and needs to be pulled back a few centimeters. If using an endotracheal tube, insert no more than 2–3 cm to avoid mainstem bronchus placement.
9. Secure the tube carefully with a ribbon and/or adhesive tape.	More challenging with a standard endotracheal tube.
10. Apply dressing and further secure the tube.	If a tracheostomy tube has been used, fashion a simple dressing by cutting a slit halfway down the middle of a 4×4 gauze dressing and placing it under the tracheostomy tube. Secure the tube with a ribbon placed through the flanges of the tracheostomy tube. For added security, use 2-0 nylon sutures to fix the tube to the skin. Consider changing endotracheal tubes to tracheostomy tubes whenever possible.

FIGURE 30-3. Locate the cricothyroid membrane. [Photo used with permission of Jennifer McBride, PhD, and Michael D. Smith, MD.]

FIGURE 30-4. Make a midline vertical incision. The pretracheal fascia is seen through the incision. Bleeding is less likely with a vertical incision. [Photo used with permission of Jennifer McBride, PhD, and Michael Phelan, MD.]

FIGURE 30-5. Perforate the cricoid membrane with a horizontal incision. [Photo used with permission of Jennifer McBride, PhD, and Michael Phelan, MD.]

FIGURE 30-6. Widen the opening. [Photo used with permission of Jennifer McBride, PhD, and Michael Phelan, MD.]

in the skin to ease penetration. Then pass the dilator, with the tracheostomy tube, over the guide wire into the trachea. Once the dilator is in the trachea, remove the guide wire, direct the tracheostomy tube into the trachea, and verify correct placement. Indications and complications are similar to the open method, and direct comparisons in real use do not exist. Multiple commercial kits exist, but proper use requires deliberate, repetitive training.

COMPLICATIONS

Acute complications after emergency cricothyrotomy occur in up to 15% of cases.[6] Venous bleeding usually occurs from small veins and stops spontaneously. Using a vertical neck incision that is not too long decreases the chance of ongoing bleeding. Arterial bleeding can be from the thyroid artery or from a small artery at the base of the cricothyroid membrane. The first step in controlling ongoing bleeding is to apply gentle pressure. If bleeding persists, topical hemostatic agents or ligation may be necessary. A small amount of bleeding usually creates no hemodynamic concerns, but it can make the procedure more challenging.

In an obese patient, it is possible to place the tube anterior to the larynx and trachea into the mediastinum, making ventilation impossible.

FIGURE 30-7. Insert a tracheostomy tube with obturator. [Photo used with permission of Jennifer McBride, PhD, and Michael Phelan, MD.]

FIGURE 30-8. Placement of a percutaneous cricothyrotomy with a commercial kit and the Seldinger technique. [Photo used with permission of David Effron, MD.]

Signs of an incorrectly positioned tube are high airway pressures, absent breath sounds, and massive subcutaneous emphysema. If this complication is suspected, remove the tube and make a second attempt at insertion. Endotracheal tubes passed through the cricoid membrane may curl toward the mouth, making ventilation impossible. A gum elastic bougie can help direct the endotracheal tube.[5]

Laceration of the trachea, esophagus, or recurrent laryngeal nerves is rare and is more likely to occur if one is unfamiliar with the neck anatomy. Pneumothorax is usually secondary to barotrauma caused by ventilation initiated immediately after tube placement.

A tube left in the narrow space between the cricoid and thyroid cartilages can erode both cartilages, and bacterial chondritis may occur. The cartilages will be destroyed and eventually scar, leading to stenosis and loss of the function of the larynx. Because cricothyrotomy has a high incidence of airway stenosis,[6] a change to tracheostomy is common after 2 to 3 days.

PERCUTANEOUS CRICOTHYROTOMY AND TRANSTRACHEAL JET INSUFFLATION

We do not recommend "needle cricothyrotomy"—defined as a 12- to 16-gauge needle catheter inserted into the trachea and connected to either a bag-valve device or wall oxygen—as a rescue technique. Although many texts and general guidelines discuss this approach, it **will not** reverse ventilation gaps and will only modestly aid oxygen delivery.[7,8] In addition, the use of needle cricothyrotomy requires rapid reestablishment of a proper airway.

The only small catheter option is ***correctly performed jet ventilation***. The proper equipment must be procured and maintained and the procedure must be practiced, because many physicians lack the proper equipment and knowledge of the procedure.[9] **Do not perform jet ventilation without the correct high-pressure equipment ready in advance and without antecedent practice**; one cannot simply "put this together" at the time of critical need.

Jet ventilation uses a small catheter but also a pressured oxygen source—35 to 50 psi (much high than exiting standard bag-valve devices and oxygen wall outlets) to deliver 500 to 12,000 cc of gas. In jet ventilation, the catheter and high-pressure gas provide volume inhalation, and the native airway is the *passive* exhalation route. **With proper jet ventilation, adequate oxygenation and ventilation occur.**[10] Duration is limited only by airway desiccation from nonhumidified gas, an effect that takes hours to a day to occur. **Properly performed jet ventilation does not create hypercarbia** or the need for *rapid* reestablishment of another airway; only poorly performed or "needle cricothyrotomy" low-pressure techniques create that situation.

Jet ventilation does not harm the lower airways because the high pressure dissipates rapidly; it also allows some aspiration control as the expelled gas clears the upper airway. The only absolute contraindication is complete, including expiratory, airway obstruction; this is exceptionally rare because most upper airway obstruction is inspiratory, including obstruction from masses. Relative contraindications are unfamiliarity, not having the equipment ready, and local infection at puncture site.

ANATOMY, INDICATIONS, AND CONTRAINDICATIONS

The anatomy and general indications are listed in earlier in "Surgical Cricothyrotomy."

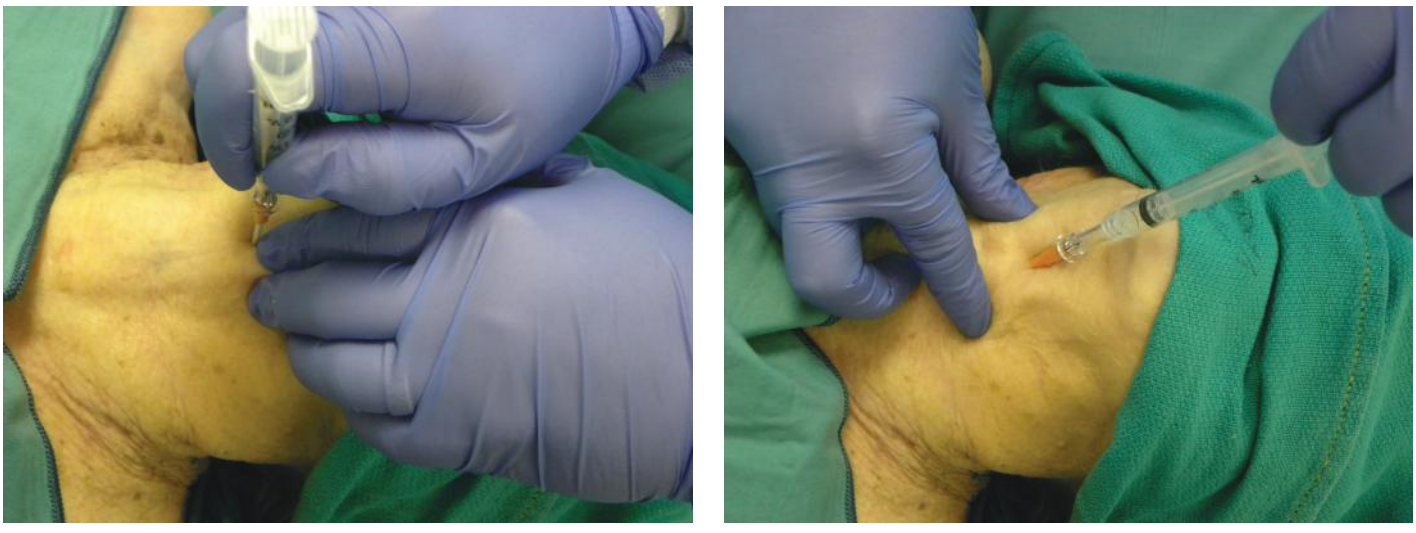
EQUIPMENT NEEDED

Equipment needed for transtracheal jet ventilation is listed in **Table 30-4**. The key is having this prepared in advance; **trying to use standard oxygen tubing, three-way stopcocks, or bag-valve devices or attaching to wall outlets turned to highest liter flow will not allow for proper jet ventilation**.

PROCEDURE

The steps of performing jet ventilation are summarized in **Table 30-5**. Optimize preprocedural oxygenation and ventilation if possible (although often failure is the reason for the procedure).

TABLE 30-4 Equipment Needed to Perform Jet Ventilation



Personal protective equipment
A 16 gauge or larger sheathed needle catheter or a commercial jet catheter
A 3-mL syringe
Connective tubing and connectors designed for high pressure (not standard oxygen tubing/securing attachments; these will not allow jet ventilation)
High-flow regulator with insufflation control
A high-pressure oxygen source; your respiratory technician can have the jet insufflator attached to an E cylinder or wall unit before downregulation to ensure high-pressure (35–50 psi) gas

TABLE 30-5 Performing Jet Ventilation

Step	Comment
1. Stand to one side of the patient at the level of the neck.	Right-handed practitioner—stand on the patient's right side. Left-handed practitioner—stand on the patient's left side.
2. Locate the cricothyroid membrane.	Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring). Roll the index finger one finger breadth above to locate the "hollow" between the cricoid and thyroid cartilages, locating the cricothyroid membrane (Figure 30-3).
3. Attach a 3-mL syringe to the catheter.	Smaller catheters tend to kink easily, as noted in photos, and limit gas flow. Use of a 16-gauge or larger, commercial catheter is preferred (13 gauge).
4. Introduce the catheter into the subcutaneous tissue at a 45-degree angle to the skin, aiming toward the patient's feet.	**Figure 30-9.**
5. Aspirate gently while advancing the catheter over the needle.	
6. When air suddenly returns (indicating entry into the airway), advance the catheter over the needle into the larynx.	Free air aspiration = intratracheal placement; any resistance means not clearly in trachea.
7. Once fully inserted, remove the needle and reaspirate to ensure ongoing free air aspiration.	If resistance to air aspiration occurs after advancement, remove catheter and retry. **Once the catheter is fully inserted, a stabilizing hand *must* always be present**; do not ever let the proximal end be unsecured.
8. Attach the high-flow regulator via connective tubing to the catheter and start ventilation with a 100% oxygen source. If a child, use 0.5 psi/kg to start and a 16-gauge catheter (**Figure 30-10**).	Connect to a high-pressure source (35–50 psi); bag-valve devices and **standard wall oxygen valves opened to 15 L/min do *not* deliver 35–50 psi**. The jet device is attached directly to wall unit before standard regulators or directly to E cylinder (latter will allow >30 min of ventilation if full). Insufflate by holding valve down (open) for maximum of 1 s, and then release the occlusion for 4 s. Listen for symmetric breath sounds, watch the chest rise and fall, and measure exhaled CO_2 if desired.
9. Hold the catheter securely to avoid dislodgement. The catheter tends to kink easily, so maintain care with positioning.	The inspiration:expiration of 1:4 allows passive exhalation and avoids over ventilation. Monitor like any volume ventilation technique.
10. Stabilization is similar to cricothyrotomy, and plan for next airway; gas exchange will be adequate for a prolonged interval, allowing a careful and controlled approach.	Dressings are not necessary, and commercial kits have straps like tracheostomy tubes. The exhaled gas offers some aspiration protection.

COMPLICATIONS

Complications from the jet ventilation procedure are infrequent. Failure to properly secure the catheter can lead to displacement. Bleeding at the puncture site and infection may occur. Inadvertent perforation of the esophagus or back wall of the trachea or larynx is rare. Massive subcutaneous emphysema can develop during ventilation. The catheter also may be misplaced in the soft tissues of the neck. Even if the cricoid membrane is not used (from misidentification), jet punctures rarely cause long-term airway complications, an advantage over cricothyrotomy.

A B

FIGURE 30-9. Introduce the catheter into the larynx. A. Introduce the catheter into the larynx skin at a 90-degree angle to the skin. B. When air returns, change the angle to 45 degrees. [Photo used with permission of Jennifer McBride, PhD, and Michael D. Smith, MD.]

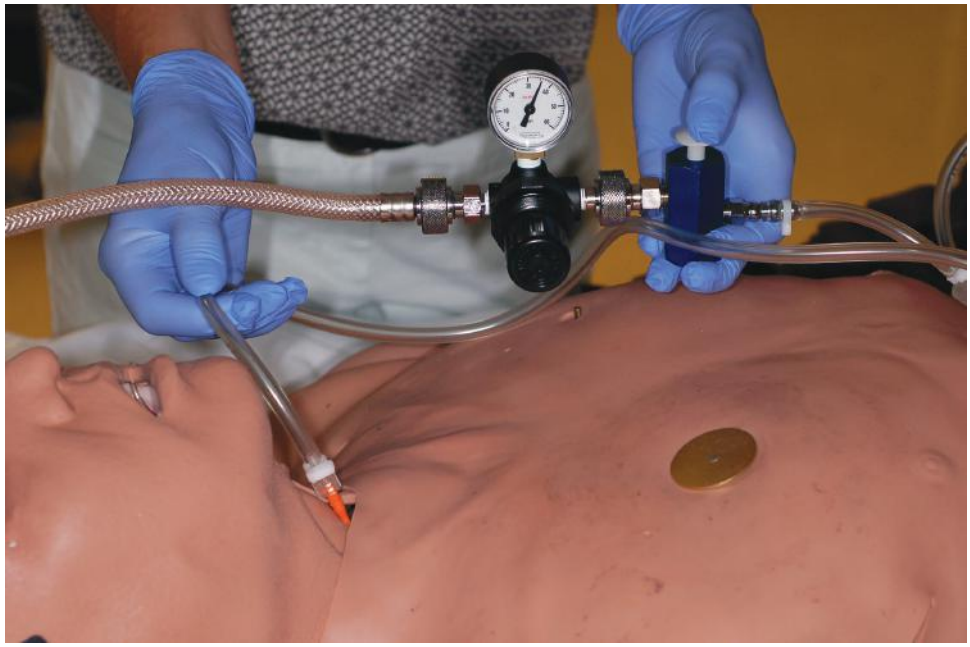


FIGURE 30-10. Attach the high-flow regulator via connective tubing to the catheter and start ventilation with high-pressure 100% oxygen source. Note: Stabilize catheter at the base to avoid dislodgement (not done in figure for display purposes). [Photo used with permission of David Effron, MD.]

DEVICE REMOVAL

Jet ventilation allows a more controlled approach to airway management; plan the next step(s) carefully and without fear of ventilation failure if done properly, avoiding any rush to another procedure. Often, a better laryngoscopic attempt or a formal tracheostomy can occur once time pressures are abated with jet ventilation.

CHAPTER 31

Vascular Access

Chris Wyatt

Multiple factors determine the route and site for vascular access, and knowing the basic anatomy, techniques, indications, and contraindications is essential to emergency care.

Infusion rate is key in the resuscitation of those with severe hypovolemia or hemorrhage.[1] Infusion rates through a medical catheter behave according to Poiseuille's law:

$$\text{Rate of flow} = \frac{\pi \times (\text{catheter radius}^4) \times \text{pressure gradient}}{8 \times \text{viscosity} \times \text{length of catheter}}$$

The rate of flow is directly proportional to the catheter radius and the pressure gradient, and inversely proportional to the dynamic fluid viscosity and catheter length. Flow rates increase with larger catheter radius, use of more pressure (gravity, manual push-pull devices, pressure bag application, or commercial rapid infusing devices), decreasing viscosity (co-administration of crystalloid with viscous blood products), or decreasing catheter length (peripheral angiocatheter vs triple-lumen catheter). **Flow rates are maximized by using the largest internal diameter catheter possible.**

PERIPHERAL VENOUS ACCESS SITES

PERIPHERAL VENOUS ANATOMY OF THE UPPER EXTREMITY

The most commonly accessed veins for peripheral catheterization of the upper extremity are the dorsal hand veins and the veins of the antecubital fossa (**Figure 31-1**).

Peripheral catheterization of the superficial veins of the lower extremity can require cutdown of the great and small saphenous veins. The femoral vein is the primary deep vein of the lower extremity. It is located medial to the femoral artery.

TECHNIQUE FOR PERIPHERAL VENOUS ACCESS

Gather all equipment before beginning the procedure (**Table 31-1**). Observe universal precautions. The procedure for peripheral IV line insertion is summarized in **Table 31-2**.

Avoid venous access through or distal to areas of infection, injury, or sites of potential vascular disruption (e.g., injury to the inferior vena cava from abdominal trauma). Also avoid using extremities with arteriovenous fistulas or grafts or those in which there have been previous lymph node dissections. If possible, avoid IV access of the lower extremity in diabetics due to an increased risk of infection and phlebitis. Do not use peripheral venous access to administer vasopressors for infusion, sclerosing solutions, concentrated electrolyte or glucose solutions, or cytotoxic chemotherapeutic agents.

POSTPROCEDURE CARE

Flush peripheral catheters with normal saline every 8 hours; change dressings that are damp or soiled, and change the catheter site every 72 to 96 hours.[2] Risk of infection and thrombophlebitis increases with time. Assess the skin for signs of infection (erythema) or infiltration (induration, edema). Reassess catheter function and neurovascular status of the distal extremity frequently.

Complications The complications of peripheral venous access are listed in **Table 31-3**. **The first step in treating all complications is catheter removal.**

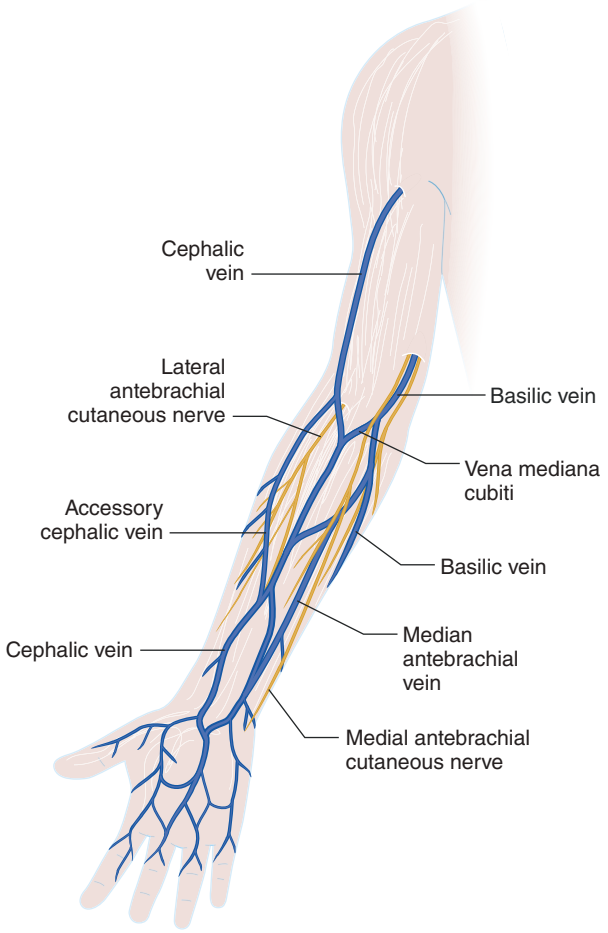

FIGURE 31-1. Venous anatomy of the upper extremity.

TABLE 31-2 Peripheral IV Line Insertion

Step	Comment
1. Apply tourniquet.	Apply tourniquet tightly enough to facilitate adequate venous filling and distention without causing patient discomfort or ischemia.
2. Locate vein.	Inspect and palpate the vein. Warm the skin, tap the vein, or apply topical nitroglycerin ointment to ease identification.
3. Clean area with either an alcohol swab or povidone iodine solution.	—
4. Apply gentle traction with the nondominant hand to anchor the vein.	—
5. Insert catheter needle into skin and vessel at a 15- to 30-degree angle with dominant hand.	Peripheral veins are easiest to access at the apex of the "Y" formed by merging veins or where veins are straight for several centimeters. Use a more obtuse (60-degree) angle for deeper veins.
6. Observe for blood flash in catheter hub.	This indicates successful vessel penetration.
7. Gently advance catheter into vessel lumen until the hub is flush against the skin.	See **Figure 31-2**. If you meet resistance, withdraw the catheter slightly, as it may have penetrated the posterior vessel wall.
8. Remove tourniquet.	—
9. Attach IV tubing and monitor for flow.	—
10. Secure catheter with tape and a sterile transparent dressing.	—

US-GUIDED PERIPHERAL ACCESS

US can localize veins with inconsistent anatomic relationships or those too deep to palpate. US-guided peripheral IV placement results in high success rates, few complications, and a decreased need for central vein cannulation.[5,6] The cephalic and brachial veins, which are not readily palpable, are easily located and cannulated using US guidance.

When inserting an IV using US guidance, use a high-frequency linear transducer. Vascular structures are anechoic (black) in US imaging. Key sonographic characteristics help distinguish veins from arteries. Veins are more easily compressed, have thinner walls, and have no arterial pulsation. Color flow may also help differentiate between the two structures. A centimeter scale on the US monitor indicates the depth of the vessel.

To locate a vessel, view it in short axis (transverse plane) and long axis (sagittal plane), then center the vessel on the screen. The midpoint of the screen correlates with the midpoint of the transducer. Introduce the catheter into the skin at the transducer's midpoint and direct it toward the vessel lumen. Use a longer catheter (2.5 in. or 6.4 cm) for deeper vessels. Watch the screen as the catheter enters the vessel lumen. Secure the catheter and apply a sterile dressing to the IV line.

TABLE 31-1 Materials for Peripheral IV Line Placement

CENTRAL VENOUS ACCESS

The indications for central venous catheterization are listed in **Table 31-4**. The indication for direct central venous access in the setting of resuscitation of cardiac arrest is debated.

CENTRAL VENOUS ANATOMY

The most frequent sites used for central venous access are the internal jugular, subclavian, and femoral veins (**Figures 31-3 and 31-4**). The external jugular vein, a superficial structure, also provides a route to the central circulation but is technically a peripheral site.

The clavicles, first ribs, sternum, sternocleidomastoid, platysma, and other strap muscles of the neck overlie the internal jugular and subclavian veins (Figure 31-3). The internal jugular vein lies lateral to the internal carotid artery inside the carotid sheath. The internal jugular vein joins the subclavian vein to form the brachiocephalic vein.

The subclavian vein crosses under the clavicle at the medial to proximal third of the clavicle. The subclavian artery lies posterior and superior to the brachiocephalic vein. The thoracic duct joins the left subclavian vein at its junction with the left internal jugular vein. The domes of the pleura lie posterior and inferior to the subclavian veins and medial to the anterior scalene muscles.

The femoral vein is the most accessible central vein below the waist. It travels in the femoral sheath with the femoral artery, nerve, and lymphatics deep to the medial third of the inguinal ligament. A mnemonic for the anatomy of the femoral structures from lateral to medial is NAVEL: nerve, artery, vein, empty space, and lymphatics.

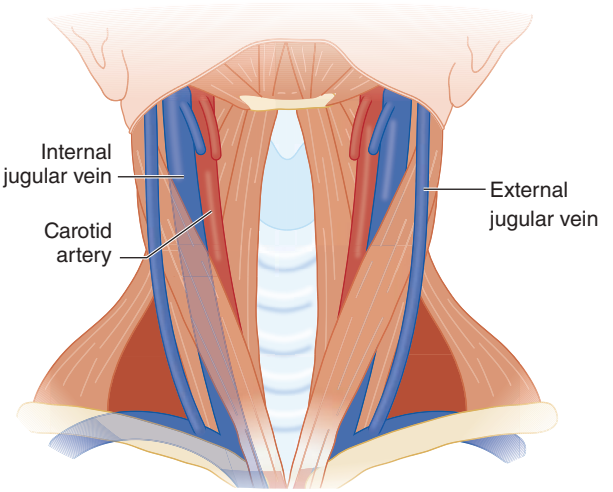

FIGURE 31-3. Vascular anatomy of the neck.

TABLE 31-3 Complications of Peripheral Venous Access

Complication	Comment
Hematoma formation and pain	Prevent hematomas by removing the tourniquet before needle removal and applying direct pressure to site after removal.
Extravasation of fluids	Apply cool or warm compresses and elevate extremity. Monitor site for tissue damage and necrosis.
Phlebitis (vein inflammation)	Occurs in 2%–13% of catheterized veins.[3,4] Presents as discomfort or pain at the catheter site with warmth, erythema, and tenderness along the vein. A palpable cord may also be present. Give anti-inflammatory medications. Apply warm compresses.
Cellulitis	Infection rates with peripheral IVs are relatively low. Typical organisms include *Staphylococcus epidermidis, S. aureus,* and *Candida.* Treat with antibiotics effective against suspected pathogens. Infection can be reduced by using sterile technique during IV placement and routine handling.
Neurovascular injury	—
Bacteremia/sepsis	—
Deep vein thrombosis	—
Tissue necrosis	—

TABLE 31-4 Indications for Central Venous Catheterization

Inability to obtain peripheral access
Access to central circulation needed for procedures (pulmonary artery catheter placement, transvenous pacemaker placement, or urgent hemodialysis)
Measurement of central venous pressure (sepsis, congestive heart failure, pericardial effusion)
Administration of sclerosing medications, continuous vasopressors, concentrated ionic solutions, or cytotoxic chemotherapeutic agents

TECHNIQUE FOR CENTRAL VENOUS ACCESS

After gaining consent if possible, identify the access site and approach and position the patient. Prepare all materials before the procedure (**Table 31-5**). Use a procedure checklist to optimize infection prevention practices.

The technique for all approaches is summarized in **Table 31-6** and depicted in **Figure 31-5**.

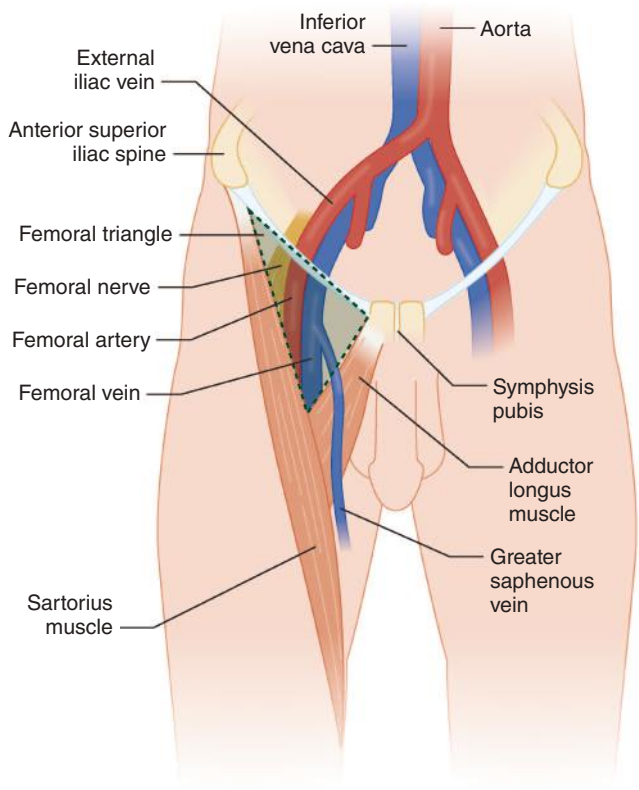

FIGURE 31-4. Vascular anatomy of the torso and lower extremities.

TABLE 31-5 Materials for Central Venous Catheterization

Sterile personal protective gear (gloves, gown, mask, hair cover)
Sterile drape and towels
Sterile prep solution (povidone-iodine or chlorhexidine)
3 × 10-mL syringes containing sterile normal saline flush
Central venous catheter set containing:
1% Lidocaine, small-gauge needle and syringe
18-Gauge introducer needle
Guidewire
#11 Blade scalpel
Venodilator
Single- or multilumen catheter
4 × 4 gauge pads
3-0 or 4-0 silk suture with straight needle or with needle driver
Sterile transparent dressing

COMPLICATIONS

Complications of central venous catheterization are listed in **Table 31-7**.

Complication rates increase with each additional attempt or percutaneous puncture. Accidental arterial puncture during internal jugular cannulation can lead to hematoma formation and airway compromise. Carotid arterial puncture may result in acute plaque rupture and stroke in patients with known carotid artery stenosis or atherosclerosis. Femoral lines often become infected and thrombose (nearly 20% each in some studies) and so are avoided for longer use. Do not use the subclavian approach in patients with coagulopathy because accidental subclavian arterial puncture or injury is not amenable to direct vascular compression.

US-GUIDED CENTRAL VENOUS ACCESS

US-guided central venous access increases first attempt success rates and decreases the number of attempts needed for success when compared to the unassisted standard method. Complication rates are similar in both techniques. The technique of US-guided central venous access is similar to peripheral venous access described previously.

TECHNIQUES OF COMMONLY USED APPROACHES

External Jugular Vein The external jugular vein is readily available due to its superficial location in the subcutaneous tissue overlying the sternocleidomastoid muscle. Place the patient in the head-down position or use Valsalva maneuvers to distend the vein and improve visualization. Entering a central vein via the external jugular vein is difficult and rarely successful without using a J wire; it is often not required because the site accommodates large-volume flow. Puncture the skin at a 10-degree angle. Placement is aided by tilting the head to the contralateral side, applying skin traction to "straighten" the course of the vein, and by rotating the guidewire 180 degrees before re-advancement if the first pass fails.

Internal Jugular Vein • *US-Guided Approach* The internal jugular vein is easily located with US guidance.

Place the probe on the sternocleidomastoid muscle (**Figure 31-6**). Identify the thyroid gland and carotid artery in addition to the internal jugular vein. Do not attempt needle insertion before visualizing all three structures.

Traditional Approaches The three traditional approaches to internal jugular vein catheterization are central, posterior, and anterior. The right internal jugular has a shorter, straighter course to the superior vena cava and avoids injury to the thoracic duct on the left; use this site unless contraindications exist.

Central Approach Place the patient in Trendelenburg position, head slightly tilted to the contralateral side. The landmark for the central approach is the triangle created by the clavicle and the sternal and clavicular heads of the sternocleidomastoid. The internal jugular vein lies just deep to this triangle. Insert the needle at a 30- to 45-degree angle to the skin, 1 cm below the apex of the triangle, parallel to the carotid artery located medially, and directed toward the ipsilateral nipple (**Figure 31-7**). Successful venous return typically occurs within 1 to 3 cm of needle advancement.

Posterior Approach The landmark for the posterior approach is the lateral aspect of the clavicular portion of the sternocleidomastoid, one third of the distance from the clavicle to the mastoid process. The needle is directed toward the sternal notch (**Figure 31-8**). Successful venous return typically occurs within 3 to 5 cm of needle advancement.

Anterior Approach Identify the pulse and course of the carotid artery, which lies just medial to the site of entry for the anterior approach. Hold the carotid artery with fingers of the nondominant hand. Hold the needle and syringe in the dominant hand at an angle of 30 to 45 degrees and enter at the midpoint of the medial aspect of the sternal portion of the sternocleidomastoid muscle. Aim the needle toward the ipsilateral nipple (**Figure 31-9**). Successful venous return typically occurs within 3 to 5 cm of needle advancement.

See **Table 31-8** for a summary of traditional approaches to internal jugular vein catheterization.

Subclavian Vein The location of the subclavian vein allows patient mobility and is an excellent choice for longer-term use.

US-Guided Approach The supraclavicular approach allows good sonographic visualization of the proximal subclavian vein anatomy. The infraclavicular approach to US-guided subclavian vein catheter placement is limited by the large acoustic shadow created by the clavicle (**Figure 31-10**).

Traditional Approaches The two traditional approaches to the catheterization of the subclavian vein are the infraclavicular and supraclavicular (**Figure 31-11**).

Infraclavicular Approach Place the patient head down and in a neutral position with a small towel under the thoracic spine to help identify the clavicle. The landmark for the site of entry is the junction of the middle and medial thirds of the clavicle. Orient the bevel of the needle inferomedially to direct the guidewire to the brachiocephalic trunk rather than the internal jugular vein. Align the numbered markings on the syringe with the bevel of the needle to guide the orientation of the bevel once the needle has breached the skin. Place the index finger of the nondominant hand at the suprasternal notch and the thumb at the midpoint of the clavicle. Direct the needle toward the suprasternal notch at a 10-degree angle parallel to the surface of the chest (**Figure 31-12**). If the clavicle is encountered, "walk" the needle down the clavicle until the needle is posterior to it. Successful venous return occurs typically at a depth of 3 to 5 cm.

Supraclavicular Approach The supraclavicular approach is often referred to as the "pocket-shot." The supraclavicular approach has fewer failures, fewer catheter malpositions, and less interference with CPR than the

Preprocedure Checklist for Central Line Access

Before the procedure, did the provider:

- Perform a time out to ensure right patient, right location/side?
- Cleanse hands immediately prior?
- Sterilize procedure site and allow site to dry?
  - 30 s for dry site
  - 2 min for moist site (femoral)
- Drape the patient from head to toe with a large sterile drape?

During the procedure:

- Did the provider wear sterile gloves, cap, mask, and gown?
- Did assisting physician(s) follow the above precautions?
- Did the provider maintain sterility of tray, site, field, and gloves at all times?
- Did ALL staff in room wear a mask?
- Was unnecessary traffic in and out of the room prevented during the procedure (did the door remain closed)?

After the procedure, did the provider:

- Apply a dated sterile dressing?

TABLE 31-6 Seldinger Technique* for Insertion of Central Venous Line

Step	Comments
1. Gown in sterile fashion.	Use sterile gloves and gown. Wear mask and hair covering.
2. Identify vessel—US guidance preferred over landmarks.	—
3. Prep and drape patient using standard sterile procedure.	Prep a wide area so an alternate site can be used if initial attempts fail. Prep the entire ipsilateral neck and upper chest when preparing to insert an internal jugular or subclavian catheter.
4. Open the central catheter kit. Inspect for content in a sterile fashion. Place kit close to bedside and operator. Maintain sterile conditions.	—
5. Anesthetize area in all conscious patients.	Inject area with 1%–2% lidocaine. Anesthetize the periosteum of the clavicle if using the subclavian approach. Reorient to landmarks after injection.
6. Hold the 18-gauge introducer needle on a 10-mL syringe in the dominant hand and align the needle to the target.	—
7. Advance the needle slowly though the skin and subcutaneous tissue until a flash of dark venous blood appears.	Maintain steady constant aspiration of syringe.
8. Stabilize the needle with the nondominant hand.	—
9. Check for continued free venous flow with aspiration.	If no flow is noted, withdraw the needle slightly, as the needle may have breached the posterior vessel wall.
10. Remove the syringe attached to the needle and immediately occlude the catheter with a finger.	This maneuver helps to prevent introducing air in the catheter and subsequent central system air embolism.
11. Insert the guidewire gently through the needle. Always maintain a firm grip on the wire—do not let go of the wire for any reason.	The wire should advance with minimal resistance. Do not force the wire for any reason. If the wire does not pass easily, reattach the syringe and aspirate to confirm continued venous flow. Reposition the needle as needed. Premature ventricular contractions or dysrhythmias during wire advancement may indicate that the wire is in the right atrium or beyond.
12. Remove the needle over the wire when the guidewire is inserted at least 10 cm into the vessel.	—
13. Incise the skin with a #11 blade scalpel at the entry site to accommodate the venodilator or catheter.	Do not cut the guidewire.
14. Advance the dilator or catheter over the guidewire into the vessel lumen with a gentle twisting motion.	—
15. Remove the dilator (if used), and advance the catheter over the wire until the wire is advanced through the distal port.	Maintain a grip on the guidewire during this procedure.
16. Grab the end of the guidewire.	—
17. Advance the catheter to the appropriate depth.	—
18. Remove the guidewire.	It is easy to "lose" the wire; if you cannot find it after a procedure, immediately obtain an x-ray to seek retention.
19. Aspirate and flush all ports to confirm catheter function.	—
20. Secure catheter with suture and apply a sterile transparent dressing.	—
21. Confirm catheter placement in the superior vena cava with chest x-ray.	A catheter tip in the right atrium can perforate the right atrium and cause hemothorax or hemomediastinum with pericardial tamponade. Examine the chest x-ray for signs of complications.

infraclavicular approach. It may also be performed in the upright position in patients unable to lay supine in the setting of severe orthopnea.

The landmark for entry is 1 cm lateral to the clavicular head of the sternocleidomastoid and 1 cm posterior to the clavicle. Enter at an angle of 10 degrees above horizontal. Orient the bevel of the needle medially, bisecting the angle formed by the clavicle and sternocleidomastoid toward the contralateral nipple. Successful venous return typically occurs at a depth of 2 to 3 cm (**Figure 31-13**).

COMPLICATIONS

The risk of pneumothorax is higher when cannulating the subclavian vein. If attempts at subclavian venous access fail on one side, assess for pneumothorax using chest x-ray or US before attempting cannulation on the contralateral side.

Femoral Vein The femoral vein is the most accessible central access site during critical illness, notably cardiac arrest.

US-Guided Approach Place the transducer in a transverse position just below the midportion of the inguinal ligament. Identify the femoral vein just below the inguinal ligament and medial to the femoral arterial pulsation. The vein is more easily compressed than the artery. The relationship among the vessels varies depending on limb position (**Figure 31-14**).

Traditional Approach Place the patient supine in reverse Trendelenburg position with the hip slightly abducted and leg slightly externally

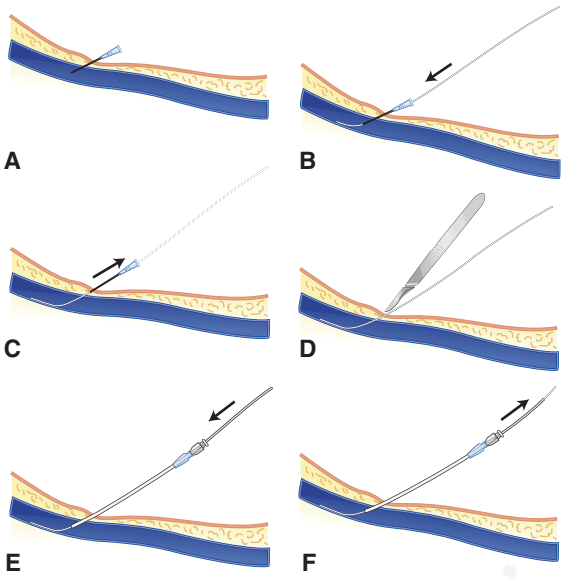

FIGURE 31-5. Seldinger technique. A. Needle is inserted through skin and vessel until venous blood is aspirated. B. Guidewire is inserted gently through the needle and advanced. C. Needle is removed over guidewire. D. The skin is incised. E. Dilator or catheter is inserted over the guidewire. F. The guidewire is removed.

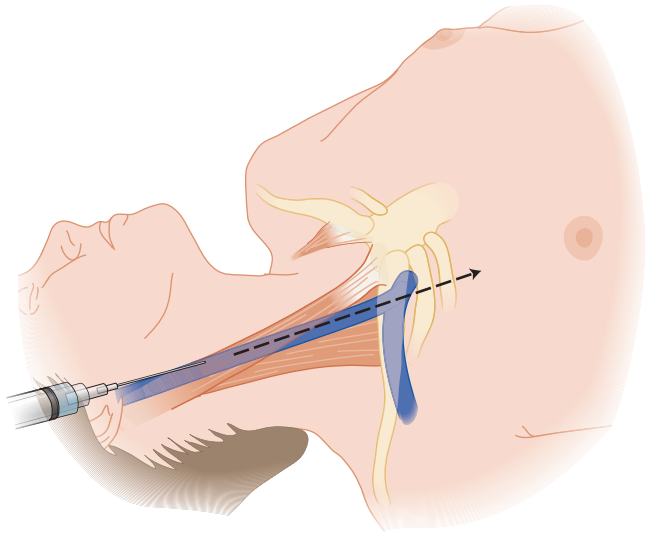

FIGURE 31-9. Anterior approach to the internal jugular vein.

rotated.[7,8] Palpate the femoral artery, if possible. Classically, the femoral vein is just medial to the femoral artery and 1 to 2 cm below the inguinal ligament, although US often demonstrates an anomalous position, which is one reason why landmark-based insertions are less successful (**Figure 31-15**). Use a 45-degree angle of approach.

In pulseless arrest, locate the femoral vein using the "V" technique. Place the thumb on the pubic tubercle and the index finger on the anterior superior iliac spine. The femoral vein is typically located at the interdigital space (the "V" of the finger and thumb) just inferior to the inguinal ligament.

Always insert the needle below the inguinal ligament, because vascular injury above the inguinal ligament may cause severe hidden hemorrhage into the retroperitoneal space.

Limit femoral vein cannulation because of the higher complication rates (notably infection and thrombosis) and the limits it places on patient mobility.

TABLE 31-8 Summary of Approaches to Internal Jugular Vein Catheterization

	Landmarks	Direction of Aim	Depth of Vein (cm)
Central	Apex of triangle formed by the clavicle and sternal and clavicular components of the sternocleidomastoid muscle	Ipsilateral nipple	1–3
Posterior	Lateral aspect of the clavicular portion of the sternocleidomastoid, one third of the distance from the clavicle to the mastoid process	Sternal notch	3–5
Anterior	Midpoint of the medial aspect of the sternal portion of the sternocleidomastoid, lateral to the carotid artery	Ipsilateral nipple	3–5

VENOUS CUTDOWN

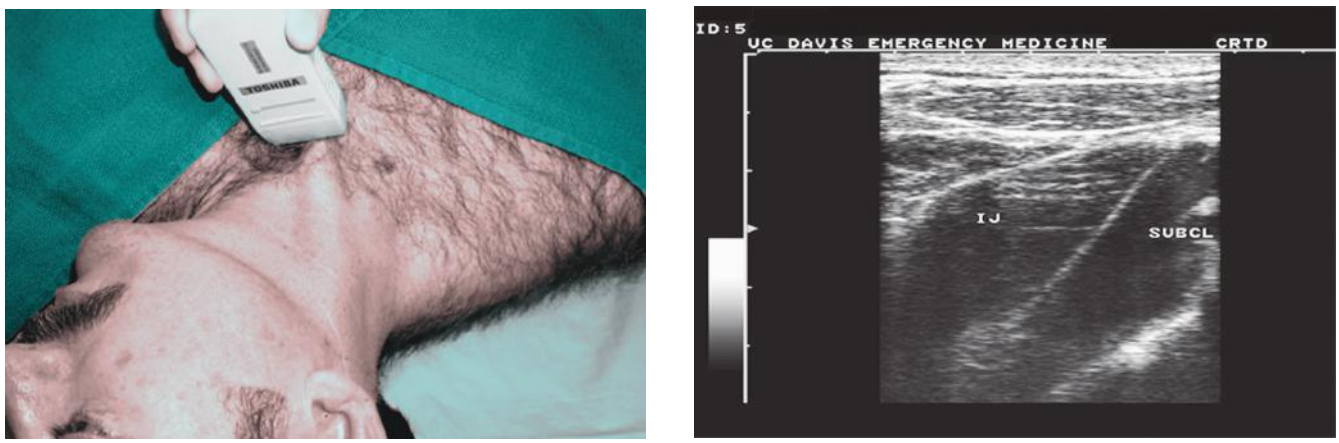
Venous cutdown is typically performed on the saphenous vein, anterior and superior to the medial malleolus.

IO VASCULAR ACCESS

IO vascular access is used in patients of all ages when venous access cannot be quickly and reliably established during circulatory collapse.[8] The commercial EZ-IO® (Vidacare Corp., San Antonio, TX) eases procedure performance (**Figure 31-16**). Contraindications to IO access include proximal ipsilateral fracture, ipsilateral vascular injury, and severe osteoporosis or osteogenesis imperfecta.

TECHNIQUE FOR IO ACCESS

Use either a standard bone marrow aspiration needle or specialized IO infusion needle. In children, the site of entry is two finger-widths (2 cm) below the tibial tuberosity on the medial, flat surface of the proximal tibia (**Figure 31-17**). Use other sites, such as the medial malleolus, distal femur, sternum, humerus, and ileum, in adults, because the tibia is thick and difficult to penetrate.



The procedure for manual insertion of IO venous needles is summarized in **Table 31-9** and illustrated in **Figure 31-18**.

COMPLICATIONS

Complications of IO access include cellulitis, osteomyelitis, iatrogenic fracture or physeal plate injury, and fat embolism (rare).

ENDOTRACHEAL SUBSTITUTION FOR VASCULAR ACCESS

A number of medications can be administered via the endotracheal tube in the critical minutes of resuscitation before IV access is obtained. These medications include lidocaine, epinephrine, atropine,

B. Transverse view of the "venous lake" created by the combined subclavian (SUBCL) vein and internal jugular (IJ) vein.

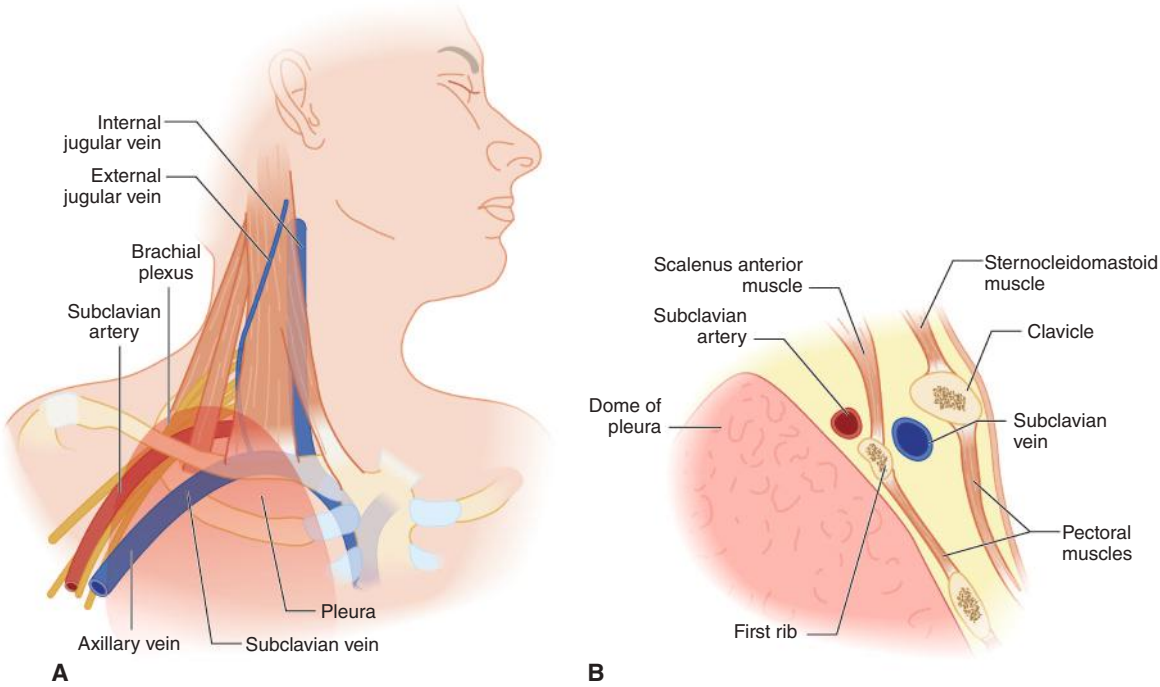

FIGURE 31-11. Anatomy of the subclavian vein. A. Anatomy of the subclavian vein. B. Cross-section of the subclavian vein with its relation to the clavicle.

and naloxone (mnemonic LEAN). The most commonly administered medication is epinephrine, given as a high-concentration preparation of 1 milligram/mL (1:1000) with a recommended dose of 2 to 2.5 milligrams in adults.[9]

Dosage recommendations are empirical and usually double or triple the standard IV dose[9] diluted in 3 to 5 mL of normal saline. After injecting the medication down the tube, administer several positive-pressure ventilations with a bag-to-tube device.

Outcomes after endotracheal drug administration during cardiac arrest are inferior to IV administration.[10] With other access techniques possible, notably IO, this route has little utility even in cardiac arrest.

ARTERIAL ACCESS

The indications for arterial line placement are listed in **Table 31-10**.

RADIAL ARTERY ANATOMY

The most common site for arterial line placement is the radial artery due to the ease of identifying its location and its accessibility at the wrist. The collateral artery blood supply provided by the arterial artery lowers the risk of complications (**Figure 31-19**). The anatomic landmarks for the radial artery are medial to the radial styloid process and lateral to the flexor carpi radialis tendon at the proximal flexor crease of the wrist. **A palpable radial pulse should be felt, and radial and ulnar artery compression tests (release of latter to assess collateral circulation, looking for hand to "pink up" rapidly—called the Allen test) are done prior to any puncture**, although the latter test has a limited ability to predict later ischemic complications.

FEMORAL ARTERY ANATOMY

As discussed in the section on femoral central venous access, the femoral artery lies in the femoral triangle inferior to the inguinal ligament, midway between the pubic symphysis and the anterior superior iliac spine (Figure 31-4). A longer catheter is typically needed to cannulate the deeper femoral artery compared to the radial artery.

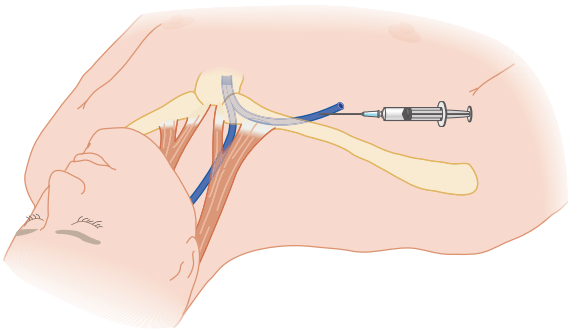

FIGURE 31-12. Infraclavicular approach to the subclavian vein.

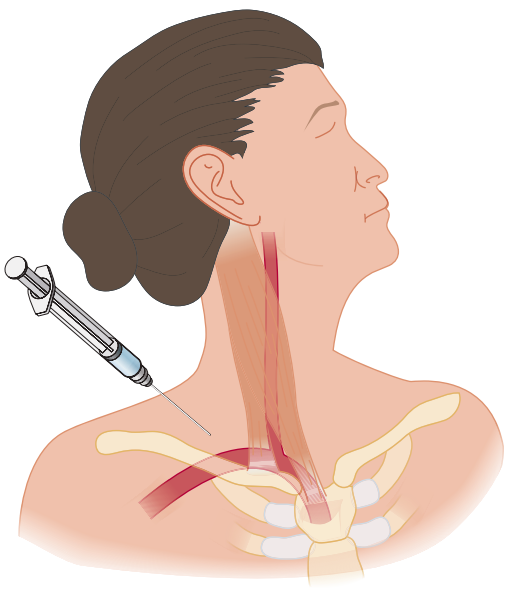

FIGURE 31-13. Supraclavicular approach to the subclavian vein.

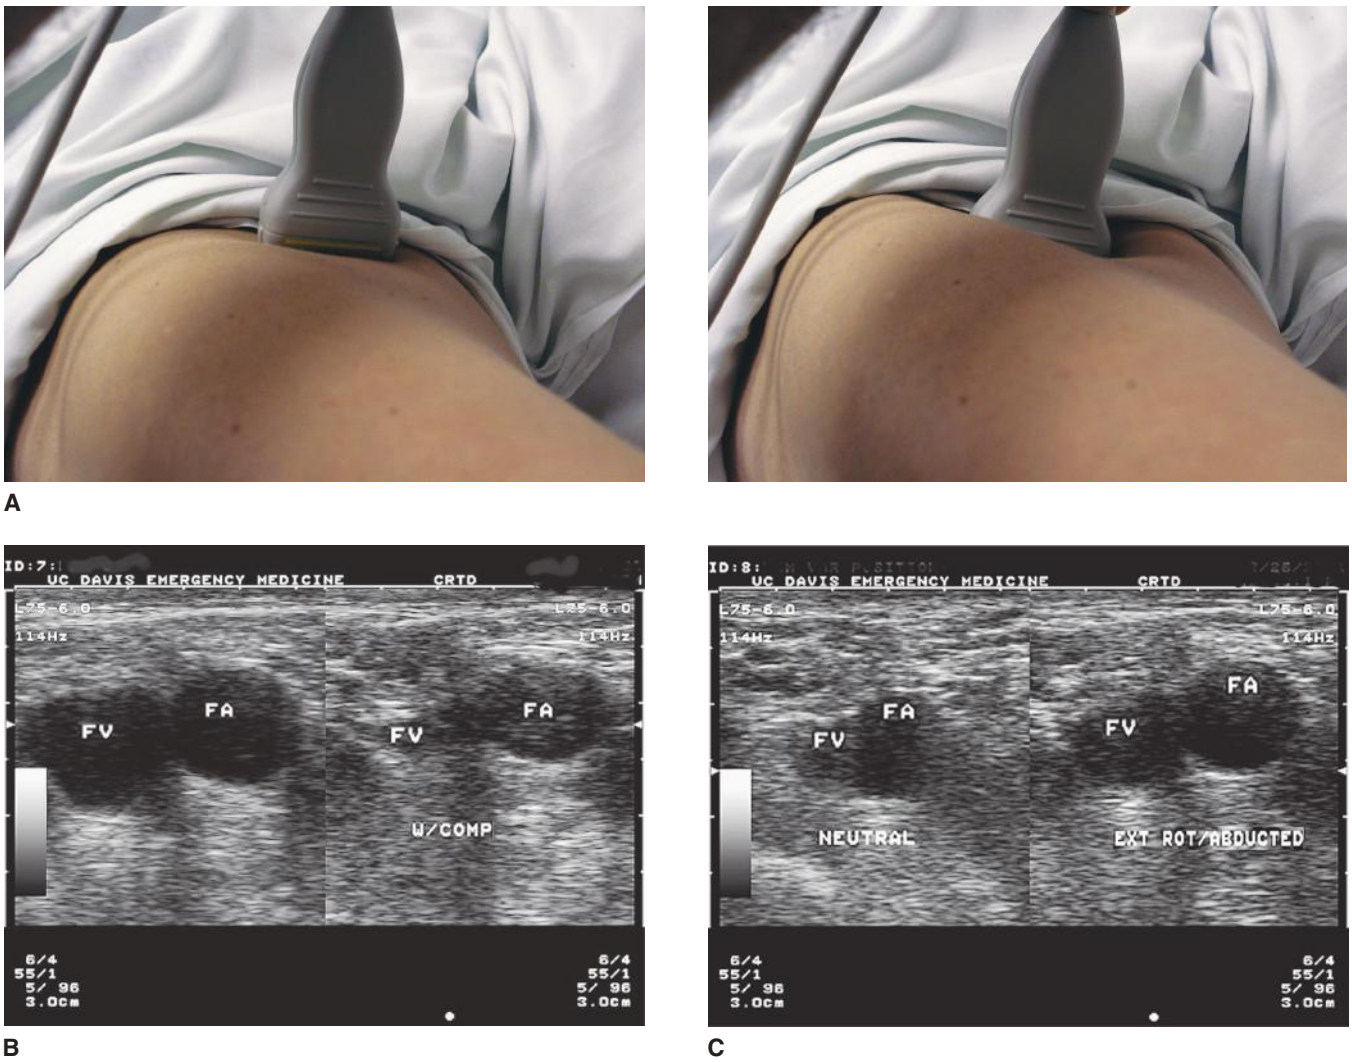

FIGURE 31-14. US-guided localization of the femoral vein. A. Gentle pressure is applied to the transducer to identify venous structures by their easy compressibility. B. Femoral vein (FV) collapses with compression, and the femoral artery (FA) retains its shape even with compression. C. FV position is seen to vary with hip abduction and external rotation. In neutral position (*left frame*), the vein is closely opposed to the FA; however, when the hip is abducted and rotated, the vein is displaced from the artery (*right frame*). [Part A used with permission of Michael Blaivas, MD.]

FIGURE 31-16. IO drill device.

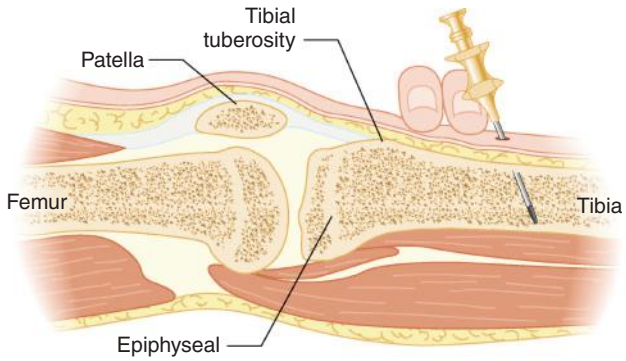

FIGURE 31-17. Location for IO placement in the proximal tibia.

TABLE 31-9 Procedure for Manual IO Venous Access

Prepare site using routine sterile fashion.
Infiltrate area with 1%–2% lidocaine to anesthetize the skin and periosteum if the patient is conscious.
Support and stabilize the leg with the nondominant hand.
Grasp the needle in the palm of the dominant hand.
Direct the needle perpendicular to the bone and away from the joint space (to avoid injury to the physeal plate in pediatric patients).
Twist and apply constant pressure until resistance is abruptly decreased and the marrow cavity is breached.
Remove the stylet.
Confirm placement by either aspiration or continuous infusion.
Observe for signs of extravasation (Figure 31-18).
Secure the IO needle with gauze and a bulky dressing.
Confirm placement and exclude iatrogenic fracture with x-ray after stabilizing the patient.

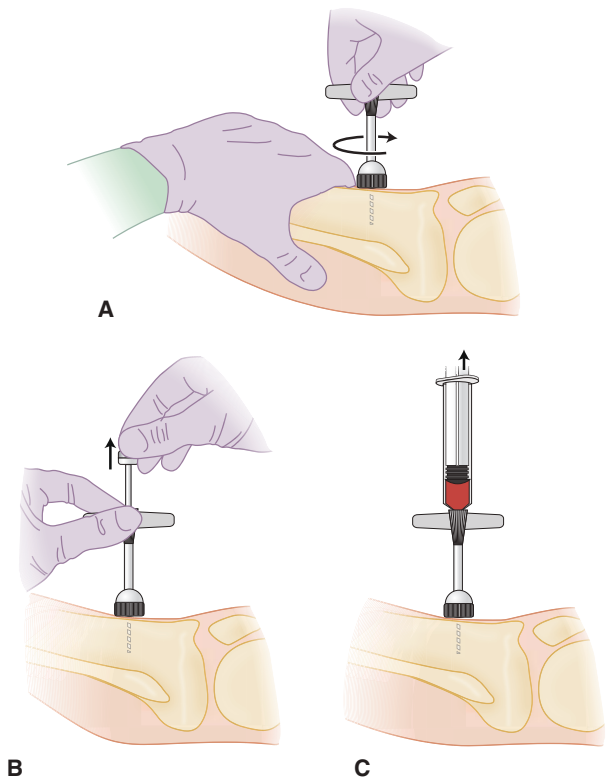

FIGURE 31-18. Technique for IO placement. A. Needle is directed perpendicular to the bone with constant pressure and a twisting motion. B. Stylet is removed. C. Placement is confirmed with successful aspiration.

TABLE 31-10 Indications for Arterial Catheter Placement

Frequent laboratory testing, including arterial blood gas sampling for acid-base status or monitoring of oxygen saturations and carbon dioxide levels in patients with respiratory failure
Need for accurate, moment-to-moment blood pressure monitoring in hypotensive patients, patients on vasopressors, or hypertensive patients with intracranial hemorrhages or vascular catastrophes (i.e., aortic dissections, abdominal aortic aneurysms)

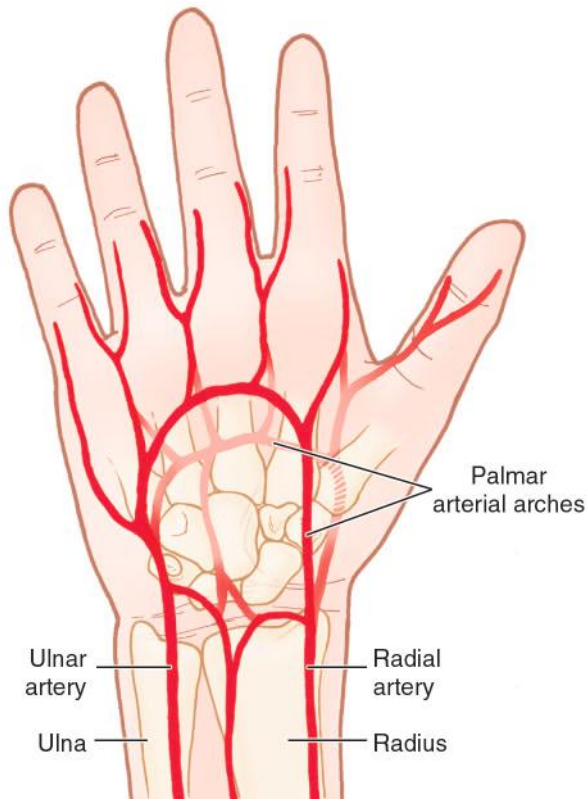

FIGURE 31-19. Arterial anatomy of the wrist and hand. [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures*, 2nd ed. Chapter 57. Arterial Puncture and Cannulation. McGraw-Hill, Inc., 2013, Figure 57-1.]

ALTERNATIVE ARTERIAL SITES

Other sites for arterial catheter placement include the dorsalis pedis artery and the brachial artery. Similar to the radial artery, the dorsalis pedis artery is superficial and easy to identify, and the foot has collateral circulation similar to the hand. The brachial artery is located just medial to the biceps brachii muscle in the antecubital fossa adjacent to the medial nerve. The lack of collateral blood flow at the level of the brachial

TABLE 31-11 Materials for Arterial Access

Sterile personal protective gear (gloves, gown, mask, hair covering)
Sterile towels
Povidone-iodine or chlorhexidine cleaning solution
1% Lidocaine, small-gauge needle, and syringe (e.g., a 1-mL tuberculin syringe)
20-Gauge angiocatheter or integral-guidewire arterial catheter
4 × 4 gauze
3-0 or 4-0 nylon suture with straight needle or needle driver
Sterile transparent dressing
Arterial line setup (pressure bag, saline, tubing, transducer, and flushing system)

TABLE 31-12 Technique for Artery Cannulation

Step	Comments
1. Position the patient for the procedure.	For radial artery approach, the wrist is extended. A towel roll under the dorsal wrist can maintain this position. See Figure 31-20. For femoral artery approach, the hip is slightly abducted and leg slightly externally rotated. See Figure 31-4.
2. Gown in standard sterile fashion.	Use sterile gloves and gown. Wear mask and hair covering. **Do not stand in direct line of the catheter**.
3. Identify artery using either landmarks or US guidance.	A palpable pulse is a must for landmark approach. Palpate pulse with 2 fingers of nondominant hand.
4. Prep and drape patient using standard sterile procedure.	Improper sterile technique increases risk of infection.
5. Anesthetize area in all conscious patients.	Inject 1% lidocaine with 1-mL tuberculin syringe.
6. Hold the 20-gauge angiocatheter or integral-guidewire catheter in the dominant hand at a 30- to 45-degree angle to the skin surface.	For direct angiocatheter cannulation, see Figure 31-21. For use of an integral-guidewire catheter see Figure 31-22.
7. Advance the needle slowly through the skin and subcutaneous tissue until pulsatile red blood return is obtained.	—
8. Stabilize the needle with the nondominant hand.	—
9. If an integral-guidewire catheter is used, advance the wire with the dominant hand.	If resistance is encountered, STOP advancing the guidewire immediately, withdraw the entire unit, and apply pressure to the puncture site.
10. Advance the catheter over the needle (or needle and guidewire if used).	A gentle rotating motion of the catheter may be helpful.
11. Remove the needle or needle-guidewire unit and *immediately occlude the catheter with a finger.*	Occlusion prevents arterial blood loss and air embolism.
12. Attach arterial line setup/IV tubing to the catheter.	Be sure to have arterial line setup prepared prior to start of the procedure.
13. Secure catheter with suture and apply a sterile transparent dressing.	—
14. "Zero" the transducer.	Align the stopcock to the level of the heart. Turn the stopcock off to the patient and open to air. Adjust the monitor display to zero.
15. Monitor for signs of bleeding, hematoma, or infection.	Assess the continued need for the arterial line daily.

artery increases the risk of upper extremity ischemia and is avoided for this reason.

TECHNIQUE FOR ARTERIAL ACCESS

After explaining the procedure and gaining consent, identify the access site and approach and position the patient with all materials at the bedside (**Table 31-11**).

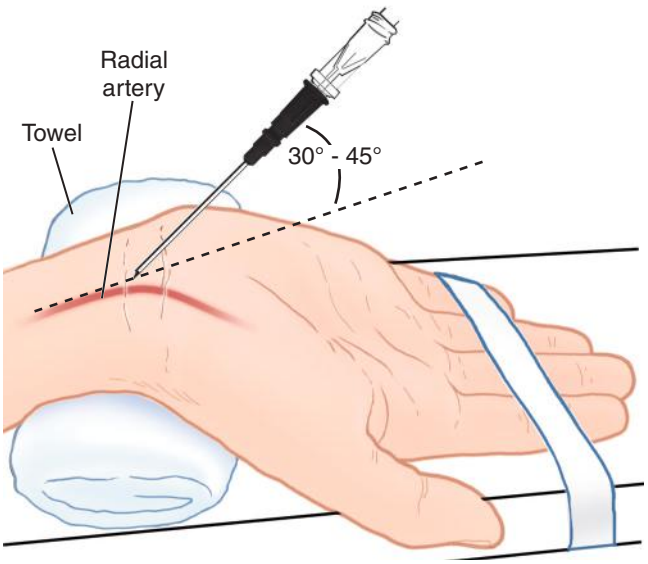

FIGURE 31-20. Correct positioning for radial artery cannulation. Flexion of the wrist is supported by a dorsal towel roll. [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures*, 2nd ed. Chapter 57. Arterial Puncture and Cannulation. McGraw-Hill, Inc., 2013, Figure 57-5.]

The technique for all approaches is summarized in **Table 31-12** and **Figures 31-20, 31-21,** and **31-22**. The direct puncture approach is less likely successful, takes longer, and requires more puncture attempts than the integral wire approach.

POSTPROCEDURE CARE

Secure the arterial catheter to the skin either by suture or adhesive catheter locking device with a sterile transparent protective dressing placed over the site. An arm board or wrist splint may aid securing a radial artery line. Monitor the site regularly for dislodgment, hematoma, bleeding, infection, or distal ischemia. The dressing should be changed regularly, and the necessity for the line should be determined daily.

COMPLICATIONS

The complications of peripheral venous access are listed in **Table 31-13**. **The first step in treating all complications is catheter removal. Direct pressure should be applied a minimum of 3 to 5 minutes after removal at all peripheral sites and 10 minutes for a femoral site.**

Air embolization from an arterial catheter is more likely to have adverse sequelae than from venous catheterization because of no pulmonary filtration. Infection rates increase with poor aseptic technique and duration of catheter use. Thrombosis occurs in up to 25% of patients who have an arterial catheter, although clinical morbidity occurs in less than 1%. Femoral artery catheterization can lead to concealed retroperitoneal hematoma and major hemorrhage. Neuropathies can occur from direct nerve injury from cannulation attempts or hematoma formation causing nerve compression. Brachial artery sites can lead to median nerve neuropathy, and an axillary artery site complication can result in brachial plexopathy.

US-GUIDED ARTERIAL ACCESS

US-guided arterial puncture aids cannulation, especially when a palpable pulse is difficult to identify.[11] Key sonographic characteristics to

CHAPTER 32

Hemodynamic Monitoring

H. Bryant Nguyen
David T. Huang
Michael R. Pinsky

INTRODUCTION

Hemodynamic monitoring can identify cardiovascular insufficiency and ensure optimal treatment of the critically ill. Advanced techniques help identify and prioritize various causes of hemodynamic instability and can enable tailored interventions.

Hemodynamic monitoring changes therapeutic decisions in more than 50% of patients and can detect cryptic cardiovascular compromise. We will focus on techniques applicable to the ED: blood pressure monitoring, central venous pressure (CVP) monitoring, cardiac output (CO) monitoring, and blood oxygenation and organ perfusion monitoring (**Table 32-1**). Use of any technology must be associated with a therapy and a response to therapy—*functional hemodynamic monitoring*. Applying a technology

TABLE 32-1 Hemodynamic Variables Obtainable in the ED

Hemodynamic Variable	Method of Measurement
Hemoglobin oxygen saturation, %	Pulse oximetry, arterial blood gas analysis
Heart rate, beats/min	Physical examination, pulse oximetry, electrocardiography
Blood pressure, mm Hg	Sphygmomanometry, oscillometry, intra-arterial catheterization
Central venous pressure, mm Hg	Jugular venous pulsation, US, central venous catheterization
Cardiac output, L/min	Thoracic bioimpedance or bioreactance, esophageal Doppler US, transcutaneous Doppler US, pulse contour analysis, lithium dilution, transpulmonary (arterial) thermodilution, pulmonary artery thermodilution
Central venous oxygen saturation, %	Central venous catheterization for intermittent venous blood sampling or continuous measurement
Lactate, mmol/L	Arterial, venous, or capillary sampling
Tissue oxygen saturation, %	Near-infrared spectroscopy

without a therapeutic strategy limits any potential benefit. In practice, it is best to use more than one approach and monitor therapeutic responses (**Table 32-2**).[1]

ARTERIAL BLOOD PRESSURE

Blood pressure is the force exerted by the circulating blood through a blood vessel. Assessing arterial pressure is very important, as hypotension implies tissue hypoperfusion; shock is a state of organ hypoperfusion but is not always associated with hypotension. **Hypotension is always pathologic and reflects a failure of normal circulatory homeostatic mechanisms, whereas normotension does not necessarily indicate cardiovascular stability.** Normal blood pressure can occur in the setting of profound circulatory shock in the face of significant vasoconstriction or in a patient with antecedent high arterial pressure. For example, a patient in cardiogenic or hypovolemic shock may remain normotensive because of a marked increase in vascular resistance.

OPTIMAL BLOOD PRESSURE

Arterial pressure is the input pressure for organ perfusion and is a function of peripheral vascular resistance and blood flow. There is no absolute level of normal CO in the unstable, metabolically active patient because CO is proportional to metabolic demand. However, organ perfusion pressure becomes compromised as mean arterial pressure (MAP) decreases below 60 mm Hg and/or cardiac index (CO/body surface area) decreases below 2.0 L/min/m^2.

Optimal MAP varies depending on the underlying cause of hemodynamic instability. In distributive shock, such as refractory septic shock, increasing MAP >65 mm Hg with fluids and vasopressors increases oxygen delivery but does not improve outcome, indices of organ perfusion, or survival.[2]

TABLE 32-2 Hemodynamic Monitoring Principles[1]

No hemodynamic monitoring technique can improve outcome by itself.
Monitoring requirements may vary over time and can depend on local equipment availability and training.
There are no optimal hemodynamic values that are applicable to all patients.
We need to combine and integrate hemodynamic variables.
Measurements of Svo_2 can be helpful.
A high cardiac output and a high Svo_2 are not always best.
Cardiac output is estimated, not measured.
Monitoring hemodynamic changes over short periods of time is important.
Continuous measurement of all hemodynamic variables is preferable.
Noninvasiveness is not the only issue.

Abbreviation: Svo_2 = venous oxygen saturation.

The American College of Cardiology/American Heart Association guidelines in 2004 recommend targeting a systolic pressure of at least 80 mm Hg in patients with acute myocardial infarction. In traumatic brain injury, a systolic pressure <90 mm Hg is an independent predictor for increased morbidity and mortality. A higher blood pressure may be required to maintain optimal cerebral perfusion pressure of 50 to 70 mm Hg (cerebral perfusion pressure = MAP – intracranial pressure), such that MAP <80 mm Hg may be an independent predictor of worse outcome.[3] In patients with hemorrhagic shock, delayed fluid resuscitation and toleration of a MAP of 40 mm Hg until definitive surgical intervention may improve survival.[4] **The International Consensus Conference recommends a target MAP of 40 mm Hg in uncontrolled hemorrhage due to trauma, a MAP of 90 mm Hg for traumatic brain injury, and a MAP >65 mm Hg for other forms of shock.**[5]

NONINVASIVE BLOOD PRESSURE MEASUREMENT

Blood pressure varies with each heartbeat. The *systolic pressure* is the maximum pressure during ventricular ejection, and the *diastolic pressure* is the lowest pressure in the blood vessels between heartbeats during ventricular filling. Because the vascular circuit is elastic, both systolic and diastolic pressures vary throughout the vascular system. Systolic pressure can increase by up to 20 mm Hg, while the diastolic pressure similarly decreases as the pressure wave moves peripherally from the aorta. However, MAP (**Formula 1**) varies by only 1 to 2 mm Hg, whether measured centrally or peripherally; in practice, estimate MAP using the sum of the diastolic pressure and one third of the pulse pressure (Formula 1).[6]

Mean arterial blood pressure =
Diastolic blood pressure + [Pulse pressure/3]

FORMULA 1. Mean arterial pressure.

PALPATION

Ability to palpate the radial, femoral, or carotid pulse in an emergency situation is traditionally thought to represent a minimum systolic pressure of 80, 70, or 60 mm Hg, respectively. However, confirmatory data are lacking, and these estimates may overestimate systolic pressure when compared to invasive measurements in patients with hypovolemic shock.

SPHYGMOMANOMETRY

Auscultation for blood pressure began with the invention of the sphygmomanometer by Scipione Riva-Rocci in 1896 and was later refined by Nicolai Korotkoff in 1905. To auscultate for blood pressure, place a cuff around the upper arm. Hold the bell of the stethoscope over the brachial artery as the cuff is gradually inflated to at least 30 mm Hg above the point at which the radial pulse disappears. Next, deflate the cuff at a rate of 2 to 3 mm Hg per second. The appearance of tapping sounds (Korotkoff sounds) corresponds to the systolic pressure. The diastolic pressure corresponds to the disappearance of Korotkoff sounds. Appropriate cuff size, cuff placement, proper placement of the stethoscope bell, appropriate cuff deflation rate, auscultation of Korotkoff sounds, dysrhythmia, observer bias, and faulty equipment all contribute to variability in the auscultatory method. Ideal cuff sizes are noted in **Table 32-3**.

An inappropriately small cuff for the size of the arm results in falsely elevated blood pressure measurements. A cuff too large for the size of the arm results in falsely low measurements.

TABLE 32-3 Blood Pressure Cuff Sizes

Arm Circumference Measurement (cm)	Cuff Size: Cuff Measurement
22–26	Small adult: 12 × 22 cm
27–34	Adult: 16 × 30 cm
35–44	Large adult: 16 × 36 cm
45–52	Adult thigh: 16 × 42 cm

Sphygmomanometric measurements of blood pressure often report slightly higher systolic pressure and lower diastolic pressure than those reported from simultaneous direct measurement using an intra-arterial catheter. This is because the reflected pressure waves summate with cuff inflation and increase systolic pressure, whereas the ischemic vasodilation downstream from the occluded cuff decreases cuff opening diastolic pressure.

OSCILLOMETRY

Most clinical blood pressure monitors use oscillometry. The amplitude of the fluctuations (or oscillations) in blood pressure in a sphygmomanometer cuff is analyzed and converted to pressure measurements by a computer device without the need for auscultation with the stethoscope. With gradual deflation of the cuff, oscillations begin above systolic pressure. The point of maximum oscillation corresponds to MAP. The systolic and diastolic pressures are estimated by an empiric algorithm. Despite widespread use, controversy exists regarding the accuracy of oscillometric blood pressure monitors. **When in doubt, use manual sphygmomanometric measurement of blood pressure.**

PHOTOPLETHYSMOGRAPHY

To measure the beat-to-beat blood pressure and thus provide continuous blood pressure monitoring, Penaz developed a technique with a small finger cuff containing a photoplethysmograph.[7] This device estimates blood volume in the finger with a light source on one side of the cuff and an infrared detector on the opposite side. The pressure in the blood vessels is proportional to the pressure in the cuff required to keep the blood volume constant. Special proprietary algorithms adjust for potential measurement errors caused by cold temperature or vasoactive agents.

INVASIVE BLOOD PRESSURE MEASUREMENT

In the vasoconstricted patient, noninvasive blood pressure measurements can underestimate systolic pressure by more than 30 mm Hg. MAP, however, is generally similar, whether measured noninvasively or invasively.[8]

The arterial catheter can be used for measuring MAP and pulse pressure, for estimating CO, and for repeated blood sampling. The International Consensus Conference for Hemodynamic Monitoring in Shock recommends invasive blood pressure monitoring for patients with refractory shock receiving vasoactive agents.[5] Uses for arterial catheterization are described in **Table 32-4**.

The radial artery is used most frequently for arterial catheterization. The femoral artery is an alternative in emergent situations, and often easier to access than the radial artery, especially in hypotensive patients. Other potential sites include the axillary, brachial, dorsalis pedis, ulnar, tibialis posterior, and temporal arteries, although these sites are rarely used (see chapter 31, "Vascular Access.")

In the presence of vasoconstriction, femoral arterial blood pressure measurements are more accurate than radial artery measurements. The risk for infection and limb ischemia is similar between radial and femoral artery cannulation (**Table 32-5**).[9] The primary risk of emergent femoral arterial catheterization is trauma to the artery during catheter insertion, with potential development of a pseudoaneurysm or retroperitoneal hematoma.

Placement of an intra-arterial catheter requires knowledge of the anatomic landmarks of the selected site. US guidance may be used.

The catheter can be inserted directly over a needle or by using the Seldinger technique over a guidewire. The Allen test, used to confirm collateral blood flow before radial artery catheterization, is inaccurate in predicting postcatheterization hand ischemia. In patients with profound hypotension, a cutdown may be required to cannulate the artery. After successful arterial catheterization, connection of the catheter to the pressure transducer should reveal an arterial waveform. The square wave flush test is applied to determine if artifacts in the tubing and recording system are damping the pressure measurements. See **Figure 32-1** for the square wave flush test with intra-arterial blood pressure measurement.

TABLE 32-4 Uses for Arterial Catheterization in the ED

Uses for arterial catheterization in the ED
Guides management of vasodilator or vasopressor drug to maintain target mean arterial pressure and avoid hypotension
Provides access port for the repetitive sampling of arterial blood in patients
Allows monitoring of cardiovascular deterioration in patients at risk for cardiovascular instability
Allows calculation of pulse pressure variation and cardiac output via pulse contour analysis
Useful applications of arterial catheterization in the diagnosis of cardiovascular insufficiency
Differentiate cardiac tamponade (pulsus paradoxus) from respiration-induced swings in systolic pressure
Tamponade reduces the pulse pressure but keeps diastolic pressure constant.
Respiration reduces systolic and diastolic pressure equally, such that the pulse pressure is constant.
Differentiate hypovolemia from cardiac dysfunction as the cause of hemodynamic instability
Systolic pressure decreases after a positive-pressure breath as compared to an apneic baseline during hypovolemia.
Systolic pressure increases during positive-pressure inspiration when left ventricular contractility is reduced.

TABLE 32-5 Complications of Intra-Arterial Catheterization

	Radial Artery (%)	Femoral Artery (%)	Axillary Artery (%)
Permanent ischemia	0.1	0.2	0.2
Temporary occlusion	19.7	1.5	1.2
Sepsis	0.1	0.4	0.5
Local infection	0.7	0.8	2.2
Pseudoaneurysm	0.1	0.3	0.1
Hematoma	14.4	6.1	2.3
Bleeding	0.5	1.6	1.4

FIGURE 32-1. Square wave flush test with intra-arterial blood pressure measurement. During a flush bolus of the catheter tubing, a square wave is observed. The number of oscillations after the square wave at the end of the bolus and prior to returning of the blood pressure tracing may result in an overestimated or underestimated blood pressure.

An overdamped system suggests that trapped air bubbles in the tubing are falsely lowering pressure measurements. An underdamped system will overestimate systolic pressure and underestimate diastolic pressure. Of note, in both situations, MAP is the most accurate measure. Flushing the system should remove the air bubbles. If this does not fix the problem, replace the tubing.

CENTRAL VENOUS PRESSURE MONITORING

By definition, CVP is the back pressure to systemic venous return, with high values indicating larger than normal volume returning to the heart from the systemic circulation. A number of factors contribute to the CVP value (**Table 32-6**). The use of CVP monitoring as a guide to resuscitation in critically ill patients is a subject of debate.

OPTIMAL CENTRAL VENOUS PRESSURE

CVP measurements range from 2 to 8 mm Hg in normal healthy individuals and are affected by multiple factors (Table 32-6).[10] A single absolute CVP value helps most when very low (such as to exclude right heart failure in a patient with a normal MAP) or very high (such as to suggest right heart failure and/or volume overload). **In general, a CVP <4 mm Hg in the critically ill patient should prompt fluid resuscitation with careful monitoring.**[5] However, CVP measures do not correlate with circulating blood volume or changes in blood volume.

Volume expansion in a healthy volunteer with normal diastolic compliance will immediately increase blood volume, whereas the CVP remains relatively normal. On the contrary, the same volume expansion in an elderly patient with cardiomyopathy, decreased diastolic compliance, and low circulating volume will elevate CVP (**Figure 32-2**).

Despite the limitations of CVP as a measure of blood volume, the classic "5-2 rule" can still provide a rapid estimation in the ED of volume status.[11] **After initial CVP measurement, infuse 250 mL normal saline IV over 15 minutes (10 to 20 mL/min bolus). An increase in CVP >5 mm Hg indicates volume overload and discontinuation of fluid. An increase in CVP of ≤2 mm Hg indicates hypovolemia and justifies additional fluid challenge.** "Volume responsiveness" is the best use of CVP in resuscitation. A target CVP of 8 to 12 mm Hg during resuscitation of the critically ill patient has been advocated, but the relative response will better guide therapy than any target alone.[12]

Respiratory changes
Intermittent positive pressure ventilation
Positive end-expiratory pressure
Tension pneumothorax

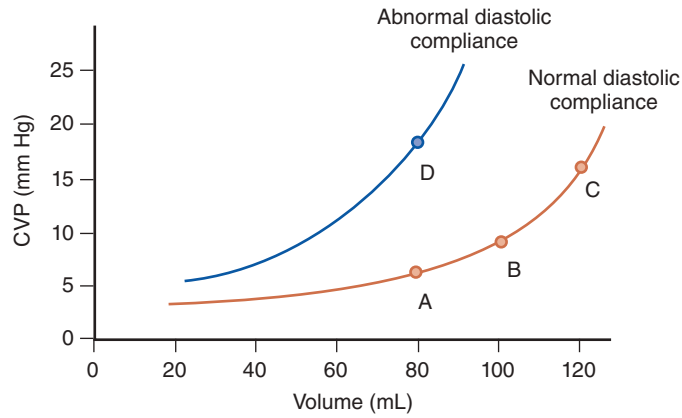

FIGURE 32-2. Right ventricular end-diastolic volume versus central venous pressure (CVP) varies with cardiac compliance. The same volume (80 mL) may result in different CVP measurements depending on diastolic compliance. The letters A-D designate response after small fluid bolus of same size in these groups.

Always measure CVP at end-expiration in both spontaneously breathing and mechanically ventilated patients. During spontaneous inspiration, the decreased intrathoracic pressure decreases transmural pressure in the heart, resulting in a decreased CVP. Conversely, intrathoracic pressure increases during an inspiratory breath of mechanical ventilation, resulting in an increase in CVP. Significant variation in inspiratory and expiratory CVP measurements suggests a compliant heart wall that will most likely respond to volume infusion. Conversely, the lack of respiratory variation in CVP may indicate that the heart is on the flat part of the cardiac function curve and will no longer respond to fluids.

NONINVASIVE CVP MEASUREMENT

JUGULAR VENOUS PULSATION

Observing internal jugular venous pulsation is a method to estimate right atrial pressure. The sternal angle is roughly 5 cm above the center of the right atrium regardless of the patient's position. With the patient sitting at a 45-degree angle, add 5 cm (distance from the sternal angle to the right atrium) to the vertical distance between the jugular pulsation and the sternal angle to estimate CVP in cm of water (cm H_2O). **A pulsation >4.5 cm vertically above the sternal angle when the patient is sitting at 45 degrees indicates a CVP of >9.5 cm H_2O (Figure 32-3).** In patients with heart failure, an elevated jugular venous pressure is independently associated with adverse outcomes, such as hospitalization and death.[13] Visualization of the internal jugular vein pulsation by physical examination is not always possible in the ED in obese or uncooperative patients.

ULTRASONOGRAPHY

US is a valuable tool to visualize the neck veins for central venous catheterization. It can also be used to determine elevated jugular venous pressure and provide a noninvasive method for measuring CVP. The right jugular vein is examined using a high-frequency linear transducer (7 to 9 MHz). The jugular venous pulse is the site where the vein tapers, resembling the neck of a wine bottle (**Figure 32-4**). Measure the vertical distance in centimeters between this point of vein collapse and the sternal angle and add 5 cm to obtain a CVP measurement in cm H_2O.

If the jugular vein is distended and larger than the adjacent common carotid artery when viewed in the transverse plane with the patient in a semi-upright position, then the CVP is >10 cm H_2O.

A nearly collapsed internal jugular vein on the transverse view in the supine position indicates a very low CVP. Correlation between US and echocardiogram is very good at high measurements.[14] Bedside US

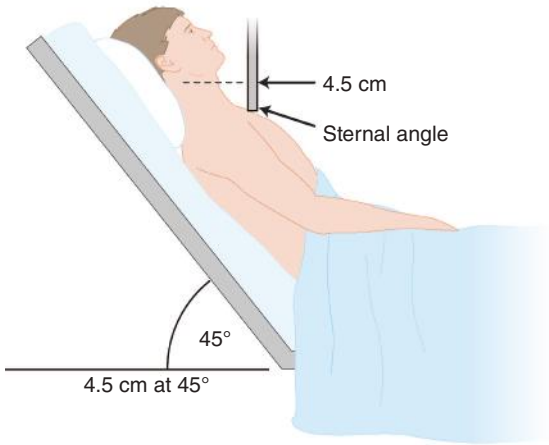

FIGURE 32-3. Internal jugular venous pulsation as an estimate of central venous pressure (CVP; or right atrial pressure). With the patient's head slightly turned to the left, shine a light tangentially in front of the neck to obtain a jugular shadow. The oscillations observed reflect the changing pressures within the right atrium and the various wave components of the CVP. The first elevation in the jugular pulse indicates the a-wave, or atrial contraction. The venous pressure is more accurately seen on the right side than the left because the right internal jugular vein has a more direct path to the right atrium. If the jugular pulse is higher than 4.5 cm at a 45-degree angle, it indicates an elevated CVP.

interpretations agree with formal echocardiographic estimates, with 83% for high, 67% for moderate, and 20% for low CVP measurements.

INVASIVE CVP MEASUREMENT

Traditionally, CVP is monitored with a fluid-filled catheter inserted in the internal jugular or subclavian vein proximal to the right atrium. The distal tip sits in the superior vena cava. Indications for central venous catheterization include fluid and vasopressor administration, unsuccessful or inadequate peripheral venous access, central venous oxygenation ($Scvo_2$) measurement, pulmonary artery catheterization, and transvenous pacemaker placement. Further details regarding central venous cannulation are provided in chapter 31.

After successful catheter insertion and radiographic verification, connect the catheter to a manometer or a pressure transducer of a monitor for continuous CVP waveform display. Place the transducer at the level of the right atrium, approximately 5 cm below the sternal angle. An acceptable

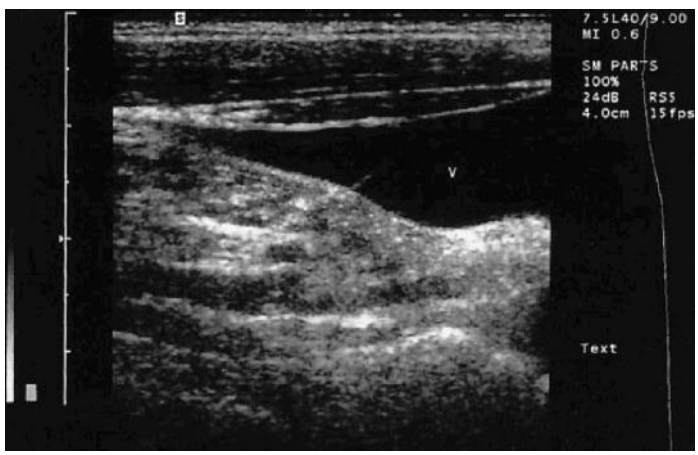

FIGURE 32-4. US longitudinal view of the neck showing the internal jugular vein tapering at the point of the jugular venous pulsation. v = vein. [Reproduced with permission from Lipton B: Estimation of central venous pressure by US of the internal jugular vein. *Am J Emerg Med* 18: 432, 2000. Copyright Elsevier.]

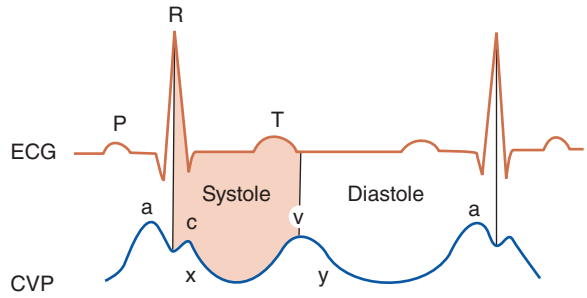

FIGURE 32-5. Central venous pressure (CVP) waveform and its relationship to the ECG. a = a-wave due to atrial contraction during diastole, which is absent in atrial fibrillation, but enlarged in tricuspid stenosis, pulmonary stenosis, and pulmonary hypertension; c = c-wave due to bulging of tricuspid valve back into the right atrium at the onset of systole; v = v-wave due to rise in atrial pressure from venous return through the vena cavae during systole and before the tricuspid valve opens at the onset of diastole, which is enlarged in tricuspid regurgitation; x = x-descent due to atrial relaxation; y = y-descent due to atrial emptying into the ventricle during diastole.

CVP waveform is needed to accurately interpret the measured values (**Figure 32-5**). The *c-wave* represents bulging of the tricuspid valve into the right atrium and occurs at the onset of systole. The base of the *c-wave* is used to determine a CVP value because it is the final pressure in the ventricle before the onset of contraction, reflecting *preload*.

Measurement of CVP from the internal jugular or subclavian vein is ideal. However, at times, measurement using femoral vein catheterization is required, such as in patients with coagulopathy, patients in whom subclavian and/or internal jugular vein catheterization is unsuccessful or has resulted in a complication, or when immediate central venous access is required. While not preferred, femoral CVP measurements are reliable.[15]

CARDIAC OUTPUT MONITORING

Oxygen delivery is a function of arterial oxygen content and CO. Perfusion pressure is the most important driving force determining regional blood flow, which in the aggregate defines CO. Because the primary goal of resuscitation from shock is to reverse tissue hypoperfusion, CO is often considered the ideal indicator of perfusion and oxygen delivery.

OPTIMAL CARDIAC OUTPUT AND DETERMINING FLUID RESPONSIVENESS

Traditionally, Starling's law (**Figure 32-6**) guided resuscitation care, with an increase in CO of greater than 15% after a fluid challenge considered the standard for assessing ideal fluid replacement. The most important contributor to increasing CO is increasing preload by successive fluid challenges.

VOLUME RESPONSIVENESS IN MECHANICALLY VENTILATED PATIENTS

Respiratory variations in blood pressure may aid in assessing volume status in the mechanically ventilated patient. Positive-pressure mechanical ventilation alters venous return and induces several predictable cyclic changes in vena caval diameters, pulmonary blood flow, and left ventricular output (**Figure 32-7**). In the volume-responsive patient, increasing intrathoracic pressure during positive-pressure inspiration will decrease venous return by decreasing the pressure gradient, which causes superior and inferior vena cava narrowing, decreased pulmonary blood flow, and a three- to four-beat phase lag decrease in left ventricular stroke volume and arterial pulse pressure.[16] A pulse pressure variation >13% predicts a >15% increase in CO in response to a 500-mL crystalloid bolus.[17]

Continuing fluid administration until the pulse pressure variation between inspiration and expiration decreases to <10% improves outcomes.[18] Because arterial pressure is directly proportional to stroke volume,

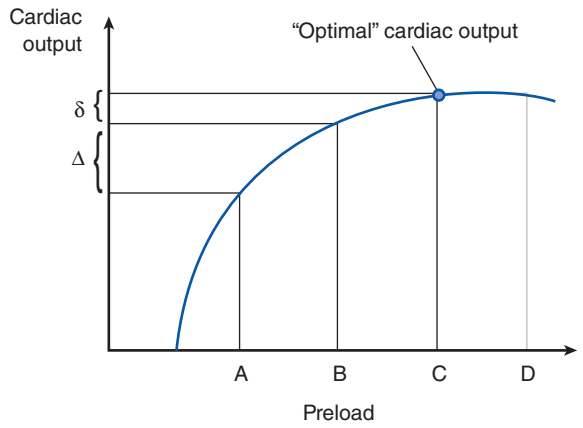

FIGURE 32-6. Starling cardiac function curve illustrating the effects of increased preload on cardiac output. As illustrated in the Starling cardiac function curve, the first increase in preload (from A to B) results in a large increase in cardiac output (Δ) as the cardiovascular system operates in the "preload-dependent" portion of the curve. The second increase in preload (from B to C) only results in a small increase in cardiac output (δ), and further increase in preload (from C to D) does not yield any increase in cardiac output as the cardiovascular system is now considered "volume resuscitated" or preload independent.

stroke volume variation strongly predicts fluid responsiveness, with a sensitivity of 81% and specificity of 80%.[19] A disadvantage of this technique is that the patient must be fully in synchrony with the positive-pressure mechanical breaths and without vigorous spontaneous breathing or dysrhythmia for stroke volume variation to be accurate. Nonetheless, this technique is useful to assess volume responsiveness in the sedated and ventilated patient.

VOLUME RESPONSIVENESS IN SPONTANEOUSLY BREATHING PATIENTS

Volume responsiveness in spontaneously breathing patients and those with dysrhythmias may be assessed by passive leg raising. Postural changes transiently increase venous return when the legs are raised to 30 degrees above the chest and held for 1 minute. This maneuver approximates giving a 300-mL blood bolus to a 70-kg patient. Changes in heart rate, blood pressure, CVP, or CO persist for approximately 2 to 3 minutes after passive leg raising. The dynamic increases in CO induced by passive leg raising are as sensitive and specific to predicting volume responsiveness as pulse pressure variation during positive-pressure mechanical ventilation.[20]

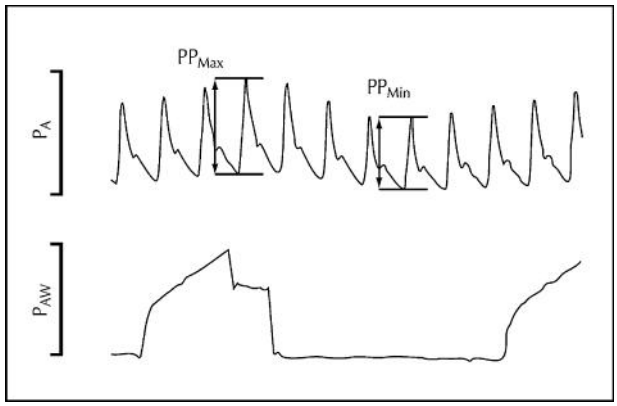

FIGURE 32-7. Pulse pressure variation (PPV) on positive-pressure mechanical ventilation. PPV is defined as the maximal pulse pressure (PP_{Max}) during inspiration minus the minimum pulse pressure (PP_{Min}) during expiration, divided by the average of these two pressures. P_A = arterial pressure; P_{AW} = airway pressure. Lippincott Williams & Wilkins, Inc. Copyright Wolters Kluwer Health.]

NONINVASIVE CARDIAC OUTPUT MEASUREMENT

Minimally invasive or noninvasive hemodynamic monitoring techniques to measure CO in the ED setting include thoracic electrical bioimpedance/bioreactance, esophageal Doppler US, transcutaneous Doppler US, and pulse pressure waveform analysis.

THORACIC ELECTRICAL BIOIMPEDANCE AND BIOREACTANCE

Thoracic electrical bioimpedance measures total blood flow within the aorta (or CO). Current is applied between the outer electrodes. The inner electrodes measure impedance to current flow through the thorax. Maximal current flow is along the path of least resistance (i.e., the great vessels). The change in impedance is proportional to change in volume and CO (**Figure 32-8**).[21]

Thoracic electrical bioimpedance was first used clinically to monitor CO in astronauts. CO measured with thoracic electrical bioimpedance correlates well with invasive measurements. It can also be used to differentiate cardiac from noncardiac causes of dyspnea and guide treatment in the ED.[22] A limit of this technique is that patient movement decreases signal reliability and accuracy.

Bioreactance is a modification of bioimpedance. Bioreactance applies a signal filter to analyze frequency shifts traversing the thoracic cavity creating a greater signal-to-noise ratio than bioimpedance. It is less sensitive to patient movement and external interference, although the accuracy in measuring CO is debated.[23]

ESOPHAGEAL DOPPLER US

Esophageal Doppler US measures instantaneous blood flow velocity in the descending aorta to determine stroke volume and CO (i.e., CO = stroke volume × heart rate). A Doppler transducer probe is inserted through the mouth or nose into the esophagus until its tip is at the midthoracic level. The probe is then rotated until the transducer faces the aorta to detect the characteristic aortic velocity signal profile (**Figure 32-9**).

Esophageal Doppler US CO readings correlate well with pulmonary artery catheter measurements.[24] However, this technique is operator dependent and often not well tolerated in awake patients, limiting ED use.

TRANSCUTANEOUS DOPPLER US

Transcutaneous Doppler US uses the same principles to measure CO as esophageal Doppler US. Measurements are obtained by applying the Doppler US probe at the sternal notch, with the US beam aimed at the ascending aorta. Significant operator training is required, again limiting the ED utility.[25]

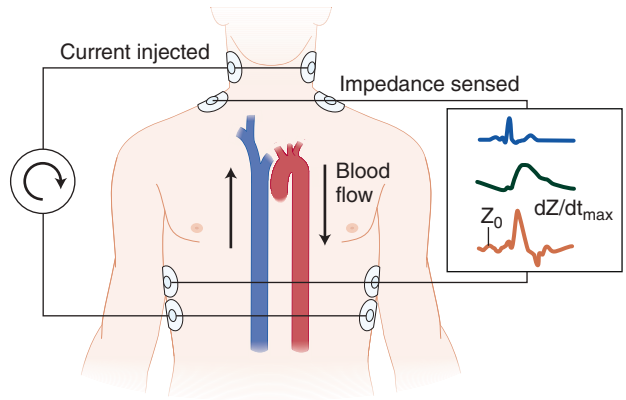

FIGURE 32-8. Thoracic bioimpedance cardiac output measurement. Z_0 = baseline impedance; dZ/dt_{max} = peak ejection velocity.

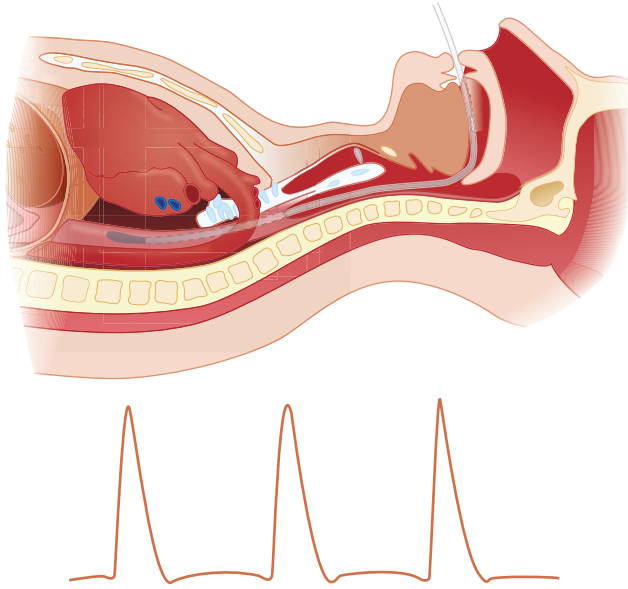

FIGURE 32-9. Esophageal Doppler cardiac output measurement. Cardiac output is proportional to the area under the curve of the aortic velocity and the aortic cross-sectional area. The tracing has been redrawn from the original.

PULSE PRESSURE WAVEFORM ANALYSIS

Pulse pressure waveform analysis uses an indwelling intra-arterial catheter to measure CO. Proprietary algorithms use arterial pressure waveform (or the pulse contour) and arterial vascular compliance to derive CO. Depending on the manufacturer, the measured CO may have to be regularly calibrated with another reference standard, such as lithium. Other systems may require the patient's specific physical characteristics for calibration. This technology has not yet been tested within a treatment protocol for the ED setting.

INVASIVE CO MEASUREMENT

CO is most commonly measured invasively with pulmonary artery catheterization using the thermodilution method. The benefit of using the pulmonary artery catheter for hemodynamic monitoring in the ED setting has not been investigated. Current expert consensus does not recommend the routine use of the pulmonary artery catheter in the management of the critically ill patient.[5,26] Given all this, pulmonary artery catheterization is usually avoided in the ED.

ORGAN OXYGENATION AND PERFUSION MONITORING

Blood pressure, CVP, and CO serve as macro-hemodynamic parameters. To assess tissue oxygenation or perfusion, venous oxygen saturation, serum lactate level, and tissue oxygenation provide further guidance during resuscitation.

CENTRAL VENOUS OXYGEN SATURATION

Venous oxygen saturation monitoring is a method to assess the relationship between tissue oxygen extraction, oxygen delivery, and oxygen consumption. A normal oxygen extraction ratio of 25% to 35% results in a *venous* oxygen delivery (reflected in venous oxygen saturation) of approximately 70% of arterial oxygen delivery. Venous oxygen saturation (SvO_2) is ideally measured in the pulmonary artery as a mixed venous sample ($Smvo_2$); this access point is generally not practical in the ED. Clinically, venous oxygen saturation reflects the balance between oxygen delivery and oxygen consumption, with low values reflecting inadequate delivery and/or excessive consumption.

Central venous oxygen saturation ($Scvo_2$) measurement only requires placement of a central venous catheter in the jugular or subclavian vein, making it an attractive alternative to $Smvo_2$. $Scvo_2$ can be easily measured by drawing a standard venous blood gas from the distal port of the central line and obtaining a *measured* oxygen saturation. Also, a special catheter allows continuous measurement if desired.

In healthy individuals, $Scvo_2$ is 2% to 3% less than $Smvo_2$; in shock states, $Scvo_2$ is typically 5% to 10% *higher* than $Smvo_2$ as blood flow is redistributed from the abdominal vascular beds to the cerebral and coronary circulation.[27] Although absolute values of $Scvo_2$ and $Smvo_2$ may be different, low values of either measurement reflect an imbalance in oxygen transport and portend worse outcomes. Most important, the two measures typically change in parallel and thus *trends* in $Scvo_2$ closely reflect trends in $Smvo_2$.[28]

Clinical Use of Central Venous Oxygen Saturation The principal value of $Scvo_2$ is its ability to detect occult inadequate oxygen delivery. During initial management, low $Scvo_2$ points to global tissue hypoxia despite normal vital signs and urine output. Left untreated, tissue hypoxia can lead to organ failure and death. Thus, regardless of the underlying pathophysiologic state (e.g., heart failure, septic shock, trauma), a low $Scvo_2$ value represents inadequate oxygen delivery relative to oxygen consumption. Troubleshooting a low $Scvo_2$ then focuses on the determinants of oxygen delivery (Is the patient hypoxic? Anemic? Is CO impaired, and if so, why? For example, low contractility, hypovolemia, or tamponade.). On the demand side, is oxygen consumption increased due to heightened metabolic demand such as from fever, pain, or seizure (**Table 32-7**)? Clinically, hypoxia and anemia are generally easily diagnosed and treated. A low $Scvo_2$ can detect occult low CO, prompting further investigation and therapy.

Normal (approximately 70%) or high $Scvo_2$ values do not necessarily mean that the patient is hemodynamically stable. $Scvo_2$ is a global measure of oxygen transport, and regional areas of tissue hypoperfusion can be present even with normal $Scvo_2$ values, particularly in the lower half of the body. In several disease states (e.g., hypothermia, terminal shock, cyanide poisoning), the ability of the tissues to extract oxygen from the blood is impaired, leading to "arterialization" of the venous blood with high $Scvo_2$.

Using $Scvo_2$ monitoring in a treatment protocol—targeting CVP 8 to 12 mm Hg, MAP >65 mm Hg, and $Scvo_2$ >70%—for septic shock patients early after arrival to the ED (or *early goal-directed therapy*) decreased mortality in single-center studies.[12,29-32] However, new data showed this invasive approach had no improved outcome compared to usual care in a multicenter study enrolling patients after early recognition, fluid boluses, and antibiotics have occured.[33] These results show

TABLE 32-7 Contributors to Abnormal Central Venous Oxygen Saturation ($Scvo_2$)

Low $Scvo_2$ (<70%)		High $Scvo_2$ (>70%)	
Low Do_2	High $\dot{V}o_2$	High Do_2	Low $\dot{V}o_2$
Hypoxia, suctioning (low Sao_2)	Exercise	Hyperoxia (high Fio_2)	Hypothermia
Anemia, hemorrhage (low Hgb)	Pain	Erythrocytosis (high Hgb)	Anesthesia, pharmacologic paralysis
Cardiac dysfunction, hypovolemia, shock, arrhythmia (low CO)	Hyperthermia, shivering, seizure	Hyperdynamic state (high CO)	Arteriovenous shunting, mitochondria defect, terminal shock

Note: Determining the causes of and treating a low or high $Scvo_2$ clinical state involves troubleshooting for conditions resulting in abnormal oxygen delivery (Do_2) and oxygen consumption ($\dot{V}o_2$).

Abbreviations: CO = cardiac output; Fio_2 = fraction of inspired oxygen; Hgb = hemoglobin; Sao_2 = arterial oxygen saturation.

that CVP and $Scvo_2$-guided care may be an appropriate option in patients where shock is failing to resolve despite efforts to identify.

LACTATE

In critical illness, an oxygen debt develops when oxygen delivery is inadequate to meet tissue oxygen demand and compensatory mechanisms are exhausted. This results in global tissue hypoxia, anaerobic metabolism, and lactate production. High lactate is a well-established prognostic marker in critically ill patients with various forms of shock, a fact identified in the 1800s.[34]

In addition to shock, causes of elevated lactate include seizure, diabetic ketoacidosis, malignancy, thiamine deficiency, malaria, human immunodeficiency virus infection, carbon monoxide or cyanide poisoning, and mitochondrial myopathies. Commonly used drugs, such as metformin, simvastatin, lactulose, antiretrovirals, niacin, isoniazid, and linezolid, can also cause a lactate elevation.[35]

Blood lactate concentrations also reflect the interaction between its production and elimination. During critical illness, a patient with hepatic dysfunction may have a higher lactate level compared with another patient without liver disease due to impaired hepatic clearance. However, lactate elevation in a patient with chronic liver disease still portends a poor prognosis, because patients with liver disease do not commonly have a high lactate level in the absence of shock.[36]

Clinical Use of Lactate Hyperlactatemia is not always accompanied by hypotension or a low bicarbonate level and/or elevated anion gap; thus, the lactate level must be separately measured. Venous lactate levels correlate well with arterial lactate levels.[37] However, repeat any elevated venous lactate level if inconsistent with the clinical condition, preferably with an arterial measurement.

A lactate level ≥4 mmol/L in normotensive patients requires further attention, because this cutoff is associated with increased intensive care unit admission rates and mortality. Furthermore, persistent elevation in lactate for >24 hours is associated with increased mortality as high as 90%.[38] Lactate clearance (or the ability to decrease serum lactate levels) as early as 6 hours in patients with septic shock improves 60-day survival.[39] When included in a treatment protocol, lactate clearance is noninferior to $Scvo_2$-guided care in the ED.[40] However, targeting both lactate clearance and optimal $Scvo_2$ may result in better outcomes than either alone.[41]

TISSUE OXYGEN SATURATION

Tissue oxygen saturation (Sto_2) can be measured by near-infrared spectroscopy, a noninvasive technique capable of continuous measurement using the varying light absorption properties of deoxygenated and oxygenated blood. Near-infrared light (680 to 800 nm) is largely transparent to biologic tissue, absorbed primarily by hemoglobin, and minimally affected by skin blood flow. Importantly, the near-infrared spectroscopy signal primarily reflects hemoglobin in the small end vessels and approximates the oxygen saturation of venous blood. Near-infrared spectroscopy Sto_2 measurements correlate and trend with $Smvo_2$ and $Scvo_2$ and can detect occult regional hypoxia even when $Smvo_2$ and vital signs have normalized.[42] However, darkly pigmented skin may impair measurement accuracy.

Clinical Use of Tissue Oxygen Saturation Sto_2 values reflect resuscitation adequacy and the magnitude of traumatic injury, as well as organ failure in critically ill patients.[43] An Sto_2 <75% measured at the thenar eminence distinguishes severe shock patients from healthy volunteers. Dynamic measurements using a brief vascular occlusion test to measure changes in Sto_2 may offer greater value than static Sto_2 measurements.[44]

Changes in Sto_2 during the vascular occlusion test are associated with the need for emergency operation or transfusion within the first 24 hours of hospitalization in trauma patients.[45] However, Sto_2 as a hemodynamic goal incorporated in an ED treatment protocol is still investigative.

CHAPTER 33

Cardiac Pacing and Implanted Defibrillation

Swee Han Lim
Wee Siong Teo
Anantharaman Venkataraman

PURPOSE OF PROCEDURE

Cardiac pacing serves to maintain or restore myocardial depolarization and thus ensure adequate cardiac output. In the ED, pacing is performed therapeutically to correct an ongoing rhythm disturbance or in anticipation of the onset of a conduction problem with hemodynamic impact.[1]

Indications for emergency pacing are listed in **Table 33-1**.

The indications for emergency cardiac pacing are found in chapter 18, "Cardiac Rhythm Disturbances."

GENERAL EQUIPMENT

All cardiac pacemakers deliver an electrical stimulus to the heart by electrodes that cause depolarization and subsequent cardiac contraction.[2] The modern pacemaker only stimulates the heart chamber if it does not recognize (sense) intrinsic electrical activity from that chamber after a selected time interval. Impulses are delivered to either the atria or ventricles, or to both.

Components of a cardiac pacemaker include:

- Pulse generator
- Electronic circuitry for sensing and pacing
- Lead system that connects the pulse generator to the electrode(s) and stimulates the myocardium

Relevant clinical details of these components are listed in **Table 33-2**.

TRANSCUTANEOUS PACING

Transcutaneous pacing is the emergency technique of choice because of its easy application. It uses externally applied electrodes to deliver an electric impulse directly across the intact chest wall to stimulate the

TABLE 33-1 Indications for Emergency Pacing

Indication	Comments
Symptomatic or hemodynamically unstable bradycardia/AV block	Symptoms include hypotension, change in mental status, angina, and pulmonary edema. Pharmacologic therapy may be used to temporize while preparing to pace.
Severe sick sinus syndrome with prolonged asystole (generally >3 s) and syncope	—
Ventricular standstill due to complete heart block or Mobitz type II AV block	—
Torsade de pointes	Overdrive pacing.
Recurrent monomorphic ventricular tachycardia	Overdrive pacing. The technique is limited by: Maximum pacing rate of the pacing device (usually 180 beats/min). Potential of accelerating the ventricular tachycardia and inducing ventricular fibrillation.
Unstable supraventricular tachycardia	Overdrive pacing should only be used after pharmacologic intervention and cardioversion have failed.

Abbreviation: AV = atrioventricular.

TABLE 33-2 Pacemaker Component Details

Pacemaker Type	Pulse Generator Location	Electrode Location
Transcutaneous	External	Skin of anterior chest wall and back or Anterior chest wall below right clavicle and apex
Transvenous	External	Venous catheter with tip in right ventricle and/or right atrium
Transesophageal	External	Esophagus
Epicardial	External or Internal	Epicardium Electrodes are usually placed on heart's surface during surgery
Permanent	Internal (subcutaneous in the prepectoral region)	Venous or epicardial

myocardium. Transcutaneous pacers differ from standard pulse generators in several important ways. The pulse duration of the stimulating impulse is longer and the current output higher than in internal pacing. Muscle contraction (usually the chest wall or diaphragm) is notable during pacing, especially at high outputs, and may be painful. Severe twitching makes palpation of the radial, carotid, or femoral pulse difficult. Cardiac monitoring with standard ECG monitors is difficult due to interference from the large current outputs that create large-amplitude pacing spikes. Most of the newer transcutaneous pacing units have a monitor that filters pacing spikes, allowing simultaneous monitoring.

RISKS AND PRECAUTIONS

There is little risk of electrical injury to healthcare providers during transcutaneous pacing. The electrodes are insulated, and closed chest compressions can be done over pads while pacing. Inadvertent contact with the active pacing surface results only in a mild shock.

EQUIPMENT

Table 33-3 lists the equipment needed to perform transcutaneous pacing.

TABLE 33-3 Transcutaneous Pacing Equipment

Pulse generator and monitor (usually a combination defibrillator/cardioversion/pacemaker unit)
Pacing cables
Pacemaker pads
ECG electrode pads
ECG monitor and cables
Medications for sedation and analgesia

TECHNIQUE

If time and conditions allow, explain the procedure to the patient and administer IV sedation and analgesia.

Apply the external pacing pads as shown in **Figure 33-1**. The same pads and electrodes are used for pacing, cardioversion, and defibrillation in most of the newer defibrillator units. If separate defibrillator pads or paddles are used, place them at least 2 to 3 cm from the pacing pads.

In bradyasystolic arrest, turn the stimulating current to maximum output and then decrease the output after capture is achieved; after restoring pulses, you may titrate energy to a level just above loss of capture. In a patient with a hemodynamically compromising bradycardia outside of cardiac arrest, slowly increase the output from the minimum setting until capture is achieved—usually between 50 and 100 mA. Continue pacing at about 1.25 times the threshold of initial electrical capture.

Transcutaneous pacing may be fixed rate (asynchronous) or demand (synchronous). **Asynchronous pacing** delivers an electrical impulse at a regular interval without regard to intrinsic cardiac pacemaker activity. This creates the potential risk of precipitating a dysrhythmia if the pacing stimulus occurs during the vulnerable period of ventricular repolarization. While many state a preference for synchronous pacing, there are little outcome or safety data to support that preference.

OUTCOMES ASSESSMENT

Assess capture using the ECG on the filtered monitor of the pacing unit. Look for the presence of a consistent ST segment and T wave after each pacer spike. Palpate for carotid and femoral pulses. Bedside US can be used to assess external pacer capture. If these appear favorable, assess blood pressure by cuff or arterial catheter.

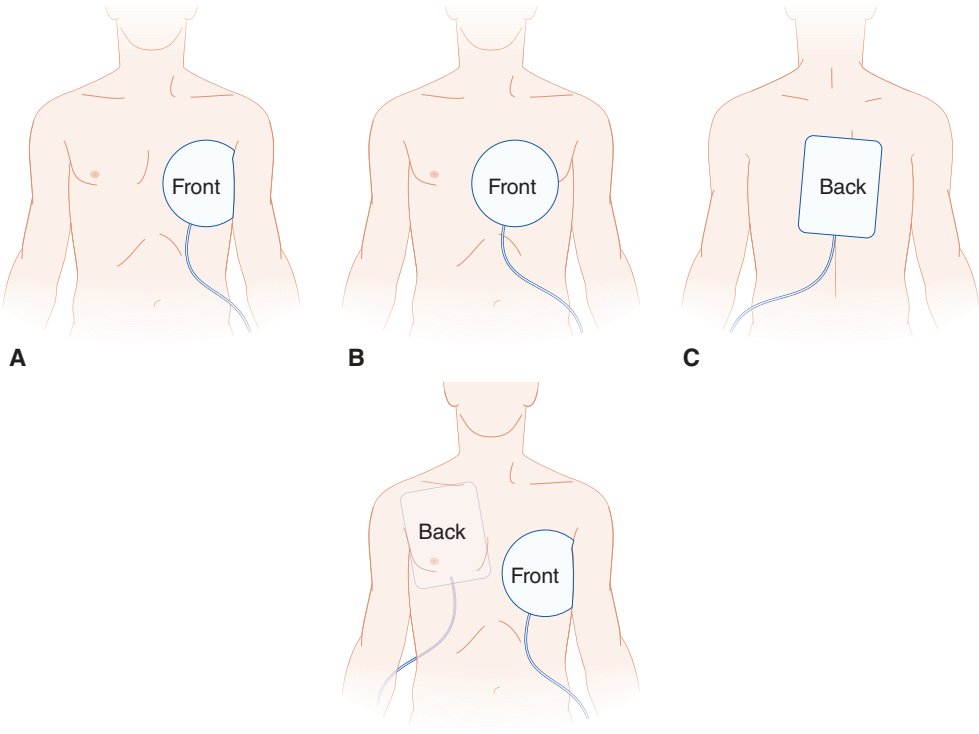

FIGURE 33-1. Placement of the transcutaneous pacing electrodes. **A.** Anterior (negative) electrode position centered over the cardiac apex. **B.** Anterior (negative) electrode position centered over the V_3 lead position. **C.** Posterior (positive) electrode position. [Reproduced with permission from Doukky R, Rajanahally RS: Transcutaneous cardiac pacing, in Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Figures 20-2 and 20-3. Copyright © 2004. The McGraw-Hill Companies, Inc., all rights reserved.]

Failure to capture with transcutaneous pacing may be related to faulty electrical contact, electrode placement, patient size, or underlying pathology. Recheck the lead connections, skin–electrode contact, and electrode placement. On occasion, pneumothorax, pericardial effusion or tamponade, severe myocardial ischemia, and metabolic derangements limit capture. No clinical myocardial damage results from properly performed transcutaneous pacing. Unless an easily resolved trigger exists, arrange for temporary transvenous pacing as soon as possible since ongoing pacing is likely needed.

TRANSVENOUS PACING

The indications for transvenous pacing are the same as for other methods of cardiac pacing.

Gather all equipment needed, including that to insert a central venous catheter (see chapter 31, "Vascular Access.") Resuscitation equipment and drugs, and the pacing needs listed in **Table 33-4**.

TECHNIQUE

You should know the equipment and practiced or done the procedure before starting. If conditions permit, explain the procedure to the patient and obtain informed consent. Next, identify the access site and approach and position the patient. The primary **sites of catheter insertion in the ED are the right internal jugular vein (preferred)** and the left subclavian vein. The right internal jugular vein allows a relatively straight line of access through the superior vena cava and right atrium into the right ventricle.

The steps for transvenous pacemaker insertion are listed in **Table 33-5**.

The most commonly encountered difficulties with transvenous pacing are securing venous access and obtaining proper placement of the stimulating electrode in the right ventricle, both of which can be time-consuming. Placement of the catheter tip into the apex of the right ventricle is the key to successful transvenous pacing.

When patients have decreased or no forward blood flow, positioning of the pacer tip within the right ventricle is difficult. Balloon-tipped catheters do not aid during low- or no-flow states. In an emergency, connect the pacemaker electrodes to the power source and advance the catheter until the tip encounters the endocardium of the right ventricle and creates capture.

Set the initial rate between 80 to 100 beats/min, using the asynchronous mode (sensitivity off) initially in patients requiring emergency pacing for hemodynamically unstable bradycardias. Follow the ECG to determine the presence or absence of capture (**Figure 33-3**). Adjust subsequent rate and sensitivity settings as clinically indicated by the response and underlying rhythm disturbance.

Transvenous pacing is best used in urgent rather than emergent situations (with transcutaneous serving as the bridge), allowing fluoroscopy.

COMPLICATIONS

Complications include perforation of the myocardium, cardiac arrhythmias, air embolism, failure of the circuit, catheter dislodgement, and delayed infection, in addition to the complications possible with central venous access (see chapter 31).

TABLE 33-4 Equipment Needed for Transvenous Pacing

Central catheter kit—introducer sheath must be one size larger than the pacer catheter
Flexible transvenous cardiac pacing catheter
Pacemaker generator and battery (and spare battery)
Cardiac monitor
Insulated connecting wire with alligator clamps at both ends

PERMANENT PACING

Permanent pacing is not performed in the ED.[1] Permanent pacemaker pulse generators (battery) are placed subcutaneously on the side of the patient's nondominant hand (thus, usually in the left prepectoral region below the left clavicle). The endocardial transvenous leads are positioned in the right ventricle at the apex, septum, or right ventricular outflow tract, and in the case of a dual-chamber device, also in the right atrium. A subclavian or cephalic vein approach is common. An epicardial lead may be implanted during concomitant open heart surgery.

Pacemaker leads are either bipolar or unipolar in configuration; unipolar leads are prone to oversensing myopotential and electromagnetic interference. The disadvantage of the bipolar configuration is that it is larger and more prone to lead fractures.

PACEMAKER NOMENCLATURE

A five-letter code is used to describe the features of the pacemaker[3] (**Table 33-6**). The first three code letters are used most commonly. The first letter refers to the chamber or chambers in which the pacing occurs: **A = atrium, V = ventricle**, and **D = dual chamber** or both A and V. The second letter refers to the chamber or chambers in which sensing occurs. The letters are the same as those for the first letter code. "**I**" indicates that a sense event inhibits the output pulse and causes the pacemaker to recycle the timing cycles, "**T**" means that an output pulse is triggered in response to a sensed event. "**D**" means that both "**T**" and "**I**" response can occur. The most common pacemakers are **VVI** and **DDD**. The fourth letter is used to indicate the presence or absence of an adaptive-rate mechanism (rate modulation). Pacemakers are then indicated as VVIR or DDDR. The fifth letter is used to indicate whether multisite pacing is present and is rarely used. See **Figures 33-4 and 33-5** for examples of ECGs with pacemaker spikes.

RESUSCITATION IN PATIENTS WITH PERMANENT PACEMAKER

If a patient who has a permanent pacemaker requires countershock, place the pads or paddles at least 8 cm from the pulse generator. The current normal positioning of the paddles—below the right clavicle and apex of the heart—is safe because the majority of pulse generators are below the left clavicle. Alternatively, place adhesive electrodes in an anteroposterior configuration. After countershock, interrogate the pacemaker to ensure that it is still functioning normally.

Potential problems after defibrillation include:

- Pacemaker inhibition due to reversion to noise mode
- Deletion (reprogramming)
- Circuit damage
- Myocardial damage adjacent to the lead tip caused by current transmission via the electrode to the myocardial interface

Another reason that immediate return of pacing (capture) fails after defibrillation is that global myocardial ischemia increases pacing threshold. If this occurs, try transcutaneous pacing at higher delivered energy settings.

PACEMAKER COMPLICATIONS

Complications for which a patient may seek care in the ED in the early period after pacemaker insertion are listed in **Table 33-7**. Two are discussed in detail.

Pacemaker Syndrome Atrioventricular synchrony and the presence of ventriculoatrial conduction are most common in the setting of VVI pacing but may occur with the DDI mode. With VVI pacing, the ventricle is electrically stimulated, resulting in ventricular contraction. If sinus node functions are intact, the atria can be depolarized by a sinus impulse and contract when the tricuspid and mitral valves are closed. This results in an increase in jugular and pulmonary venous pressures and may produce symptoms of congestive heart failure. Atrial distention can result in reflex vasodepressor effects mediated by the central

TABLE 33-5 Transvenous Pacemaker Insertion

Step	Comments
1. Gown in standard sterile fashion.	Use sterile gloves and gown. Wear mask and hair covering.
2. Identify vessel using either US guidance or landmarks.	—
3. Prep and drape patient using standard sterile procedure.	Prep a wide area in case initial attempts fail and an alternate site is needed. Prep the entire ipsilateral neck and upper chest when preparing to insert an internal jugular or subclavian catheter.
4. Open a central catheter kit that contains an introducer catheter. Inspect for content in a sterile fashion. Place kit close to bedside and operator. Maintain sterile conditions.	The introducer catheter should be one size larger than the pacing catheter.
5. Open pacing catheter and pacing kit (if available).	Pulmonary artery catheters with dedicated atrial and ventricular ports may also be used. Assess integrity of the pacing catheter balloon by inflating it with 1.5 mL of air and immersing it in sterile saline. Air bubbles indicate a leaky balloon.
6. Attach the pacemaker to any of the V leads and ensure it is recording.	—
7. Anesthetize area in all conscious patients.	Inject area with 1%–2% lidocaine. Anesthetize the periosteum of the clavicle if using the subclavian approach. Reorient to landmarks after injection.
8. Hold the 18-gauge introducer needle on a 10-mL syringe in the dominant hand and align the needle to the target.	—
9. Advance the needle slowly though the skin and subcutaneous tissue until a flash of dark venous blood appears.	Maintain steady constant aspiration of syringe.
10. Stabilize the needle with the nondominant hand.	—
11. Check for continued free venous flow with aspiration.	If no flow is noted, withdraw the needle slightly, as the needle may have breached the posterior vessel wall.
12. Remove the syringe attached to the needle, and immediately occlude the catheter with a finger.	This maneuver helps to prevent introducing air in the catheter and subsequent central system air embolism.
13. Insert the guidewire gently through the needle. Always maintain a firm grip on the wire—do not let go of the wire for any reason.	The wire should advance with minimal resistance. Do not force the wire for any reason. If the wire does not pass easily, reattach the syringe and aspirate to confirm continued venous flow. Reposition the needle as needed. Premature ventricular contractions (PVCs) or dysrhythmias during wire advancement may indicate that the wire is in the right atrium or beyond.
14. Remove the needle over the wire when the guidewire is inserted at least 10 cm into the vessel.	—
15. Incise the skin with a #11 blade scalpel at the entry site to accommodate the introducer.	Do not cut the guidewire.
16. Advance the introducer over the guidewire into the vessel lumen with a gentle twisting motion.	Maintain a grip on the guidewire during this procedure.
17. Remove the guidewire.	—
18. Insert and advance the pacing catheter approximately 10 cm.	This ensures that the balloon is past the introducer catheter and within the vascular system. Inflate the balloon with 1.5 mL of sterile saline.
19. Slowly advance the catheter into the right ventricle.	Use fluoroscopy or bedside US to guide placement. The ECG tracing recorded from the electrode also helps localize the position of the catheter tip. Inflate the balloon after the catheter enters the superior vena cava. Stop advancing when the pacing catheter is in the apex of the right ventricle. See **Figure 33-2**.
20. Reassess balloon integrity.	—
21. Connect the pacemaker generator to the catheter.	—
22. Disconnect the negative terminal of the pacemaker catheter from the ECG lead.	—
23. Connect the proximal pacemaker catheter terminals to the terminals of the pacemaker generator.	—
24. Set the pacemaker generator on demand mode with a rate of 80–100 beats/min.	Start with 5 mA of energy on the output dial.
25. Turn on the pacemaker.	With optimal tip position, capture should occur at <2 mA. Pacing spikes and a wide QRS complex in lead V_1 reflect capture.
26. After capture, decrease the pacemaker generator output to just below where pacing stops.	Continue pacing at 1.5–2.0 times the threshold output required for capture
27. Examine the chest x-ray for catheter tip placement and signs of complications.	—
28. Secure catheter and apply a sterile transparent dressing.	—

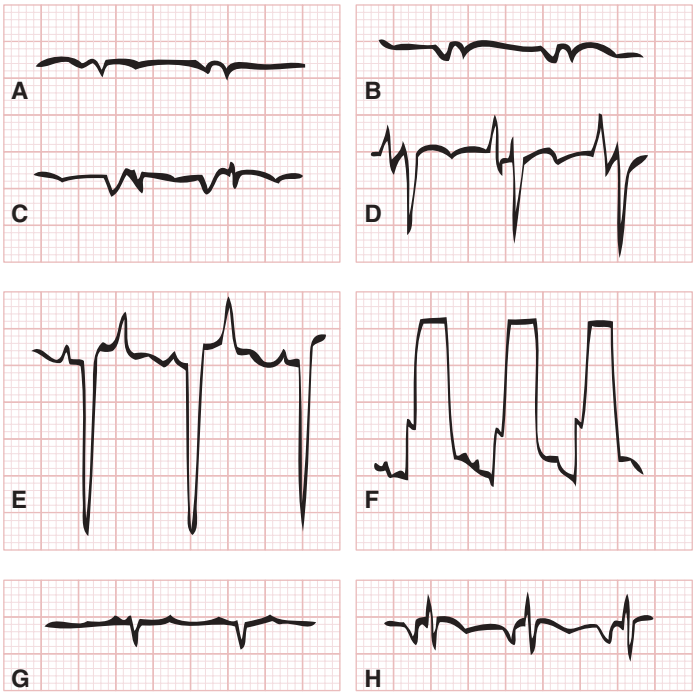

FIGURE 33-2. Typical ECG tracings seen with a transvenous pacing catheter within the different anatomic sites. **A.** The subclavian or internal jugular vein. **B.** The superior vena cava. **C.** The high right atrium. **D.** The low right atrium. **E.** Free-floating in the right ventricle. **F.** Abutting the right ventricular wall. **G.** The inferior vena cava. **H.** The pulmonary artery. nervous system. If the contribution of atrial contraction to late diastolic ventricular filling is important in maintaining an adequate cardiac output, orthostatic hypotension may occur. DDI pacing in a patient with atrioventricular block can result in pacemaker syndrome if the sinus node discharge rate exceeds the programmed rate of the pacemaker.

In most instances, symptoms are mild and patients adapt to them. In about one third of these patients, symptoms are severe. Treatment usually requires upgrading a VVI pacemaker to a dual-chamber pacemaker or lowering the pacing rate of the VVI unit, so that ventricular pacing does not occur but provided intrinsic conduction occurs. If symptoms occur in a patient paced in the DDI mode, optimizing the timing of atrial and ventricular pacing is usually required. Consult with a cardiologist.

PACEMAKER MALFUNCTION

Pacemaker malfunction is divided into four areas: failure to sense, failure to pace, failure to capture, or overpacing or pacemaker-associated tachycardia.[4]

Failure to Sense (Undersensing) Undersensing occurs when the pacemaker cannot adequately detect the intrinsic electrical cardiac activity. This results from lead placement in an area of the heart with poor or variable conductivity, or if a lead is loose, dislodged, or physically broken. Sensing failure can occur if the programmed sensing threshold is set too high. With undersensing, if the pacer is set in an inhibit mode, it will fire at a set rate that is not coordinated with the patients underlying cardiac cycle (**Figure 33-6A**).

Failure to Pace (Oversensing) Oversensing occurs when the pacemaker experiences interference from electrical signals within the body (i.e., skeletal or smooth muscle myopotentials) that are not related to the normal cardiac cycle. Sources of interference may include skeletal muscle, the diaphragm, nerve stimulators, broken pacer leads, and uncommonly, coarse atrial fibrillation. When electrical activity is oversensed, the pacemaker erroneously inhibits the pulse generator and the patient may develop bradycardic rhythms (**Figure 33-6B**).

Failure to Capture Failure to capture occurs when the pulse generator fires but the current delivered to the endocardium is too low to initiate depolarization and wavefront propagation. Dislodged leads, poor cardiac conductivity due to myocardial disease (e.g., ischemia, acidosis, fibrosis), and programming problems are the most common reasons for this malfunction. Failure to capture can be intermittent (**Figure 33-6C**).

PACEMAKER-ASSOCIATED TACHYCARDIA

Occasionally the patient with an implanted device may present with a rapid paced rhythm. This may be due to:

- Rapid atrial arrhythmia triggering an upper rate response in a patient with complete heart block
- Pacemaker-mediated tachycardia
- Runaway pacemaker

Unless preprogrammed to mode switch, pacemakers detect rapid atrial rhythms and track them, resulting in pacing at the upper rate limit. Pacemaker-mediated tachycardia can occur in a *dual-chamber pacemaker* when a premature ventricular ectopic beat triggers a retrogradely conducted atrial depolarization outside the atrial refractory period, which is then sensed by the pacemaker, initiating ventricular pacing. If this continues, it can cause an endless loop tachycardia. Rarely the pacemaker may malfunction with acceleration of pacing (runaway pacemaker). This occur when the pulse generator discharges at a rapid rate above its preset upper limit and is most commonly associated with a battery failure or damage from external interference. Placing a magnet over the pacemaker may help in the pacemaker-mediated tachycardia or runaway pacemaker. However, interrogation of the device is usually required, and the device must be replaced if programming is not successful.

PACEMAKER PROGRAMMING ERRORS

Pacemakers are computer-controlled devices with complex software that requires adjustment and maintenance. Reprogramming is accomplished

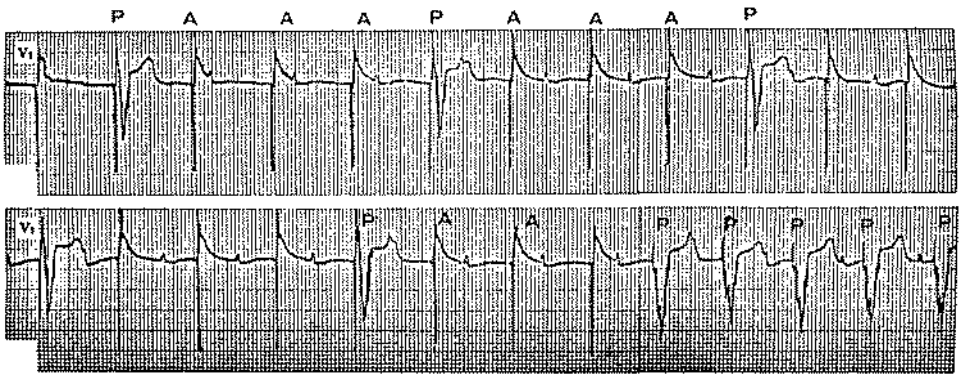

FIGURE 33-3. Pacing with intermittent capture. "P" indicates paced beats, and "A" indicates pacer artifact without capture.

TABLE 33-7 Complications Seen after Pacemaker Insertion

Complication	Comment
Infection	Infection rate is <1%. Infections are more common in patients after pacemaker replacement or prolonged procedure. Early infections are most commonly caused by *Staphylococcus aureus or Staphylococcus epidermidis*. Pacemaker infection presents as: Local inflammation or abscess formation in the pacemaker pocket, as evidenced by pain, tenderness, or redness at the site. Skin adherence to the device, especially with discoloration of the skin over it, is highly indicative of localized infection. Do not aspirate the pocket because this can worsen the infection. If only a superficial infection is suspected, antibiotics and analgesics may be given with an early referral to the device implanter to review. Erosion of the device or lead through the skin resulting in the leads or pulse generator being exposed. Complete device and lead removal is almost always required. Cardiac device–related infective endocarditis involving the lead or valves. Patient may present with sepsis and positive blood culture without sign of local inflammation.
Thrombophlebitis and venous obstruction	Symptomatic thrombosis of the upper extremities and central veins is uncommon, possibly because of extensive venous collaterals (0.3%–3.0% of patients). Site of insertion does affect incidence. Symptoms include edema, pain, or venous engorgement of the arm ipsilateral to lead insertion. Treatment includes IV heparin therapy followed by long-term warfarin administration.
Pneumothorax	1% of patients. More common with subclavian introducer technique. Hemothorax and pneumomediastinum are rare.
Pacemaker syndrome	20% of patients. New or worsening of symptoms such as syncope or near-syncope, orthostatic dizziness, exercise intolerance, dizziness, uncomfortable pulsation over the neck and abdomen, right upper quadrant pain, etc.

noninvasively with devices that communicate to the pacemaker through radiofrequencies. Occasional settings can be inadvertently altered, and software, as with any computer, can fail. Software changes may occur in set rates, sensing thresholds, and current outputs.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Implantable cardioverter-defibrillators are the treatment of choice for sudden cardiac death, reducing mortality from approximately 30% to 45% per year to <2% per year.[5] This remarkable efficacy, coupled with the failure (and potentially proarrhythmic effects) of pharmacologic therapy and the increasing sophistication and miniaturization of the devices, has led to an explosion in implantable cardioverter-defibrillator use. Expanding indications for implantable cardioverter-defibrillator implantation make it likely that emergency physicians will regularly see patients with these devices.

An implantable cardioverter-defibrillator consists of a pulse generator, a lead system with both sensing and shocking electrodes, circuitry to analyze the cardiac rhythm and trigger defibrillation, and a power supply.

In the past, these devices generally were placed by thoracotomy or sternotomy, and defibrillation occurred through electrodes positioned inside or outside the pericardium. Rate-sensing electrodes were placed epicardially or transvenously. Roughly one third of patients with second-generation implantable cardioverter-defibrillators received inappropriate shock(s) triggered by a supraventricular tachycardia during the working life of the device.

In newer implantable cardioverter-defibrillators, sensing-pacing-defibrillation electrodes are placed transvenously, and the device itself is generally implanted subcutaneously in the subpectoral region or in an abdominal pocket. Newer implantable cardioverter-defibrillators are better at discriminating supraventricular tachycardia and are capable of a variety of responses to ventricular tachycardia and fibrillation. Most are programmed to follow a tiered approach to ventricular dysrhythmias: antitachycardia pacing, low-energy cardioversion, and finally defibrillation. Depending on the frequency of discharge and whether the pacemaker function is used, the latest implantable cardioverter-defibrillators have a projected life span of approximately 6 to 9 years, depending on whether they are single- or dual-chamber devices.

Implantable cardioverter-defibrillators are remarkably effective in preventing sudden cardiac death. The most common cause of death in patients with implantable cardioverter-defibrillators is congestive heart failure, which should be managed in standard fashion in the ED.

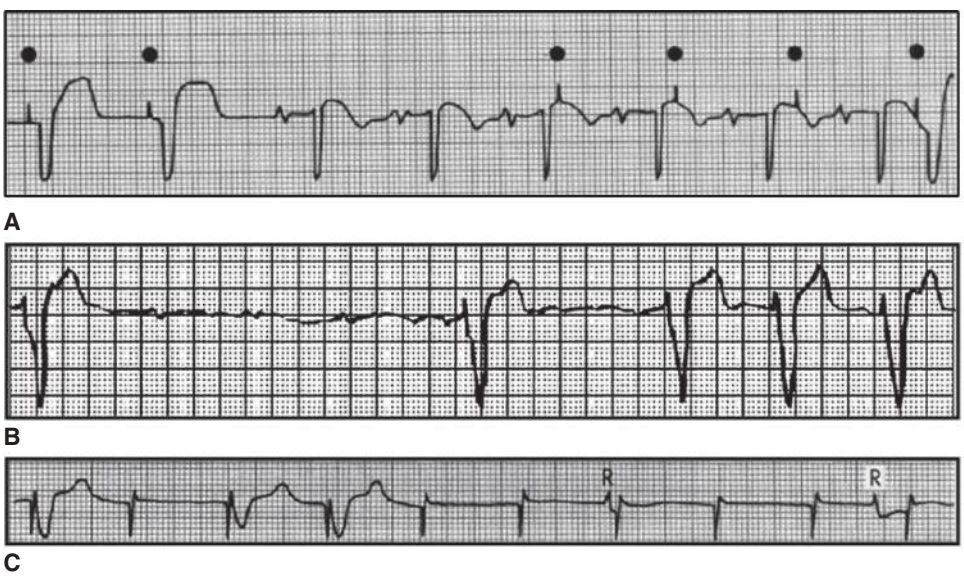

FIGURE 33-6. Various pacemaker malfunctions. **A.** Undersensing. **B.** Oversensing. **C.** Failure to capture.

TABLE 33-8 Potential Causes of Inappropriate Implantable Cardioverter-Defibrillator (ICD) Shock Delivery

False sensing
Supraventricular tachycardia with rapid ventricular response
Muscular activity (shivering, diaphragmatic contraction)
Extraneous source (tapping of chest wall, vibrations, pacer spikes)
Sensing T waves as QRS complex (double counting)
Sensing lead fracture or migration
Unsustained tachyarrhythmia
ICD–pacemaker interactions
Component failure

ED EVALUATION

The most common reason an patient with an implantable cardioverter-defibrillator comes to the ED is evaluation after a delivered shock. Causes of inappropriate shock delivery are summarized in **Table 33-8**. Determine the number of shocks delivered, the activity of the patient at the time of shock, and any prodromal symptoms or postshock trauma. Ask about any recent changes in rhythm-directed drug therapy. Focus the physical examination on the vital signs, the cardiovascular status, the generator pocket, and evidence of incidental trauma. Place each patient on a continuous ECG monitor, and **obtain a 12-lead ECG; any shock-related ST-segment elevations or depressions should resolve within 15 minutes; ongoing changes suggest new ischemia.** Examine a chest radiograph for electrode migration, displacement, or fracture. Obtain rhythm-related drug levels and serum electrolyte levels.[6,7]

If the patient is receiving repeated inappropriate shocks for a nonlethal rhythm, temporarily deactivate the implantable cardioverter-defibrillator by placing a magnet over the device. Defibrillation can be re-enabled by removing the magnet. All implantable cardioverter-defibrillators should be evaluated by a cardiologist after exposure to a magnet.

For a patient with an implantable cardioverter-defibrillator in cardiac arrest, follow all normal resuscitation measures. **If defibrillation is necessary, do not place either the paddle or pad directly over the implantable cardioverter-defibrillator pulse generator.** Perform CPR in the usual fashion. If the implantable cardioverter-defibrillator discharges during CPR, the CPR provider may perceive a small electrical shock, but the shock is neither uncomfortable nor dangerous.

DISPOSITION AND FOLLOW-UP

Admission criteria depend on the reason for shock delivery; consultation with the treating cardiologist is key. The ICD can be interrogated by external telemetry devices that are manufacturer and model specific. General admission recommendations include any sign of cardiovascular instability, a history of two or more shocks in a 1-week period, correctable causes of dysrhythmia, and any sign of infection or mechanical disruption of the implantable cardioverter-defibrillator or lead system.

CHAPTER 34

Pericardiocentesis

Carolyn K. Synovitz
Eric J. Brown

INTRODUCTION AND EPIDEMIOLOGY

Cardiac tamponade is a relatively rare condition. **If a pericardial effusion compromises hemodynamics, pericardiocentesis can be lifesaving.** The cause of cardiac tamponade may be determined by fluid analysis after pericardiocentesis (**Table 34-1**).[1-4]

In a small study of medical cardiac tamponade, the mean volume drained was 593 ± 313 mL. When the primary cause was malignancy, the 1-year mortality was almost 80%.[5] In Africa, up to 70% of pericardial effusions in patients with human immunodeficiency virus are caused by tuberculosis.[6]

Maintain a high degree of suspicion of cardiac tamponade for oncology patients who fit the clinical signs and symptoms of tamponade.

Blunt cardiac rupture is rare, occurring approximately in 1 in 2400 blunt trauma patients. Of this subgroup, 89% arrive alive to the ED.[7] Those who arrive alive may benefit from a bedside US examination to detect a traumatic effusion. **Tamponade, as a result of trauma, may require a temporizing pericardiocentesis while the patient is prepared for definitive surgical repair.**

In a South African study, the mortality rates from gunshot wounds and stab wounds were 81% and 15.6%, respectively.[8] This comparison underlines the probability that patients with stab wounds to the heart are more likely to survive to the ED and may benefit from pericardiocentesis.

PATHOPHYSIOLOGY

The pericardium is a fibrocollagenous sac covering the heart that contains a small amount of physiologic serous fluid. The fibrocollagenous pericardium has elastic properties and will stretch in response to increases in intrapericardial fluid. Accumulation of fluid that exceeds the stretch capacity of the pericardium precipitates hemodynamic compromise and results in pericardial tamponade.

The initial portion of the pericardial volume–pressure curve is flat, so early on, relatively large increases in volume result in comparatively small changes in intrapericardial pressure. The pericardium becomes less elastic as the slope of the curve marches upward. As fluid continues to accumulate, intrapericardial pressure rises to a level greater than that of the filling pressures of the right atrium and ventricle. When this occurs, ventricular filling is restricted and results in cardiac tamponade.[9]

Pulsus paradoxus is commonly seen with cardiac tamponade and is defined as an abnormal decrease in systolic blood pressure and pulse wave amplitude. During normal respirations, systolic blood pressure drops less than 10 mm Hg. In pulsus paradoxus, systolic blood pressure drops >10 mm Hg, resulting in a cardiac contraction that does not result in a normal radial pulse. This causes a paradoxical pulse.[10]

In blunt trauma, forces within the thorax can compress the right atrium, resulting in rupture of the atrium or the right atrial appendage. This occurs when blood continues to fill the relatively inelastic pericardial sac. Deceleration injuries can lead to a cardiac or pericardial rupture, herniation, or a myocardial contusion with intrapericardial hemorrhage. Blast injuries can cause acute cardiac tamponade.[11] **During an acute rapidly expanding pericardial effusion, stroke volume will increase with removal of even a small amount of fluid (as little as 50 mL) from the pericardial sac (Figure 34-1).**

CLINICAL FEATURES

HISTORY

Trauma as a cause of pericardial tamponade is generally evident from history and clinical presentation. Oncology patients comprise the largest

TABLE 34-1 Causes of Pericardial Effusions

Cause	Sagrista-Sauleda et al[1] (n = 322) (%)	Corey et al[2] (n = 75) (%)	Levy et al[3] (n = 204) (%)	Kil et al[4] (n = 116) (%)

group with pericardial effusions leading to hemodynamic compromise. Other conditions that may predispose a patient to pericardial effusion and tamponade include acute infection (viral, bacterial, mycoplasma, fungal, parasitic, or endocarditis) or radiation exposure. Other chronic conditions in which this diagnosis may be considered include tuberculosis, renal failure, autoimmune diseases, drugs that induce a lupus-like syndrome, hypothyroidism, or ovarian hyperstimulation syndrome.[12] Many cases are idiopathic.

The **key symptoms of tamponade** are dyspnea and chest pain. Trauma patients may or may not exhibit pleuritic pain, tachypnea, and dyspnea before becoming confused, losing consciousness, or developing shock.[13] Other symptoms include chest fullness, nausea, esophageal pain, or abdominal pain from hepatic and visceral congestion. Other nonspecific symptoms include lethargy, fever, weakness, fatigue, anorexia, palpitations, and shock. Be aware of these symptoms and accordingly focus the examination to exclude life-threatening conditions, such as cardiac tamponade.

PHYSICAL EXAMINATION

Common clinical signs of cardiac tamponade may resemble other severe cardiopulmonary disease processes, such as tension pneumothorax or decompensated congestive heart failure. The sensitivities of examination findings are pulsus paradoxus >10 mm Hg (82%), tachycardia (77%), jugular venous distention (76%), diminished heart sounds (28%), and hypotension (26%). These findings are not surprising because the **Beck triad** includes low blood pressure, elevated jugular venous distention, and decreased heart sounds.[10] Detection of jugular distention may be difficult to appreciate in patients with a short, thick neck or if working under levels of low lighting. **The combination of pulsus paradoxus and elements of the Beck triad should prompt imaging with bedside US to search for a pericardial effusion.** Any disorder that increases intrathoracic pressure may result in pulsus paradoxus, including chronic obstructive pulmonary disease, obesity, tense ascites, severe asthma, congestive heart failure, mitral stenosis, and massive pulmonary embolism.

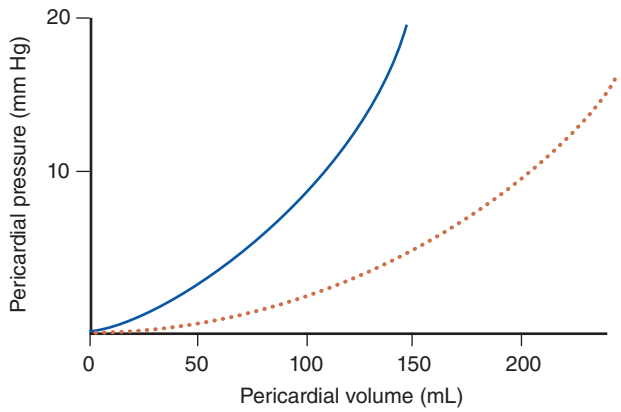

FIGURE 34-1. Acute versus chronic pericardial effusion. Pericardial volume–pressure curve with acute (*solid line*) versus chronic effusion (*dotted line*). DIAGNOSIS

The diagnosis in an undifferentiated patient relies on clinical suspicion using the signs and symptoms of cardiac tamponade, with confirmation by bedside US (see discussion in "Echocardiography" section, below).

The ECG can be normal. The classic ECG finding is electrical alternans. Electrical alternans is alternating high- and low-voltage QRS complexes as the heart swings toward and then away from the ECG leads on the chest wall with each contraction (**Figure 34-2**). Other findings can include nonspecific ST-T wave changes or bradycardia, which can be seen in the late stages of cardiac tamponade progressing to pulseless electrical activity (PEA). In the absence of hypotension and tension pneumothorax in a patient with PEA, consider the diagnosis of cardiac tamponade.

IMAGING

Chest radiographs may show a normal or enlarged cardiac silhouette with clear lungs, as demonstrated in **Figure 34-3**. On lateral chest radiographs, a double lucency sign demonstrates the epicardial fat pad.

Echocardiography Cardiac tamponade can be imaged at the bedside with two-dimensional echocardiography and Doppler echocardiography. This allows for visualization of a pericardial effusion and the compression of the ventricles. The most characteristic sign on echocardiogram is right-sided heart collapse. During diastole, the right ventricle presses inward (**Figure 34-4**), and during systole, the right atrium presses inward. Right-sided collapse portends rapid development of cardiac tamponade. Right atrial collapse during at least 30% of the cardiac cycle is more sensitive than the finding of right ventricular collapse for cardiac tamponade. In 25% of patients with tamponade, a late finding is left atrium collapse. Doppler US can be used to monitor the respiratory changes in flow between ventricle and atrium.[9]

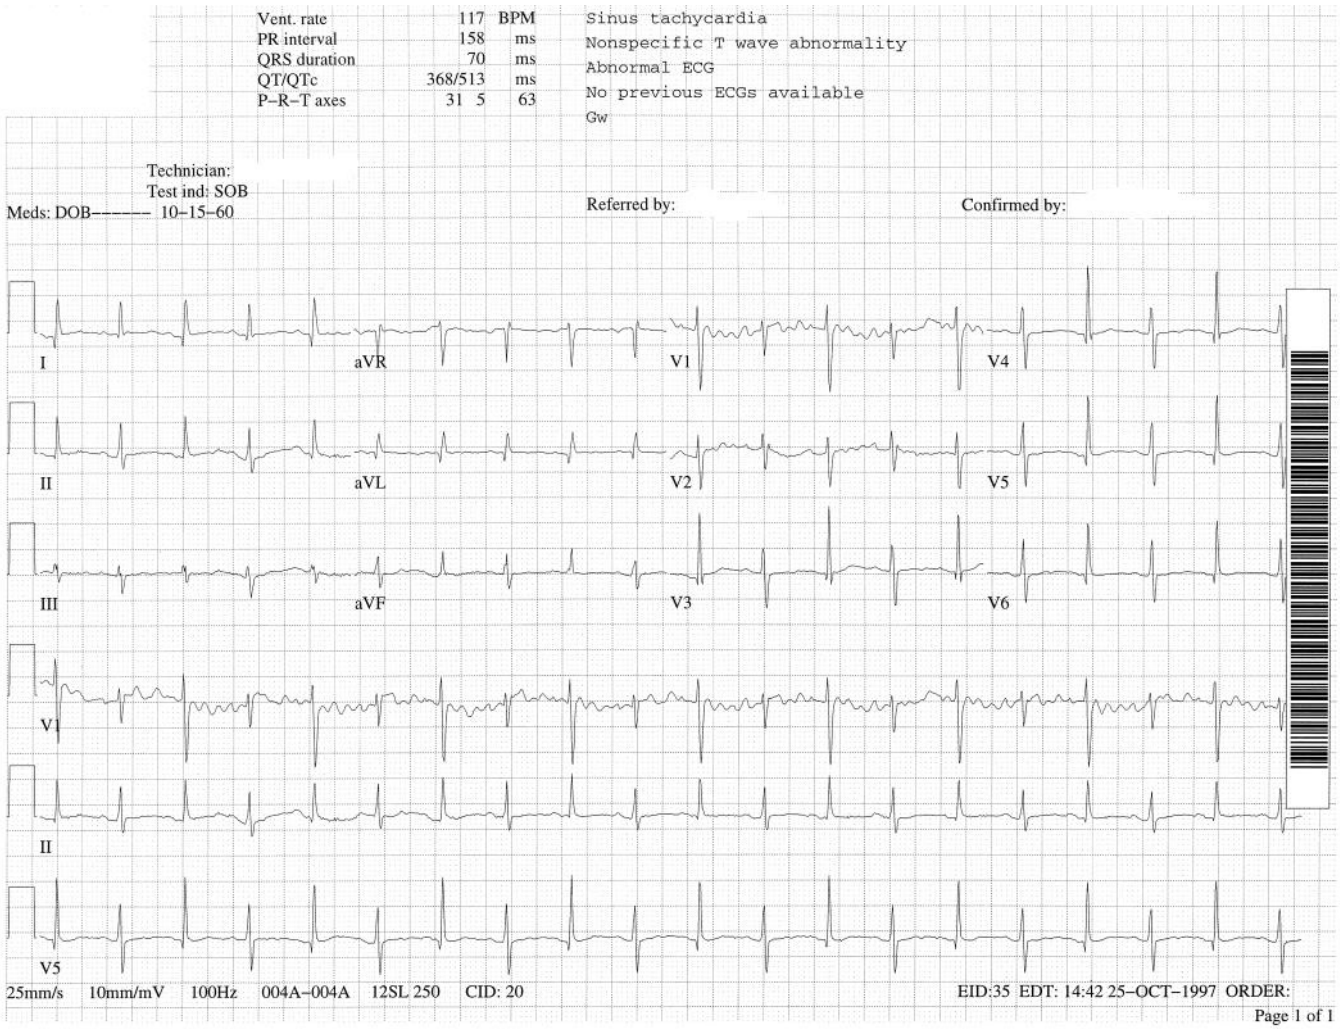
PROCEDURE: EMERGENCY PERICARDIOCENTESIS

When hemodynamic compromise is present, infusion of a normal saline fluid bolus can be temporizing by improving right ventricular volume while preparations are made for emergency pericardiocentesis.[1]

PURPOSE AND INDICATIONS

The purpose of emergency pericardiocentesis is treatment of hemodynamic compromise from cardiac tamponade. Emergency pericardiocentesis is also

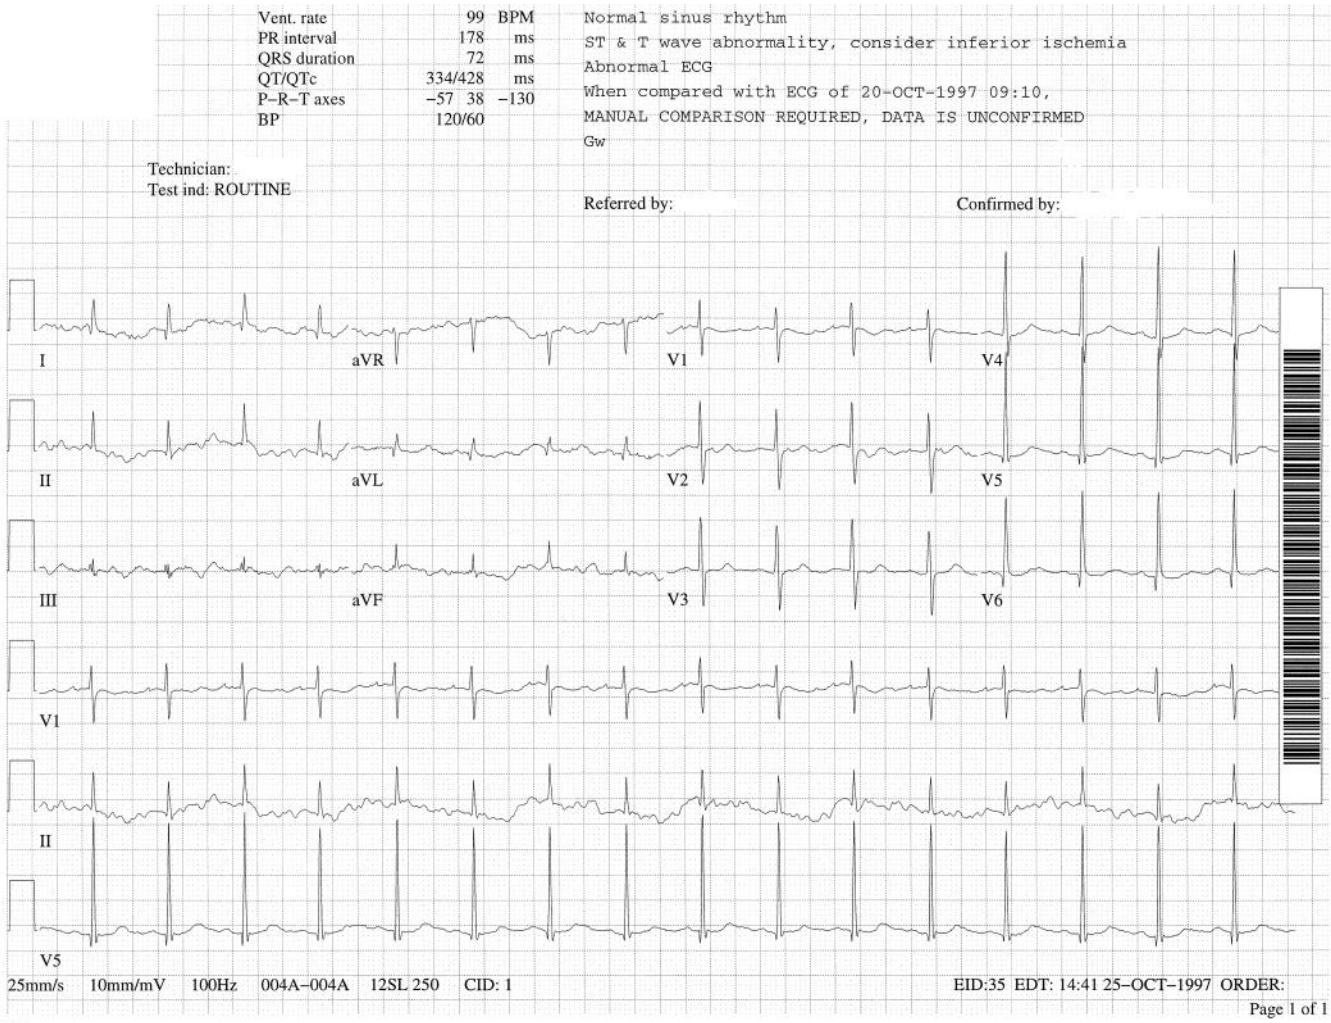
indicated during resuscitation from PEA after other causes of PEA have been excluded.



Postoperative or penetrating trauma patients may develop tamponade 2 weeks or more after surgery.[7] In one study of traumatic tamponade, the most common indications for pericardiocentesis were clinical tamponade (83%), with echocardiographic findings of ventricular diastolic collapse (69%) and right atrial collapse (33%).[14] Pericardiocentesis for a traumatic effusion from penetrating cardiac trauma may be performed during resuscitation to stabilize a patient until surgery for definitive repair is available, but surgical drainage is preferred in traumatic effusions and purulent pericarditis.[15] **If the patient is hemodynamically compromised and on the verge of cardiac arrest, perform emergency pericardiocentesis in the ED, rather than delay treatment by transporting to the OR.**

BEDSIDE US

If bedside US is available, two-dimensional echocardiographic imaging is preferred to guide pericardiocentesis[16-19] and can also evaluate the size of the effusion and its effect on cardiac output. The 2010 Focused Cardiac Ultrasound in the Emergent Setting guidelines state: "When emergency pericardiocentesis is indicated ultrasound can provide guidance by first imaging the fluid collection from the subxiphoid/subcostal or other transthoracic windows to define the best trajectory for needle insertion."[20] The guidelines further emphasize that bedside US results in fewer complications and greater success in performance of pericardiocentesis.[20] The European Society of Cardiology's 2004 Guidelines on the Diagnosis and Management of Pericardial Disease has evidence-based guidelines on pericardiocentesis. Pericardiocentesis is lifesaving in cardiac tamponade (level of evidence B, Class I indication) and indicated in effusions >20 mm in echocardiography but also in smaller effusions for diagnostic purposes (pericardial fluid and tissue analyses, pericardioscopy, and epicardial/pericardial biopsy; level of evidence B, Class IIa indication). American College of Cardiology/American Heart Association 2005 guidelines for the use of echocardiography gives Class I recommendations to using this methodology for visualizing effusions and detecting hemodynamic compromise secondary to tamponade. The European Society of Cardiology 2004 guidelines recommend that practitioners use US guidance rather than blind approaches and the ECG-alone guided approach for pericardiocentesis.[21] Using echocardiographic-guided pericardiocentesis reduces radiation associated with fluoroscopy and allows the procedure to be performed safely at the bedside.[22]



CONTRAINDICATIONS TO PERICARDIOCENTESIS

Some authors list aortic dissection as an absolute contraindication. Relative contraindications include uncorrected coagulopathy, anticoagulant therapy, thrombocytopenia, and small posterior loculated effusions.

RISKS AND PRECAUTIONS

Traditional blind subxiphoid approaches increase risk of damage to adjacent structures, such as the liver, lung, diaphragm, and GI tract. The cardiovascular system may also sustain injuries during the procedure, including chamber puncture, myocardial damage, and laceration of coronary arteries/veins. Resultant arrhythmias may develop as well, secondary to myocardial damage. Although risks must be considered, use of specific techniques and imaging can significantly reduce injury from the procedure itself. If bedside US is not available and the patient has cardiac or hemodynamic compromise, the blind subxiphoid approach for cardiac tamponade for acute hemopericardium can be used.[23] See **Table 34-2** for a list of equipment needed.

PATIENT PREPARATION AND POSITIONING

If time and conditions permit, obtain and review a stat portable chest x-ray to identify mediastinal shift or pneumothorax. Traditional positioning for pericardiocentesis is with the head of the bed elevated to approximately 30 to 45 degrees, but in cardiac arrest or near-arrest, this position may not be feasible. Therefore, the procedure is often performed with the patient supine. Before choosing the needle insertion site, it must be noted if the patient has mediastinal shift, as this can displace structures and alter normal anatomic locations. In some instances, very small effusion volumes (50 to 100 mL) precipitate cardiac tamponade, and therefore, fluid may collect in dependent portions of the pericardial space. If the size of the effusion is small, rolling a patient to the

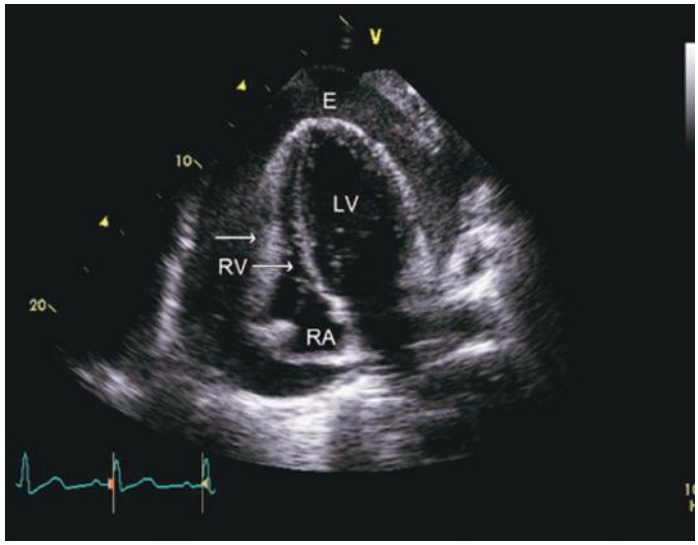

FIGURE 34-4. RV compression (*arrow*) in cardiac tamponade (apical four-chamber plane). E = effusion; LV = left ventricle; RA = right atrium; RV = right ventricle. [Reproduced with permission from Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P: *Hurst's the Heart*, 12th ed. New York: McGraw-Hill Inc.; 2008. Figure 16-135B.]

left lateral decubitus position allows fluid to collect around the apex and provides easier access. This positioning also allows the left lung to move laterally, thereby increasing cardiac exposure.

ANESTHESIA AND MONITORING

Patients undergoing emergency pericardiocentesis in the ED are often in significant distress and are being resuscitated. They may therefore already be sedated or paralyzed, or both. If local anesthesia is needed, immediately before the procedure, administer 1% to 2% lidocaine SC and along the plane of expected needle insertion. Aspirate during infiltration to avoid injection of lidocaine directly into vascular structures.

Institute cardiac monitoring and pulse oximetry, and provide supplemental oxygen. Assistants can monitor the pulse amplitude.

TABLE 34-2 Equipment for Emergency Pericardiocentesis

Antiseptic (e.g., povidone-iodine, ChloraPrep)
Local anesthetic (1%–2% lidocaine)
25-gauge needle, $^5/_8$ in. long
18-gauge catheter-type needle, $1^1/_2$ in. long (for parasternal or apical approaches)
Syringes (10, 20, and 60 mL)
4 × 4 gauze squares
Plastic tubing
Collection system or basin
US machine
Sterile US probe cover (can be sterile glove)
Sterile drapes
Yankauer suction catheter
Suction tubing
Cardiac monitoring
Optional
18-Gauge spinal needle $3^1/_2$ in. long (if needed for subxiphoid blind approach)
Alligator clips connected by wire (for ECG approach)
Bedside ECG
Nasogastric tube
Variable angle needle guide attachment for US
Towel clips
#11 scalpel blade
J-tipped guidewire 0.035 mm diameter
6F–8F pigtail catheter
Three-way stopcock

STEP-BY-STEP TECHNIQUE

1. Use universal precautions.
2. Organize needed materials.
3. Position patient as needed.
4. Identify point of maximal effusion with US (i.e., closest to transducer/skin and where accumulation is maximal). Pericardial effusions are dark, or anechoic, areas surrounding the heart. Usually the pericardium can be seen overlying the effusion. In addition, paradoxical motion of the right ventricular wall with collapse during diastole is noted in states of tamponade. Distance from the skin surface to the effusion border can be measured with most US models to better assess expected needle depth.
5. Choose needle trajectory. Trajectory should be chosen to coincide with the plane of the US beam. Identify any anatomic structure between the skin and pericardial space that lies within the expected needle path. Although many approaches can be used, the best approach should aim for the point of maximal effusion with the fewest intervening structures. For most patients, the optimal approach is the left chest wall. Most common is the left parasternal approach or the apical approach, both at the fifth intercostal space (**Figure 34-5**), or the subxiphoid approach. If using the left parasternal approach, select a site approximately 3 to 5 cm from the sternal edge to avoid the left internal mammary artery. Direct the needle over the superior margin of the rib to avoid injuring the neurovascular bundle on the inferior margin of each rib. The site may be marked with a surgical pen for easier location after sterile preparation.
6. Sterile preparation. Prepare area with povidone-iodine or equivalent antiseptic. Drape the surrounding area with sterile towels or a premade drape (clear drapes available commercially).
7. Inject local anesthetic. Inject 1% to 2% lidocaine with a 25-gauge, $^5/_8$ inch needle at the selected site before the procedure. Produce a subcutaneous wheal, and then inject into deeper tissues while avoiding entry into the chest cavity. Aspirate before injection to avoid injection of anesthetic into vascular structures.

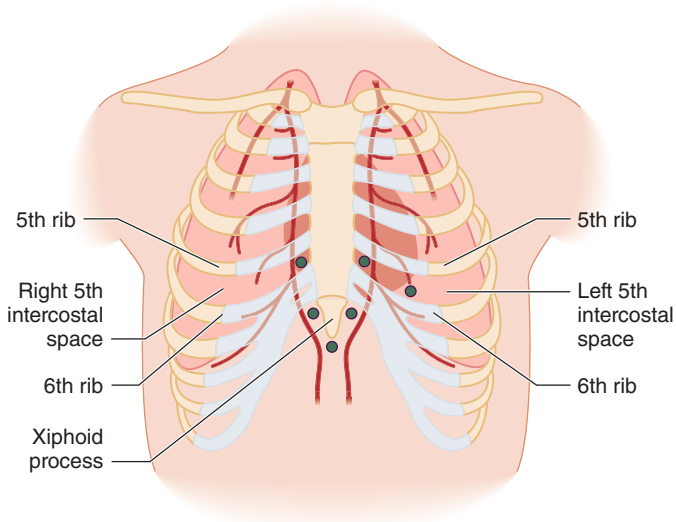

FIGURE 34-5. Potential sites to perform a pericardiocentesis. [Adapted with permission from Smith RF: Pericardiocentesis, in Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. New York: McGraw-Hill, 2004.]

8. Preparation of US. Using the cardiac probe, place a sterile cover over the probe (may use sterile glove) after placing US gel on the probe tip. Place sterile US gel over the planned site of entry. Using the nondominant hand, hold the US probe in the plane of planned needle insertion. A second operator technique may be used.
9. Pericardial needle insertion. Under direct US guidance, insert needle at the predetermined site at an approximately 45-degree angle to the skin at the transducer. Visualize the needle "tenting" the pericardium. Upon entry into the pericardial sac, a return of blood, serous fluid, pus, and so on, should be obtained. Clotted blood may prevent aspiration. Blood can clot within the needle or may have clotted within the pericardial space. Often, clotted blood within the pericardial space can be identified on US examination as echogenic material. If you suspect needle obstruction, attempt flushing the needle with 1 to 2 mL of normal saline to cleanse the needle. If aspiration is too easy, suspect ventricular puncture. To decrease complications of needle insertion, do not redirect the needle within the pericardium while aspirating. This may reduce the number of occurrences of inadvertent coronary artery lacerations or penetrating the pericardium.
10. Fluid collection. Fluid may be collected for diagnostic testing to assess for protein or albumin, cell counts, Gram stain, and cultures, among others.
11. Catheter removal. Once adequate fluid has been withdrawn from the pericardial space and hemodynamic equilibrium has returned, the catheter may be removed. The site should be dressed as with any needle insertion site. Alternatively, an optional indwelling flexible J-tip catheter may be placed as in step 2 under "Optional Steps." Although recurrence rates have been shown to decrease significantly with indwelling or extended catheter drainage, this is not routinely performed in the ED secondary to patient acuity and ongoing resuscitative measures. Once hemodynamics have been returned to normal and the patient stabilized, evaluation and possible indwelling catheter placement can be performed by the cardiologist.

OPTIONAL STEPS

1. Saline echo-contrast technique. When confirmation of the needle tip is necessary, agitated saline solution can be used. Using a three-way stopcock, attach one end to the catheter. Attach one syringe with 3 mL of normal saline and one syringe with an equivalent amount of air to the remaining two ports. Quickly mix the saline and air together and then inject into the pericardial sac under US visualization. Alternatively, the saline may be agitated by simply shaking a 10-mL syringe filled with 3 to 5 mL of normal saline and then injecting this into the pericardial space. An echo-contrasted medium should appear in the pericardial space. If the contrast disappears quickly after injection, suspect tip placement in ventricle. Rather than attempting to reinsert needle into the catheter, it is best to start again with a new needle should this complication arise.
2. Catheter placement. Using the standard Seldinger technique, a flexible J-tip guidewire is introduced through the catheter. The catheter is then removed. Next, a small "stab" incision is made at the needle entry site. A 6- to 8-French dilator is introduced over the guidewire and then removed. A 6- to 8-French pigtail catheter is then introduced over the guidewire. The guidewire is then removed. Confirmation of placement can be done by saline echo-contrast as in step 1 above. Catheter is then placed to suction.
3. Dressing. Secure catheter to chest wall with suture, dressing, or both.
4. Catheter drainage and maintenance. Pericardial fluid should be aspirated intermittently approximately every 4 to 6 hours. To prevent catheter blockage, continuous drainage is avoided. Flushing of the catheter with saline after drainage will ensure patency. Strict inputs and outputs should be measured by staff.
5. Catheter removal. Although not routinely done by ED staff, the catheter may be removed once drainage has decreased to <30 mL in 24 hours. In addition, follow-up two-dimensional echocardiography should confirm resolution of the effusion.

BLIND SUBXIPHOID APPROACH

The blind subxiphoid approach starts with similar preparation and anesthetic. The point of needle insertion starts either directly below or adjacent to the xiphoid process. An 18-gauge needle is inserted at a 45-degree angle to the patient's skin, and the needle tip is directed to *either* the left or right shoulder (**Figure 34-6**). Some authors advocate using the right shoulder as the direction of choice because this direction is parallel to the ventricular wall (in contrast to perpendicular for left shoulder direction), thereby theoretically reducing the chance of myocardial injury. In either approach, the needle is aimed toward the heart with continuous aspiration of the syringe until return of pericardial fluid.

ECG MONITORING TECHNIQUE

The ECG monitoring technique uses ECG monitoring to detect myocardial injury patterns and localize needle location. However, ECG injury monitoring alone is not an adequate safeguard.[17] The approach is similar to the blind approach in orientation. Attach the V_1 monitor lead to the needle. Watch the monitor while introducing the needle. ST elevation on

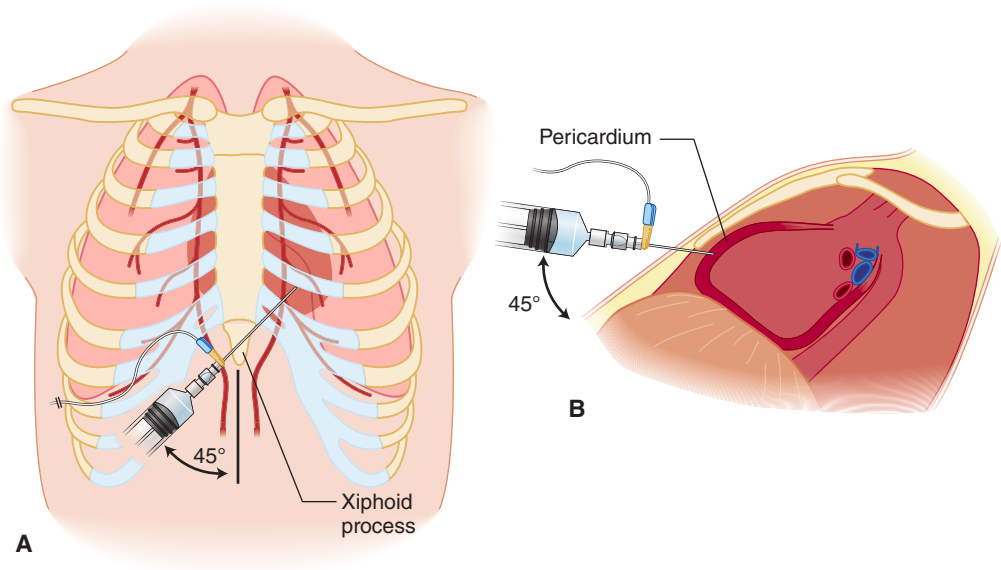

FIGURE 34-6. The subxiphoid approach. The needle is inserted at a 45-degree angle to the midsagittal plane **(A)** and at a 45-degree angle to the abdominal wall **(B)**. [Adapted with permission from Smith RF: Pericardiocentesis, in Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. New York: McGraw-Hill, 2004.]

the monitor indicates that the needle tip has contacted the myocardium. Withdraw the needle slightly and aspirate. This technique is rarely used currently due to complexity in the emergent setting and advances in US allowing for safer alternatives.

OUTCOME ASSESSMENT

A favorable outcome is the restoration of hemodynamic stability with return of normal blood pressure and heart rate. Two-dimensional echocardiography should also show decreased effusion, increased cardiac contractility, and increased cardiac output.

COMPLICATIONS

Complications may vary widely, dependent on approach and the underlying cause of tamponade. Traditional blind techniques have been associated with morbidity of 20%, with mortality as high as 6%. The overall complication rate of US-guided approaches is <5%.[16]

Major complications include chamber lacerations requiring surgery, intercostal vessel injury requiring surgery, pneumothorax requiring chest tube placement, ventricular tachycardia, and bacteremia. Minor complications include transient chamber entries, small pneumothorax not requiring intervention, hypotension secondary to vasovagal response, sinus tachycardia, pericardial catheter occlusion, and possible pleuropericardial fistulas.[16] Cardiac arrhythmias, such as atrial fibrillation, ventricular tachycardia, or asystole, may occur when the needle penetrates the pericardium. Monitor the patient closely for reaccumulation of pericardial fluid after pericardiocentesis.

DISPOSITION AND FOLLOW-UP

All patients undergoing pericardiocentesis in the ED require admission to the intensive care unit. Consult the trauma surgeon, cardiologist, or cardiothoracic surgeon, as appropriate, early in patient evaluation.

SECTION 5

Analgesia, Anesthesia, and Procedural Sedation

CHAPTER 35

Acute Pain Management

James Ducharme

INTRODUCTION

Pain is the most common presenting symptom for patients coming to the ED, with 75% to 80% of all patients having pain as their primary complaint.[1] Despite increasing research and information about pain management, oligoanalgesia, or the under treatment of pain, persists.[2-5] While all patients are susceptible to oligoanalgesia, certain subgroups, such as ethnic minorities, the aged, the very young, and those with diminished cognitive function, are more at risk (**Table 35-1**).[6-9] Pain management is further influenced by concerns of prescription opioid misuse, a rising concern in all age groups but most notably in adolescents and young adults. Pain and addiction are not mutually exclusive,[10] and appropriate treatment of acute pain should not be withheld for fear of facilitating drug misuse.

Specific measures to treat pain should occur *in addition* to, and at the same time as, treatment of the underlying illness or injury. **It is not possible to generalize the extent and quality of pain control needed for a specific patient.** For example, pain is an indicator of ongoing cardiac ischemia, and the goal should be to eliminate all pain. On the other hand, a patient with a traumatic injury may choose to endure more pain out of personal or cultural beliefs. Physicians may limit analgesics in those with head injuries to perform serial neurologic examinations. Whenever possible, medications that act on specific sites that initiate the pain signal—a mechanistic approach—are preferred to agents such as opioids that mask pain, which is a symptomatic approach. Current migraine treatment is an excellent example of the mechanistic approach; preferred treatment includes a serotonin agonist (triptan)[11] or a dopamine antagonist (phenothiazine),[12] rather than opiates.[13,14]

PATHOPHYSIOLOGY

Pain is the physiologic response to a noxious stimulus, whereas suffering—the expression of pain—is modified by the complex interaction of cognitive, behavioral, and sociocultural dimensions. Individual pain experience is therefore not static, but varies depending on current and past medical history, physical and emotional maturity, cognitive state, meaning of pain, family attitudes, culture, and environment. Emotions can modify pain either negatively or positively: fear and anxiety may accentuate pain, or pain can be suppressed completely if an essential task must be performed or if there is acute concern about a loved one.

The peripheral nervous system (e.g., nociceptors, C fibers, A-δ fibers, and free nerve endings) initiates the sensation of somatic pain by responding to a noxious stimulus and sending a neuronal discharge to the dorsal horn of the spinal cord.[15] Neurons in the dorsal horn of the spinal cord integrate and modulate input from multiple peripheral nerves and other sensory stimuli. Transmission then proceeds up the spinal cord to the CNS (e.g., hypothalamus, thalamic nuclei, limbic system, and reticular activating system) where further integration and processing generate the perception of pain. Identification and localization of pain, cognitive interpretation, and triggering of emotional and physiologic reactions also occur at these central sites. Unlike somatic pain, which is easily localized, visceral pain pathways are more complex and differ in structure from somatic pain pathways, which may explain the poor localization of visceral pain.

Opioid analgesics work by binding to receptors in the spinal cord and brain. There are four types of **opioid receptors**: three classic families (**delta, kappa, and mu**, each with identified subtypes) and nociceptin, a receptor with significant structural homology. These receptors are found in the brain, spinal cord, and GI tract where their physiologic function is to interact with endogenous dynorphins, enkephalins, endomorphins, endorphins, and nociceptin. Opioid analgesics interact with these receptors in varying degrees, accounting for the difference in desired and adverse effects among the drugs in this class. Stimulation of the mu-1 (μ_1) receptor produces supraspinal analgesia. Stimulation of the mu-2 (μ_2) receptor results in euphoria, miosis, respiratory depression, and depressed GI motility. Stimulation of the delta (δ) receptor produces analgesia, but less than the μ_1 receptor, and also exerts an antidepressant effect. Stimulation of the kappa (κ) receptor produces dysphoria, along with dissociation, delirium, and diuresis by inhibiting antidiuretic hormone release.

EVALUATION

Document the degree of pain on initial assessment. This process serves to identify patients with severe pain, facilitates treatment, and meets the mandates of regulatory agencies that promote assessing and treating pain. ED pain assessment should determine duration, location, quality, severity, and exacerbating and relieving factors. **The patient's subjective reporting of pain, not the physician's impression, is the basis for pain assessment and treatment.** There is at best a weak correlation between nonverbal signs, such as tachycardia, tachypnea, and changes in patient expression and movements, and the patient's report of pain, so do ***not*** rely on these to determine the severity of a patient's pain[16,17] or response to treatment.[18] Because pain is dynamic and changes with time, periodic pain reassessment is needed.

Although standardized scales for measuring reported pain are commonly used, their impact on effective pain control is uncertain.[19,20] The primary value of pain scales is their essential role in research enabling reproducible comparisons of interventions. Some studies have suggested that the use of pain scales may actually *decrease* the provision of analgesics. Given the subjectivity both of pain reporting and the provider's interpretation of such reporting, the use of simple descriptors such as "a little" or "an awful lot" is equally valid in the clinical setting. What *is* important is that the patient's subjective reporting should be the basis for assessment and management. For most, but not all, painful conditions, the goal is to control pain to the level the patient desires. **Asking if the patient requires more analgesic may even be simpler and accomplish more than using any standardized pain evaluation tool.**[21,22]

PAIN SCALES

The purpose of pain scales is to quantitate pain severity, guide the selection and administration of an analgesic agent, and reassess the pain response to determine the need for repeated doses or more effective analgesics. Several self-report instruments are valid in patients with acute pain, and some require only a verbal response (**Table 35-2**). Each tool has advantages and specific limitations. ED personnel in any one location should use the same tool so information collected is standardized. **A value assigned by a patient is not an absolute value but rather a reference point *based on past personal experience*.**[23]

PAIN SCALE PERFORMANCE IN SPECIAL PATIENT POPULATIONS

The elderly often report pain differently from younger patients because of physiologic, psychological, and cultural changes associated with aging. Visual, hearing, motor, and cognitive impairments can be barriers to effective pain assessment. Using a numerical pain scale, the elderly may also experience a decrease in the minimum clinically significant

TABLE 35-1 Barriers to Adequate ED Pain Control

Patient Related	Provider Related	System Related
Ethnicity, gender, age (very young, very old)	Inadequate education	Lack of clearly articulated standards
Diminished cognitive function	No objective measuring tool for pain	Paucity of treatment guidelines
Fear of medications: addiction, side effects	Accepting only pain reports that conform to our expectations	Fear of regulatory sanctions
Acceptance of pain as being inevitable	Perception of addiction and drug-seeking behavior	Lack of healthcare provider accountability
Unwillingness to bother healthcare providers		

noticeable difference in acute pain over time.[24,25] Family members and caregivers are often able to judge nonverbal actions of the patient as representing pain or distress, so they should be used if available to help with pain assessment in the noncommunicating elderly patient.

Trauma patients and those with acute intoxication do not perform as well on pain scales.[26] Women are more likely to express pain and to actively seek treatment for pain,[27,28] yet there is a tendency to underestimate and undertreat pain in women. Ethnicity of both the patient and the physician has a bearing on different cultural concepts of pain and on the characteristics of culturally appropriate pain-related behaviors.[7] Translators and family members should be asked to provide assistance. There is also interplay between the ethnicity of the patient and that of the physician.[7] **When there are language difficulties or cross-cultural differences, the visual analog scale is the preferred pain assessment tool because it is the least affected by these factors.**

PHARMACOLOGIC PAIN TREATMENT

The administration of pharmacologic agents is the mainstay of acute pain management. **The key to effective pharmacologic pain management in the ED is selection of an agent appropriate for the intensity of pain and it's time to onset of analgesic activity, ease of administration, safety, and efficacy.**[29] Acute pain is usually accompanied by anxiety and feelings of loss of control. If verbal reassurance combined with an analgesic does not suffice, an anxiolytic may be useful.

The "tiered approach" to pain management starts with an agent of low potency regardless of pain intensity, assesses the response after a clinically relevant period, and sequentially changes to agents of higher potency if pain persists. **The tiered approach for acute pain management unnecessarily subjects the patient to more prolonged suffering. It is preferable to select initial analgesics that are appropriate to treat the intensity (mild, moderate, or severe) of the patient's pain.** Agents such as nonsteroidal anti-inflammatory drugs should be considered for mild to moderate pain, and systemic opioids for moderate to severe pain (**Table 35-3**). In specific instances such as renal and

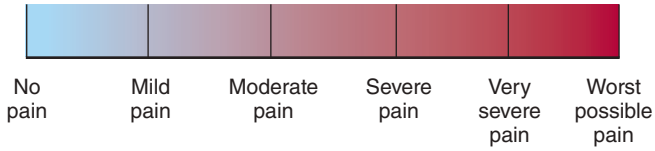

FIGURE 35-1. Pain scale: Adjective rating scale.

FIGURE 35-2. Pain scale: Visual analog scale (VAS).

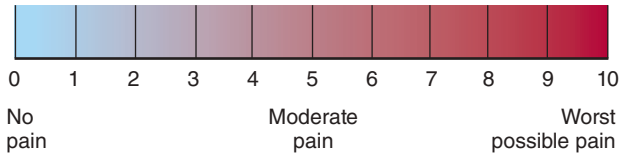

FIGURE 35-3. Pain scale: Numeric rating scale.

TABLE 35-3 Pain Severity with VAS or NRS

Pain Severity	VAS (0 to 100 mm) or NRS (0 to 10)
Mild	VAS: 0 to 30–40 mm or NRS: 0 to 3–4
Moderate	VAS: 40 to 60–70 mm or NRS: 4 to 6–7
Severe	VAS: >60–70 mm or NRS: >6–7

Abbreviations: NRS = numeric rating scale; VAS = visual analog scale.

TABLE 35-2 Pain Scales[29A]

Scale	Method	Comments
Adjective rating scale (**Figure 35-1**)	Patient rates pain by choosing from an ordered list of pain descriptors, ranging from *no pain* to *worst possible pain*, with allowance for marks between discrete labels.	Easy to administer.
Visual analog scale (VAS) (**Figure 35-2**)	Patient places a mark that best describes pain intensity along a 10-cm linear scale marked at one end with a term such as *no pain* and at the other end with *worst imaginable pain*.	Pain intensity measured in millimeters from the no-pain end. A difference of 13 mm is the minimum clinically significant change *noticeable* by patients, whereas an average decrease of 30 mm appears to be the minimum *acceptable* change for pain control.*
Numeric rating scale (**Figure 35-3**)	The patient is asked to self-report pain on a scale of 0 to 10 with descriptors.	Can be used in patients with visual, speech, or manual dexterity difficulties by using upheld fingers. Not as discriminating as the VAS.
5-Point global scale	Patient rates pain as: 0 = none 1 = a little 2 = some 3 = a lot 4 = worst possible	A decrease of 1 point is a large change; scales with more choices allow monitoring of small changes in pain and may be more sensitive to changes.
Verbal quantitative scale	The patient is asked to self-report pain on a scale of 0 to 10 without descriptors.	Most commonly used scale; easy to administer.

TABLE 35-4 Pain Treatment: Comparison of Pharmacologic Classes

Class	Route	Advantages	Disadvantages
Nonsteroidal anti-inflammatory drugs	PO	Mild/moderate somatic pain plus severe colicky pain	Use caution in the elderly and in those with renal, GI, and hematologic disorders
	Parenteral	Does not require GI absorption	No more effective than PO More costly
Opioids	PO	Can be effective if adequately dosed	Variable absorption, somewhat slower onset
	IM	No IV access required	Painful injections Unreliable absorption
	IV	Ideal for titrated dosing	Need for IV access
Local anesthetics	Infiltration	Technical ease	Limited duration of action
	Peripheral nerve block	Opioid sparing	Technically difficult at some sites Facilitated with use of US guidance

biliary colic, a parenteral nonsteroidal anti-inflammatory drug may control severe pain, although combination therapy with an opioid is usually superior.

When possible, local anesthesia is a useful adjunct (**Table 35-4**). Peripheral nerve blockade for pain control and for procedures is a useful option, especially if guided by US (see chapter 36, Local and Regional Anesthesia).[30,31]

OPIOID ANALGESICS

Opioid analgesics are the cornerstone of pharmacologic management of moderate to severe acute pain (**Table 35-5**). The term *opiate* refers to agents that are structurally related to natural alkaloids found in opium, the dried resin of the opium poppy. The term *opioid* describes any compound with pharmacologic activity similar to an opiate, regardless of

TABLE 35-5 Pain Treatment: Initial Opioid Dosing

Drug [Class]	Typical Initial Adult Dose	Pharmacokinetics	Comments
Morphine [natural alkaloid]	0.1 milligram/kg IV	Onset: 1–2 min (IV) and 10–15 min (IM/SC)	Histamine release may produce transient hypotension or nausea and emesis; neither require routine adjunctive treatment.
	10 milligrams IM/SC	Peak effect: 3–5 min (IV) and 15–30 min (IM)	
	0.3 milligram/kg PO	Duration: 1–2 h (IV) and 3–4 h (IM/SC)	
Hydromorphone [semi-synthetic alkaloid]	0.015 milligram/kg IV	Onset: 3–5 min (IV)	More euphoria inducing than morphine.
	1–2 milligrams IM	Peak effect: 7–10 min (IV)	
		Duration: 2–4 h (IV)	
Fentanyl [synthetic piperidine]	1.0 microgram/kg IV	Onset: <1 min (IV)	Less cardiovascular depression than morphine. High doses can cause chest wall rigidity (>5 micrograms/kg IV).
		Peak effect: 2–5 min (IV)	
		Duration: 30–60 min (IV)	
	100-microgram nasal spray in 1 nostril		Used for breakthrough pain in opioid-tolerant cancer patients. Wait >2 h before treating another episode. May increase dose by 100 micrograms per episode.
	100-microgram buccal mucosa tablet		Used for breakthrough pain in opioid-tolerant cancer patients. May repeat after 30 min. Wait >4 h before treating another episode. May increase dose by 100 micrograms per episode. Available transmucosal forms not bioequivalent.
Meperidine (pethidine) [synthetic piperidine]	1.0–1.5 milligrams/kg IV/IM	Onset: 5 min (IV)	Contraindicated when patient is taking a monoamine oxidase inhibitor. Neurotoxicity may occur when multiple doses are given in the presence of renal failure.
		Peak effect: 5–10 min (IV)	
		Duration: 2–3 h (IV)	
Oxycodone [semi-synthetic alkaloid]	5–10 milligrams PO OR 0.125 milligram/kg PO	Onset: 10–15 min (PO)	Lower incidence of nausea. Possible inadvertent acetaminophen overdose with combination agents.
	30 milligrams PR	Duration: 3–6 h (PO)	
Hydrocodone [semi-synthetic alkaloid]	5–10 milligrams PO	Onset: 30–60 min (PO)	Lower incidence of nausea. Possible inadvertent acetaminophen overdose with combination agents.
		Duration: 4–6 h (PO)	
Codeine [natural alkaloid]	30–60 milligrams PO	Onset: 30–60 min (PO)	High incidence of GI side effects. Some patients cannot convert to codeine-6-glucuronide and morphine. Possible inadvertent acetaminophen overdose with combination agents.
	30–100 milligrams IM	Duration: 4–6 h (PO)	
Tramadol [other]	50–100 milligrams PO	Onset: 10–15 min (PO)	CNS side effects common.
		Duration: 4–6 h (PO)	

TABLE 35-6 Equipotent Opioid Doses

Drug	Equipotent IV Dose (milligrams)	Equipotent PO Dose (milligrams)	Equipotent IM Dose (milligrams)
Morphine	10	60 (acute) and 30 (chronic)	10
Hydromorphone	1.5	7.5	1.5
Fentanyl	0.1	0.2 (transmucosal)	0.1
Meperidine (pethidine)	75	300	75
Oxycodone	15	30	15
Hydrocodone	—	30	—
Codeine	130	200	130
Tramadol	—	350	—

chemical structure. Opioid use in the ED is often affected by concern for the precipitation of adverse events, such as respiratory depression or hypotension, or for facilitating drug-seeking behavior. As noted, a greater concern is oligoanalgesia and inadequate dosing of opioids when used. Considerations for use of opioids include (1) desired onset of action, (2) available routes of administration, (3) achievable frequency of administration, (4) concurrent use of nonopioid analgesics and adjunctive agents, (5) possible incidence and severity of side effects, and (6) continuation of the agent in an inpatient or ambulatory setting

Opioids need to be titrated to effect; patients differ greatly in their response to opioid analgesics.[32-34] Variation in pain reduction is related to age, initial pain severity, and previous or chronic exposure to opioids, but not body mass[35,36] or gender.[37] Relative potency estimates provide a rational basis for selecting the appropriate starting dose to initiate analgesic therapy,[38] changing the route of administration (e.g., from parenteral to PO), or switching to another opioid (**Table 35-6**), but undue reliance on these ratios is an oversimplification with potential for over- or underdosing.[39]

Opioid hypersensitivity is uncommon, and true allergic reactions are extremely rare. There is minimal evidence of clinical cross-sensitivity within opioid classes, with the possible exception that cross-sensitivity has been suggested among the piperidines (fentanyl, alfentanil, sufentanil, and meperidine). **Until more is known, it would be prudent to switch to a drug from a different opioid class if a patient develops a hypersensitivity reaction.** When used in equianalgesic doses, there is no compelling evidence to recommend one opioid over another. As much as possible, avoid using multiple agents, and titrate a single drug to the desired effect.

The use of **meperidine** is discouraged for several reasons: it is often underdosed; meperidine can interact with many drugs to precipitate a serotonin syndrome; and the parent drug is metabolized to normeperidine, which has neuroexcitatory properties and a long elimination half-life (24 to 48 hours).[40] Normeperidine can accumulate and produce toxicity in the elderly and those with renal failure, although this is a rare event.

Codeine is not a reliable analgesic, and it produces more nausea, vomiting, and dysphoria than other opioids. The analgesic effect of codeine is highly dependent on the metabolic conversion to the active metabolites codeine-6-glucuronide and morphine. Up to 10% of the U.S. population is deficient in the relevant enzymes for this conversion and, therefore, has an inadequate analgesic response to codeine. Conversely, there are case reports of neonatal deaths as a result of breastfeeding from mothers who were hypermetabolizers of codeine. In addition, the standard PO dose of 30 to 60 milligrams produces little analgesic effect above that of acetaminophen or nonsteroidal anti-inflammatory drugs.[41]

Tramadol binds to mu-receptors and weakly inhibits the reuptake of norepinephrine and serotonin producing a central opioid analgesic effect. Common side effects include dizziness, nausea, constipation and headache. Tramadol can induce the serotonin syndrome. Severe toxicity can include agitation and seizures. It is one of the many substances that can produce a false-positive result on the urine phencyclidine screen.[42]

Adverse effects of opioids include nausea, vomiting, constipation, pruritus, urinary retention, confusion, and respiratory depression. Pruritus, urinary retention, confusion, and respiratory depression are more common with IV, transmucosal, and epidural administrations as opposed to PO administration.

Adjuncts are sometimes used to enhance the analgesic effect, reduce the amount of opioid required, and prevent side effects (**Table 35-7**). Depending on the agent, amount, route, and setting, a beneficial effect can be seen. However, appropriate titration with opioids in the ED is highly effective, and there are few data to support the routine use of adjuncts with opioids in the ED.[43] Pretreatment with antiemetics is not necessary given the low risk of emesis,[44] but symptom-targeted therapy is sometimes necessary.

Transdermal formulations are not useful for acute pain treatment because of delayed onset and prolonged duration of action. **Transdermal fentanyl** and **transdermal buprenorphine** preparations are used for chronic pain, particularly in cancer patients. When such patients are treated for acute pain in the ED, it is best to remove the delayed-release transdermal opioid patches to better titrate the acute opioid dose and to minimize adverse reactions from the combination of agents.

OPIOID AGONISTS-ANTAGONISTS

Opioid agonists-antagonists are used to minimize some of the adverse effects of pure opioid agonists (**Table 35-8**). The major benefit claimed is a ceiling on respiratory depression (no further reduction in respiration with increasing doses past a set amount). It is not clear if there is a ceiling effect for analgesia. The variability in efficacy relates to each particular agent's affinity for the various central opioid receptors. **Because of the antagonistic effects, these agents should be used with extreme caution in patients with opioid addiction as they may precipitate withdrawal symptoms.**

NONOPIOID AGENTS

Acetaminophen (paracetamol) is an effective analgesic for mild to moderate pain (**Table 35-9**).[45] Acetaminophen does not affect platelet aggregation and does not have anti-inflammatory properties. No change is required for renal or mild hepatic impairment (see chapter 190, Acetaminophen).

Aspirin and the *nonsteroidal anti-inflammatory drugs* are both anti-inflammatory agents and analgesics. As anti-inflammatory agents, aspirin and nonsteroidal anti-inflammatory drugs decrease the production of prostanoids and arachidonic acid–mediated inflammatory peptides generated at the site of tissue injury, diminishing the inflammatory

TABLE 35-7 Pain Management: Adjunctive Medications

Drug	Initial Dosing	Pharmacokinetics	Comments
Prochlorperazine	5–10 milligrams IV/IM	Duration: 4–6 h	Can cause extrapyramidal reactions
Promethazine	25–50 milligrams IV/IM	Duration: 4–6 h	Can cause extrapyramidal reactions
Metoclopramide	5–10 milligrams IV/IM	Duration: 4–6 h	Can cause extrapyramidal reactions

TABLE 35-8 Pain Management: Initial Opioid Agonist-Antagonist Dosing

Drug [Class]	Initial Dosing	Pharmacokinetics	Comments
Buprenorphine [synthetic oripavine]	0.3 milligram IV/IM every 6 h 0.4 milligram sublingually every 6-8 h	Onset: rapid Duration: 4–10 h	Sedation, dizziness, nausea
Butorphanol [synthetic morphinan]	0.5–2.0 milligrams IV every 3–4 h 1–4 milligrams IM every 3–4 h	Onset: <1 min Duration: 2–4 h	Sedation, dizziness, nausea
Dezocine [synthetic benzomorphan]	2.5–10.0 milligrams IV every 4 h 5–20 milligrams IM every 6 h	Onset: 15 min (IV) and 30 min (IM) Duration: 4–6 h	Dizziness, respiratory depression
Nalbuphine [synthetic morphinan]	10–20 milligrams IV/IM/SC every 3–6 h	Onset: 2–3 min (IV) and 30 min (IM) Duration: 3–6 h	Sedation, headache, dizziness
Pentazocine [synthetic benzomorphan]	30 milligrams IV/IM/SC every 3–6 h	Onset: 2–3 min (IV) and 15–20 min (IM) Duration: 2–3 h	CNS side effects

response seen with some noxious stimuli. As analgesics, inhibition of the cyclooxygenase-2 enzyme in the spinal cord decreases the excitability of dorsal horn neurons that produce hyperalgesia and allodynia. These agents do not cause sedation or respiratory depression or interfere with bowel or bladder function. Nonsteroidal anti-inflammatory drugs have significant opioid dose-sparing effects.

Adverse effects of nonsteroidal anti-inflammatory drugs include platelet dysfunction, GI irritation and mucosal bleeding, nephropathy, headaches, and dizziness. All nonsteroidal anti-inflammatory drugs increase the risk of cardiac death in patients with ischemic heart disease,[46,47] although the cyclooxygenase-2–specific agents appear to carry higher risk than the nonselective agents.[48,49] Nonsteroidal anti-inflammatory drug–induced acute renal failure is more common in elderly patients and in those who are volume depleted, have preexisting renal or cardiac disease, or are taking loop diuretics.

OTHER PHARMACOLOGIC AGENTS

Ketamine A phencyclidine derivative, ketamine produces analgesia and/or dissociative anesthesia with the advantage of causing minimal respiratory depression with usual doses (see chapter 37, Procedural Sedation). Low-dose (subdissociative) infusions of ketamine are effective in combination with opioids for patients in severe pain.[50-52] Ketamine dosing for analgesia is typically a loading dose of 0.15 to 0.4 milligrams/kg IV over 10 minutes followed by an infusion if desired. Ketamine can be used in trauma patients, resulting in a lower opioid requirement for pain control, and is also effective in controlling acute flare-ups of neuropathic pain. Ketamine is also useful as an SC infusion in palliative care patients. Adverse effects include hypersalivation and reemergence phenomena (disagreeable dreams or hallucinations upon awakening), especially when larger induction doses are used (1.5 milligrams/kg IV).

TABLE 35-9 Pain Management: Nonopioid Analgesics

Drug	Adult Dosage	Comments
Acetaminophen (paracetamol)	325–1000 milligrams PO every 4–6 h 325–650 milligrams PR every 4–6 h If >50 kg: 1 gram IV every 6 h If <50 kg: 15 milligrams/kg IV every 6 h	Liver dysfunction and necrosis. Maximum oral dose is 3.9 grams per day when using the 325-milligram oral preparation and 3 grams per day when using the 500-milligram oral preparation. Maximum IV dose is 4 g per day.
Aspirin	325–650 milligrams PO every 4 h 300–600 milligrams PR every 4–6 h	GI irritation and mucosal bleeding. Platelet dysfunction. Tinnitus, CNS toxicity, metabolic acidosis. Maximum dose is 4 g per day.
Ibuprofen	400–800 milligrams PO every 4–6 h 400–800 milligrams IV every 6 h	GI upset, platelet dysfunction, renal dysfunction, bronchospasm. Maximum dose is 2400 milligrams per day.
Naproxen	250–500 milligrams PO every 8–12 h	GI upset, platelet dysfunction, renal dysfunction, bronchospasm. Maximum dose is 1250 milligrams per day for acute therapy.
Indomethacin	25–50 milligrams PO every 8 h 50 milligrams PR every 6 h	GI upset, platelet dysfunction, renal dysfunction, bronchospasm. Maximum dose is 200 milligrams per day.
Ketorolac	Multiple dose therapy: 30 milligrams IV/IM every 6 h, 15 milligrams IV/IM every 6 h if age >65 y or weight <50 kg Single dose therapy: 60 milligrams IM or 30 milligrams IV, 30 milligrams IM or 15 milligrams IV if age >65 y or weight <50 kg 10 milligrams PO every 4-6 h	GI upset, platelet dysfunction, renal dysfunction, bronchospasm. Greater risk of GI bleeding than ibuprofen. Use limited to 3 d IV and 5 d PO. Maximum IV/IM dose is 120 milligrams per day, but if age >65 y or weight <50 kg, then maximum dose is 60 milligrams per day. Maximum PO dose is 40 milligrams per day.
Ketamine	0.15–0.4 milligrams/kg IV over 10 min; can follow by IV infusion 0.1–0.2 milligrams/kg/h	No renal or hepatic adjustment; adverse effects uncommon with single doses; dizziness, agitation, hallucinations possible with higher doses.

TABLE 35-10 Pain Management: Neuropathic Pain Syndromes

Drug	Use	Initial Dosage	Titrate	Typical Effective Dosage (Maximum Daily Dose)
Amitriptyline or nortriptyline	Chronic pain	0.1 milligram/kg PO once in the evening	Increase over 2–3 wk	0.5–2.0 milligrams/kg per day PO (maximum 150 milligrams per day)
Carbamazepine	Trigeminal neuralgia	100 milligrams PO twice per day	Increase 100–200 milligrams per day	200–400 milligrams PO twice per day (1200 milligrams per day)
Oxcarbazepine	Trigeminal neuralgia	300 milligrams PO twice per day	Increase 300–600 milligrams per day every week	450–1200 milligrams PO twice per day
Duloxetine	Diabetic neuropathic pain	30 milligrams PO once per day	Increase after 1 wk on initial dose	60 milligrams PO once per day (maximum 120 milligrams per day)
Gabapentin	Neuropathic pain, postherpetic neuralgia	300 milligrams PO per day	Increase up to 300 milligrams per day	300–1200 milligrams PO three times per day (maximum 3600 milligrams per day)
Pregabalin	Neuropathic pain, postherpetic neuralgia	50 milligrams PO three times per day	Increase over 1 wk	150 milligrams PO twice per day to 100 milligrams PO three times per day (maximum 600 milligrams per day)

Nitrous Oxide Nitrous oxide is a fast-onset, short-acting analgesic and sedative inhalational agent useful for brief, minor procedures (see chapter 37) and for prehospital analgesia.[53] The primary adverse effects are nausea and vomiting. Nitrous oxide is usually supplied as a preblended 50% mixture with oxygen and administered to the patient by face mask, but if available, the 70/30 nitrous oxide/oxygen mixture is more effective. Barriers to ED use of nitrous oxide include the need for patient cooperation and an effective scavenging system. In addition, nitrous oxide is contraindicated in patients with altered mental status, head injury, suspected pneumothorax, or perforated abdominal viscus. Severe pulmonary disease also may alter the respiratory elimination of nitrous oxide.

Cyclic Antidepressants and Anticonvulsants Patients with acute-onset neuropathic pain, such as postherpetic or trigeminal neuralgia, are difficult to treat with short-acting opioid analgesics. It may be difficult to identify neuropathic causes of pain in ED patients, but if suspected, more specific therapy and follow-up instructions are needed. ***Long-acting* opioids, cyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and anticonvulsants are effective for neuropathic pain (Table 35-10).** When initiating an agent for patients with new-onset neuropathic pain, close follow-up with the primary care physician is important so that titration to effect may continue.[54,55] Patients already taking one of these agents for chronic neuropathic pain may require either titration upward of their medication or addition of a second agent; this should be discussed with the patient's regular physician.

Topical Medications Topical administration of medications at the site of injury or inflammation can provide pain relief with reduced systemic drug absorption and a lower risk of adverse drug reactions (**Table 35-11**).[56] This approach differs from the transdermal drug administration to achieve systemic effects, typically with opioids (see Route of Administration). Topical nonsteroidal anti-inflammatory drugs are effective for treating acute soft tissue injuries such as sprains and strains and also for chronic joint pain from osteoarthritis. Topical lidocaine therapy is effective for patients with postherpetic neuralgia and diabetic neuropathy. Topical capsaicin has produced variable results depending on the treatment population and dose applied; regular use appears necessary for prolonged pain relief. A single 60-minute application of a high-dose preparation (8% capsaicin topical patch) is effective for postherpetic neuralgia but requires professional application and removal to minimize side effects.

The primary adverse reaction of topical medications is local burning, particularly seen with capsaicin, which is derived from chili peppers. Rare cases of localized burns have been reported with topical muscle and joint pain relievers.[57] Most of the serious burns were associated with agents containing menthol (>3% concentration) and/or methyl salicylate (>10% concentration).

ROUTE OF ADMINISTRATION

Systemic pain medications can be given by multiple routes (**Table 35-12**). Oral administration is convenient, inexpensive, and appropriate once the patient can tolerate oral intake; it is a mainstay of pain management in the ambulatory ED population.

IV opioids are suitable for bolus administration or continuous infusion and are preferred to intermittent IM injections. IM injections are painful, do not allow for easy titration, and have no clinically relevant advantage over PO medications. Absorption can be variable, especially in sickle cell patients (due to scarring) and hypotensive or volume-depleted patients. Patient-controlled IV analgesic systems are particularly effective for ED patients with acute abdominal pain and in addicts

TABLE 35-11 Pain Management: Topical Analgesic Agents

Agent	Preparation	Comments
Diclofenac	1% gel 1.3% topical patch	Gel: apply using dosing card—4 grams for knees, ankles, and feet, and 2 grams for elbows, wrists, and hands. Lightly rub until absorbed. Use up to 4 times a day. Maximum total daily dose 32 grams. Patch: apply to intact skin at most painful site twice a day.
Ibuprofen*	5% gel	Squeeze 50–125 milligrams (4–10 cm) of the gel from the tube and lightly rub into the affected area until absorbed. Apply up to 4 times per day.
Ketoprofen*	2.5% gel	Squeeze 2–4 grams (5–10 cm) of the gel from the tube and lightly rub into the affected area until absorbed. Apply 2–4 times per day.
Lidocaine	5% gel 5% topical patch	Gel: apply a moderately thick layer to the affected area (approximately 1/8 inch thick). Allow time for numbness to develop. Best results obtained 20 min to 1 hour after application. Patch: apply to intact skin to cover the most painful area. Use only once for up to 12 h within a 24-h period.
Capsaicin	0.025% cream 0.075% cream 0.1% gel 8% patch	Cream and gel: apply to affected area not more than 3–4 times daily. Massage into area until thoroughly absorbed. Patch: only for postherpetic neuralgia. Requires physician or healthcare professional application. Applied for 60 min. Treatment may be repeated every 3 months.

*Not available in the United States.

TABLE 35-12 Delivery Routes of Systemic Analgesia

Method	Advantages	Disadvantages
PO	Ease Painless Minimal cost No technical skill required Patient acceptability	Unreliable GI absorption Requires gastric motility Slow onset Titration less reliable
IV	Rapid onset Titratable Usually easier to reverse	Venous access required Potential for overdose
IM or SC	Convenient	Painful Titration difficult and requires repeated injections Absorption variable More expensive than PO route
PR (transmucosal)	No first-pass hepatic metabolism No reliance on gastric motility	Requires patient acceptance and cooperation Variable absorption
Buccal/nasal (transmucosal)	Ease Painless	Difficult to control dose Can irritate nasal mucosa Available buccal mucosal fentanyl preparations are no bioequivalent
Transdermal	Ease Painless	Variable dose and duration Difficult to titrate Slow onset Prolonged duration after removal
Inhalational	Rapid onset and offset	Requires patient cooperation Scavenger equipment required
Intra-articular	Direct action No systemic side effects Can last up to 48 h	Only in major joints Risk of joint infection

with pain when compared with the usual approach of intermittent nurse-administered parenteral medications.[58-60] Intra-articular analgesia using opioids or bupivacaine can provide sustained relief during the immediate postoperative period following hip and knee surgery.[61-63] Nasal and buccal preparations of fentanyl are available primarily for breakthrough pain in opioid-tolerant cancer patients, and these routes may have a role in prehospital and ED acute pain management.[64] Sublingual buprenorphine is described as effective for ED management of acute pain from fractures.[65]

DOSAGE AND PRECAUTIONS

Safe and effective use of opioids is facilitated by choosing an appropriate initial dose[66] and subsequently titrating additional doses toward the desired effect, thus avoiding overmedication and minimizing unwanted effects. In unmonitored opioid-naïve patients, excessive doses of opioids can result in respiratory depression and decreased levels of consciousness. Hypotension is infrequent, is almost always due to histamine release with the first dose of medication, and is usually of short duration. With comorbidities, such as altered mental status, hemodynamic instability, respiratory dysfunction, or multisystem trauma, initial dosing should be decreased, and dose titration is important for achieving satisfactory pain relief.

The Elderly Acute pain management for the elderly can be a challenge; these patients may have more than one source of pain and/or multiple comorbidities and are at increased risk for drug–drug and drug–disease interactions.[67] Opioid-naïve elderly patients are more sensitive to the analgesic effects of opioid drugs, because they experience a higher peak and longer duration of pain relief. Moreover, they are more sensitive to sedation, respiratory depression, and cognitive and neuropsychiatric dysfunction. Initial IV opioid doses in the elderly are typically half those used in younger adults (e.g., morphine 0.05 milligram/kg and hydromorphone 0.0075 milligram/kg), although single doses may not achieve adequate pain control for elderly patients with acute severe pain.[68]

Addiction and Dependence Addiction is the misuse of a medication or drug to the detriment of the patient's well-being. Dependence infers that abrupt cessation of a medication will result in acute withdrawal symptoms. Dependence on opioids requires regular daily usage for 4 to 6 weeks in most patients, whereas addiction may occur after one use of heroin. Care should be taken to assess a patient's risk for addiction or diversion of prescription medications, but when uncertainty exists, the general approach is to err on the side of acute pain control, although management in opioid-tolerant patients can be a challenge.[69] Contemporary and rigorous evidence is that dependence and addiction occur in up to one-third of patients on chronic opioid therapy,[70] but there is little knowledge regarding the risk of short-term (<2 weeks) opioid therapy following an ED visit for an acute injury or temporary illness. Although EDs are not where most cases of opioid abuse originate, they are perceived as a potential perpetuator of misuse.[71] Distinguishing patient requests for medications because of oligoanalgesia from addiction often requires multiple patient assessments over time; subjective assessment in the ED during a single visit is usually inaccurate for identifying addiction versus aberrant behavior due to oligoanalgesia.[72] Use of an assessment tool such as the Drug Abuse Screening Test may provide a more objective means of screening for addiction.[73]

Renal and Hepatic Dysfunction Because most analgesics are metabolized by the liver or kidney, take care when using opioids in patients with impaired hepatic or renal function. Renal excretion is a major route of elimination for such pharmacologically active opioid metabolites such as norpropoxyphene, normeperidine, morphine-6-glucuronide, and dihydrocodeine. Mild renal failure can impede excretion of the metabolites of many opioids, resulting in clinically significant narcosis and respiratory depression. **In patients with renal failure, hydromorphone and fentanyl are the preferred opioids.** Mild hepatic dysfunction has little effect on opioid metabolism. In patients with severe hepatic dysfunction, titration with low doses of analgesics will minimize the risk of overdose.

Respiratory Insufficiency Patients with respiratory insufficiency and those with chronic obstructive pulmonary disease, cystic fibrosis, and neuromuscular disorders affecting respiratory effort (e.g., muscular dystrophy and myasthenia gravis) are particularly vulnerable to the respiratory depressant effects of opioids and nitrous oxide. Careful dose titration and monitoring of oxygenation and ventilation are necessary. Ketamine may be a useful alternative agent in such cases.

Drug Interactions Opioids may have adverse synergistic sedative effects in patients with psychiatric illnesses taking anxiolytics or other psychoactive drugs. **The use of monoamine oxidase inhibitors with meperidine is associated with severe adverse reactions, including death as the result of precipitating a serotonin syndrome (see chapter 178, Atypical and Serotonergic Antidepressants).** The cyclic antidepressants clomipramine and amitriptyline may increase morphine levels and potentiate the opioid effects.

NONPHARMACOLOGIC MODALITIES

Traditionally, nonpharmacologic techniques of pain management in the ED have been limited to application of heat or cold and immobilization and elevation of injured extremities. Other techniques may be useful in the ED and after discharge. Cognitive-behavioral techniques can be effective in reducing pain and anxiety, may control mild pain when used alone, and can enhance patient satisfaction. Such techniques include reassurance, explanation, relaxation, music, psychoprophylaxis, biofeedback, guided imagery, hypnosis, and distraction. They are a useful adjunct to pharmacologic management of moderate to severe pain. Successful application of these therapies requires a cognitively intact patient

and skilled personnel, but many of the techniques require only a few minutes to teach the patient.

Physical nonpharmacologic agents are becoming increasingly relevant to acute pain management. In addition to the traditional techniques noted above, less commonly used physical modalities, such as transcutaneous electrical nerve stimulation and acupuncture, may have some potential role in the ED. Although specific technical skills and equipment are required, there is no need for IV access, and there is no systemic effect such as respiratory depression or altered mental status.

SPECIFIC SITUATIONS

ABDOMINAL PAIN

Early administration of IV opioids is safe for the treatment of acute abdominal pain in the ED and does not affect the accuracy of the evaluation, diagnosis, or management.[74-77] The dogma against the use of opioids for patients with acute abdominal pain stated in previous editions of *Cope's Early Diagnosis of the Acute Abdomen* was revised in 2000.[78] The one valid concern regarding analgesia and abdominal pain is that reduction in pain does not indicate improvement in pathophysiology. Analgesia without proper evaluation is as inappropriate as proper evaluation without analgesia.

MIGRAINE

There is no one, consistent, best analgesic agent for the management of a patient with migraine headache in the ED.[11,12,14] Opioid use for acute migraine treatment has lost favor due to poor performance in clinical trials, but can be considered if other agents have been ineffective.[14] The high success rates with promethazine, chlorpromazine, and prochlorperazine are tempered by the extrapyramidal side effects, seen in as many as 45% of patients, and occasional intense dysphoria (see chapter 165, Headache).[13]

TRAUMA

Patients in shock and those with trauma, burns, and hemodynamic or respiratory instability need judicious use of opioids.[2] Fentanyl, first as a bolus and then as an infusion, may be the opioid of choice due to its lesser impact on hemodynamic function. Use of regional analgesia is encouraged.[29] Nonsteroidal anti-inflammatory drugs should not be given to patients with major trauma due to the risks of excessive bleeding from platelet dysfunction and gastric stress ulcers and the potential for acute renal failure in a volume-depleted patient.

DISPOSITION

Although rare, intractable acute pain can be a primary reason for hospital admission. Otherwise, most patients may be safely discharged with a plan for pain management that includes instructions for use of short-acting analgesics (i.e., those with a duration of action of up to 6 hours). Persistent pain after ED discharge is common.[79-81] Prescriptions for long-acting agents (e.g., methadone, controlled-release preparations of morphine or oxycodone) are generally avoided upon ED discharge but are sometimes used for special patients, such as those with cancer in whom short-acting agents are no longer effective (see chapter 38, Chronic Pain).

Patients should be counseled to take subsequent doses on a regular basis or when their pain begins to return, rather than when it approaches its peak. Patients with recurrence of severe pain or changes in the quality of pain should be told to return to the ED for reassessment. It is best to prescribe only a few days' worth of analgesics, because conditions with a longer duration of pain require follow-up with the primary care physician. If opioids are prescribed to the elderly or those naïve to narcotics, home observation by a responsible adult is recommended so that adverse effects can be quickly recognized. **Discharge instructions for those given opioids should include instructions to avoid making important decisions while medicated and to avoid driving, operating machinery, climbing or working from heights, and so on, and should also include instructions for treatment of constipation.** Education about securing opioid prescriptions is important because up to 85% of prescription opioids misused by adolescents come from their parents' medication cabinet.

CHAPTER 36

Local and Regional Anesthesia

Douglas C. Dillon
Michael A. Gibbs

INTRODUCTION

Before the availability of local anesthetics, local pain control for lacerations, fractures, and minor surgery was achieved by minimizing the pain response centrally, typically with opiates or alcohol. Procaine, which entered clinical use in 1904, was the only local anesthetic available for almost 40 years, but the short duration of action and high rate of allergic reactions limited its effectiveness. Lidocaine was introduced in 1943 and continues to be the local anesthetic most commonly used in the ED.[1,2] Additional local anesthetics are available for both topical and injectable use (**Tables 36-1** and **36-2**). Emergency physicians commonly use local and regional anesthetic techniques for potentially painful procedures performed in the ED.[3] Regional anesthesia can also be used to control the pain of acute injuries and reduce the utilization of systemic analgesics.[4,5]

LOCAL ANESTHESIA

PHARMACOLOGY

Local anesthetics are divided into two classes: **esters** and **amides**.[1,2] Both classes work by reversibly blocking sodium channels and inhibiting the propagation of nerve impulses.[1,2] Sodium channel blockade first affects the smaller nerve fibers, causing a reduction in pain and temperature sensation, followed by loss of touch, deep pressure sensation, and, finally, motor function. Esters are hydrolyzed by cholinesterase enzymes in plasma, whereas amides are metabolized by hepatic microsomal enzymes. Onset of action, duration of anesthesia, and potential for systemic toxicity are the three primary factors in selecting a local anesthetic.

The onset of action of a local anesthetic is dependent on the pK_a (the pH at which 50% of the drug is ionized and 50% of the drug is nonionized). If the ambient pH is higher than the pK_a of the agent, a greater percentage of the drug will be in the nonionized form, which diffuses more rapidly across lipid membranes, and the onset of action is shorter. Thus, drugs with a lower pK_a have a more rapid onset of action. The pH of available local anesthetic solutions is acidic, varying from 3.3 to 6.8, depending on the agent, additives, and buffers. The duration of action of the local anesthetics is a function of receptor affinity. Agents with a higher receptor affinity (e.g., bupivacaine, ropivacaine, levobupivacaine) have a longer duration of action than those with lower receptor affinity (e.g., lidocaine, prilocaine).[6] Selecting agents with a longer duration of action provides superior results for long procedures or for those in which postprocedure analgesia is desired. Longer-acting agents also offer continued analgesia when providers are pulled away from the procedure. The downside of long-acting agents is the greater risk of systemic toxicity.[7] Levobupivacaine[8] and ropivacaine[9] appear to have a lower risk of systemic toxicity than bupivacaine.

Systemic Toxicity of Local Anesthetics The systemic toxicity of local anesthetics occurs with dose-related clinical progression of sodium

TABLE 36-1 Topical Anesthetic Agents

Agent	Active Ingredients	Application	Time to Effectiveness
Intact Dermis			
Eutectic mixture of local anesthetic agents (EMLA®)	Lidocaine 2.5% Prilocaine 2.5%	Apply thick layer, 5–10 grams (maximum 20 grams), to area to be anesthetized; cover with semiocclusive dressing.	60 min
Tetracaine (amethocaine) gel (Ametop®)	Tetracaine 4%	Apply 1 gram (one tube) to area to be anesthetized; cover with occlusive dressing.	30 min
Liposome encapsulated tetracaine	Tetracaine 5%	Apply 0.5 gram to area to be anesthetized.	60 min
Liposome encapsulated lidocaine (LMX4® and LMX5®)	Lidocaine 4% or 5%	Apply 2.5 grams to area to be anesthetized.	30–60 min
Open Dermis			
Lidocaine, epinephrine, tetracaine (LET)	Lidocaine 4% Epinephrine 0.1% Tetracaine 0.5%	Apply 5 mL to gauze pad placed into wound; cover with semiocclusive dressing.	20–30 min
Mucosa			
Topical anesthetic gel (ZAP®)	Benzocaine 18% Tetracaine 2%	Apply 0.2 mL (one dispenser application) with cotton swab to area to be anesthetized.	5 min
Benzocaine spray (Hurricaine®)	Benzocaine 20%	Apply 1-s spray to area to be anesthetized; volume delivered is highly dependent on canister orientation and residual volume.	15–30 s
Viscous lidocaine	Lidocaine 2%	Apply 10–15 mL to area (e.g., topical anesthesia before upper airway procedures).	2–5 min

channel blockade in nontarget tissues, primarily the brain and heart.[10,11] Toxicity can range from subtle neurologic symptoms to refractory seizures and, ultimately, cardiovascular collapse (**Figure 36-1**).[12-14] The risk of systemic toxicity can be reduced by adherence to dose limitation and techniques to minimize systemic absorption.[15-18] Seizures due to neurologic toxicity should be treated with benzodiazepines.[19] Typical agents used to treat cardiac arrest (e.g., vasopressin) and tachyarrhythmias (e.g., β-blockers and calcium channel antagonists) should be avoided in the setting of local anesthetic systemic toxicity.[19] **IV 20% lipid emulsion** is an effective treatment for systemic toxicity from local anesthetics, especially if due to bupivacaine with its high lipid solubility.[19-27] Published reports have utilized different dosing protocols, but one consensus guideline recommends an initial dose of 20% lipid emulsion, 1.5 mL/kg infused over 1 minute with continuous infusion or repeat

TABLE 36-2 Local Anesthetic Agents

Agent	Lipid Solubility*	Protein Binding	Duration† (min)	Onset‡ (min)	Maximum Dose (milligrams/kg, with epinephrine)	Concentration (subdermal use)	Concentration (regional anesthesia use)
Amides

Abbreviation: NA = not applicable.

*Lipid solubility determines the potency of the anesthetic, with the more lipophilic anesthetics having enhanced potency compared with less lipophilic agents.

†The more an anesthetic is bound to proteins, generally, the longer the duration of action.

‡The onset of action of an anesthetic is determined by the total dose of anesthetic given and the pH at which 50% of the drug is ionized and 50% of the drug is nonionized.

#Diphenhydramine 1% or 10 milligrams/mL (created by mixing 4 parts normal saline and 1 part 5% diphenhydramine).

ƒBenzyl alcohol 0.9% solution (created by mixing 0.2 mL of epinephrine 1:1000 with a 20-mL vial of normal saline containing benzyl alcohol 0.9%).

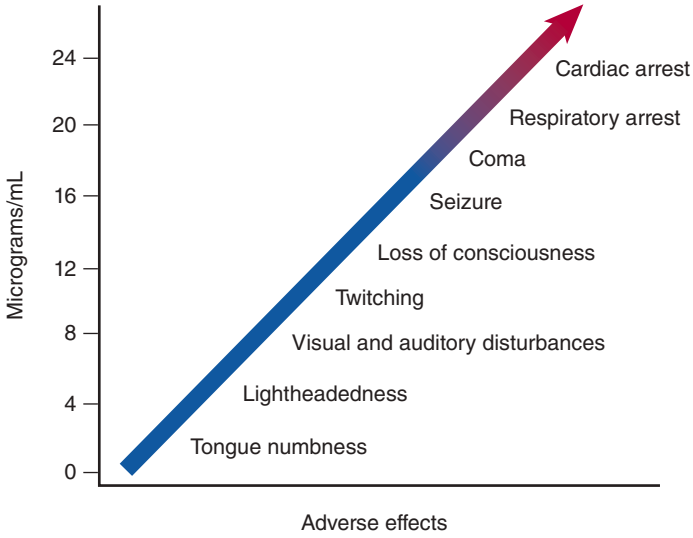

FIGURE 36-1. Adverse effects of local anesthetics. Plasma concentration of local anesthetics versus toxic effects.

doses according to the clinical condition.[19] The recommended maximum dose is about 10 mL/kg over the initial 30 minutes.[19]

Prilocaine and benzocaine can cause the oxidation of the ferric form of hemoglobin to the ferrous form, creating methemoglobin that becomes visible as cyanosis when methemoglobin concentration exceeds 1.5 grams/dL.

GENERAL PRINCIPLES OF LOCAL ANESTHETIC USE

When using any local anesthetic, calculate the volume and concentration of drug used, especially when treating smaller patients or tending to large wounds (**Table 36-2**). Aspiration before injection helps to avoid inadvertent deposit of local anesthetic in a vein or artery. When the use of a large quantity of local anesthetic seems unavoidable, procedural sedation or alternative regional blocking techniques and supplementation with systemic analgesics or anxiolytics should be considered (see chapter 37, Procedural Sedation).

The addition of **epinephrine** to the injected local anesthetic solution increases the duration of anesthesia, helps to control wound bleeding, and slows the systemic absorption.[28] The use of local anesthetic with epinephrine is safe for use in end-arterial fields (fingers, toes, etc.) in selected healthy patients,[29-34] but probably should be avoided in suspected digital vascular injury; patients with vascular disease, such as Raynaud's or Berger's disease; or other conditions in which end-arterial vascular supply is problematic. An alternative to epinephrine is clonidine (U.S. Food and Drug Administration unlabeled use), an α-adrenergic agonist, which can also be used in combination with a local anesthetic to prolong the duration of anesthesia.[35-37] A dose of 0.5 micrograms/kg of clonidine (maximal dose 150 micrograms) can be mixed with the anesthetic to prolong the duration of anesthesia by >50%. Do not exceed a maximal dose of 150 micrograms because sedation, hypotension, and bradycardia can result.[36,37]

Adverse reactions to local anesthetics are most often local reactions to preservatives or the epinephrine in the solution, and true allergic reactions are extremely rare.[38,39] In patients with true allergies to local anesthetics, two nontraditional agents can be used for wound repair via local injection—**diphenhydramine** and **benzyl alcohol** (**Table 36-2**).[40-42]

The addition of **sodium bicarbonate** to local anesthetics shortens the onset of action by raising tissue pH and reduces the pain of injection.[3,43-45] Lidocaine can be buffered by adding 1 mL of sodium bicarbonate 8.4% (1 mEq/mL) to 9 mL of 1% lidocaine. Bupivacaine can be buffered by adding 1 mL of sodium bicarbonate 8.4% (1 mEq/mL) to 29 mL of bupivacaine 0.25%. However, the addition of bicarbonate can cause precipitation of the anesthetic agent (most prominently bupivacaine) and accelerate the degradation of epinephrine in the solution, so **bicarbonate should not be added to the anesthetic unless it can be used immediately**. Additional means of reducing the pain of infiltration include the use of a 27- to 30-gauge needle, slow injection, warming the solution to body temperature, and injecting through the margins of a wound rather than through intact skin surrounding the wound.[3,43-48]

Local anesthetics can be administered topically, intradermally, subdermally, or infiltrated near peripheral nerves. When considering which approach best meets the patient's needs, many factors should be considered. In the setting of wound management, these include patient factors (age, anticipated pain tolerance, comorbidities), wound factors (location, depth, presence or absence of contamination, and/or neurovascular injury), and technical factors (time required, clinician experience). Clinical judgment combined with individual patient needs should dictate the best approach.

TOPICAL ANESTHESIA

Topical anesthetics are used in three major situations: on *intact skin* before dermal instrumentation, applied to *intact mucosa*, and placed on *open skin* for pain control or before wound repair.[49-51] Topical anesthetics are probably as effective as local anesthetic infiltration for suturing of many dermal lacerations, although the comparison studies are of modest quality.[52]

An alkaline (pH approximately 9) cream mixture of lidocaine and prilocaine [eutectic mixture of local anesthetics (**EMLA®**)] was the first topical anesthetic formulated to penetrate intact skin. When applied for at least 60 minutes under a semiocclusive dressing before dermal instrumentation, this lidocaine/prilocaine mixture is as efficacious as the infiltration of local anesthetic and is ideal for venous catheter insertion and lumbar puncture. Liposome-encapsulated tetracaine, liposome-encapsulated lidocaine, and tetracaine gel have all been compared to the lidocaine/prilocaine mixture and found to be equally efficacious (**Table 36-1**).[53-57]

The tetracaine, epinephrine, and cocaine mixture is a topical anesthetic used on open dermis. Due to the potential for CNS and cardiovascular toxicity, the cocaine component of this combination has been replaced with lidocaine. This mixture—**lidocaine, epinephrine, and tetracaine**—has a variety of formulations and is usually compounded by the hospital pharmacy in accordance with the concentration preferences of local clinicians. A common version is 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine prepared in 5-mL vials.

INTRADERMAL AND SUBDERMAL ANESTHESIA

Intradermal injection produces a visible wheal, whereas subdermal injection does not. Intradermal injection produces more immediate pain upon injection due to stretching of the compact dermal structure, but can enhance the anesthetic effect by applying pressure to and numbing the cutaneous pain sensors. Intradermal injection raises the skin surface and is useful when shaving off a cutaneous lesion. Subdermal injections have a slower onset of action, are less painful, and are the most commonly used method of achieving local anesthesia in the ED and for office-based surgery.[3,58] Local anesthetics may be delivered directly into the subdermal space in most clean lacerations or as a field block for contaminated wounds.

In addition to modifying the injected solution, a variety of techniques are used to reduce the pain of needle puncture and local anesthetic injection[43-45,59]: application of a topical anesthetic prior to injection,[60,61] warming the local anesthetic agent,[46-48] stretching the skin at the puncture site, vibrating the skin adjacent to the area,[62,63] talking during the process to distract the patient, inserting the needle through enlarged pores or hair follicles, inserting the needle with bevel up position,[64] or numbing the skin with an aerosol refrigerant.[65-69]

REGIONAL ANESTHESIA

Regional anesthesia is a technique that infiltrates local anesthetic agents adjacent to peripheral nerves ("nerve blocks") and is typically used for complicated lacerations, abscesses, fractures, and dislocations.[70-72]

Providing adequate anesthesia quells patient anxiety, provides greater patient satisfaction, and increases the likelihood of an optimal result when treating complex injuries. With careful technique, serious complications from peripheral nerve blocks are uncommon.[73-75] Assess and document distal neurovascular status before application of a regional nerve block to prevent masking a primary traumatic neurovascular injury. Distal vascular function is assessed by noting skin color and temperature, measuring capillary refill time, and palpating pulses. Distal neurologic function is assessed by noting cutaneous sensation (pain, touch) and motor function (active movement, strength). For digital injuries, assess digital nerves by determining two-point discrimination on the volar pad before anesthetic injection. **Normal two-point discrimination is <6 mm at the fingertips and is often <2 mm. Compare the injured digit with the contralateral normal digit.**

Regional anesthesia for laceration repair eliminates wound distortion caused by large-volume subdermal injection. Regional anesthesia on the extremities provides superior pain control when compared with subdermal infiltration of anesthetic.[70] Topical anesthetic before peripheral nerve blocks can minimize the pain associated with the block.[53-57,60,61]

When selecting a local anesthetic for regional anesthesia, consider the onset of clinical effects, duration of analgesia, and risk of toxicity.[70] Although lidocaine continues to be the most popular agent, bupivacaine, levobupivacaine, and ropivacaine offer a longer duration of action, with levobupivacaine and ropivacaine being significantly less cardiotoxic.[6,8,9] Peripheral nerve blocks require time to achieve optimal analgesia, approximately 10 to 20 minutes for lidocaine and 15 to 30 minutes for bupivacaine. Pain and temperature sensation are affected first, followed by loss of touch, deep pressure, and then motor function. Intraneural injection of anesthetic causes significant pain.[76] Thus, if excessive pain upon injection is noted, withdraw the needle a few millimeters, and after pain abates, resume the injection.

The regional nerve blocks commonly performed by emergency physicians are often done using the "landmark" technique to identify the site of local anesthetic injection.[70] The major disadvantage of the landmark approach is anatomic variation. Large volumes of anesthetic are typically administered, in case the needle tip is not close to the desired nerve. Two devices in common use help localize and direct the needle to maximize the rate of successful anesthesia: a peripheral nerve stimulator using electrically insulated needles and US guidance to localize the nerve.[77-81] US guidance shortens the block performance time, reduces the number of needle passes, and enables blocks to be performed using lower anesthetic doses.[82-84] Training to use US-guided regional anesthesia in the ED typically involves a didactic session, supervised practice in ultrasonographic identification of the relevant structures, and procedural practice on simulation mannequin.[85,86] The use of US is recommended when performing more complex nerve blocks.

The performance of peripheral nerve blocks requires an element of hand–eye coordination that is difficult to display in words and photographs.

DIGITAL BLOCKS

Digital Nerve Block • *Purpose* A digital nerve block provides anesthesia to the entire digit and is an excellent block when tending to lacerations of the fingers or toes, drainage of paronychia, finger or toenail removal or repair, and reduction of fractured or dislocated fingers or toes.[87] Use of topical anesthesia before instrumentation can quell anxiety about the procedure and minimize pain. Assess distal capillary refill and two-point discrimination (normal <6 mm) on the volar pad before application of the block. For digital blocks, there is less pain with injection using lidocaine 1% with epinephrine compared to bupivacaine 0.5%, but the duration of anesthesia is only about half as long.[88]

Patient Positioning and Anatomy The hand and wrist are placed in a prone (palm down) position. The common digital nerves are derived from the median and ulnar nerves. In the distal palm, the common digital nerve divides into paired palmar branches that travel on both sides of the flexor tendon sheath and innervate the lateral and palmar aspect of each digit. The dorsal digital nerves are smaller, derived from the radial and ulnar nerves, and travel on the dorsal lateral aspect of each finger to provide sensation to the back of the finger.

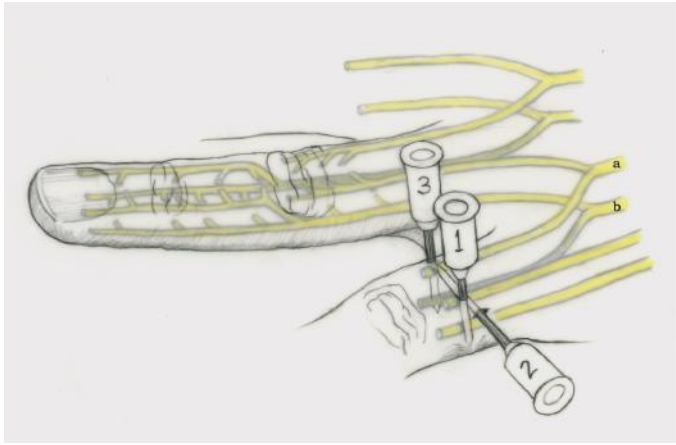

FIGURE 36-2. Digital nerve block. Anesthetic placed as shown blocks both the dorsal (a) and palmar (b) digital nerves, ensuring circumferential anesthesia of the finger. By using the sequence shown, the prior injection provides relief from the injection to follow. See Digital Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

Technique Insert the needle on the dorsal surface of the proximal phalanx, advance toward the volar surface staying tangential to the phalanx, aspirate to ensure no inadvertent vascular puncture has occurred, deposit 1 mL of anesthetic solution, and inject an additional 1 mL while withdrawing the needle back to the skin surface (**Figure 36-2**). Reinsert the needle in the same location, but direct it across the dorsum of the digit to the other side, and inject a 1-mL band of anesthetic solution into the subcutaneous space across the dorsum of the digit. Repeat the initial injection process on the other side of the digit.

Transthecal or Flexor Tendon Sheath Digital Nerve Block • *Purpose* A transthecal or flexor tendon sheath digital nerve block provides anesthesia to the entire digit by utilizing the flexor tendon sheath to apply anesthetic to the digital nerves.[89] This procedure can be performed in addition or as an alternative to a digital nerve block. However, **flexor tendon sheath block may not fully anesthetize the distal fingertip**.

Patient Positioning and Anatomy The hand and wrist are placed in a supine (palm up) position. The flexor tendon sheath surrounds the flexor tendon on the palmar side of the digit.

Technique Identify the distal palmar crease on the palmar aspect of the hand. Have the patient flex the finger against resistance to improve visualization of the flexor tendon. Identify the distal palmar crease of the digit to be blocked, and insert the needle at a 45-degree angle to the palmar plane with the tip pointed distally (**Figure 36-3**). Advance the needle until a "pop" is felt, indicating penetration of the flexor tendon sheath. Inject 2 to 3 mL of anesthetic solution. If bone is struck before the "pop" is felt, withdraw the needle 2 to 3 mm and inject the solution.

A modification of the transthecal approach is to inject into the flexor tendon sheath at the base of the digit in the metacarpal crease[90,91] or into the midportion of the proximal phalanx.[92]

HAND AND WRIST BLOCKS

The median, radial, and ulnar nerves supply the sensory innervation to the hand and can be used in part or in combination to provide anesthesia for lacerations, puncture wounds, or fracture/dislocation reductions (**Figures 36-4** and **36-5**).

Median Nerve Block • *Purpose* A median nerve block provides anesthesia to the thumb, index, long, and half of the ring finger distal to the proximal interphalangeal joint, but not the dorsum of the thumb (**Figures 36-4** and **36-5**).

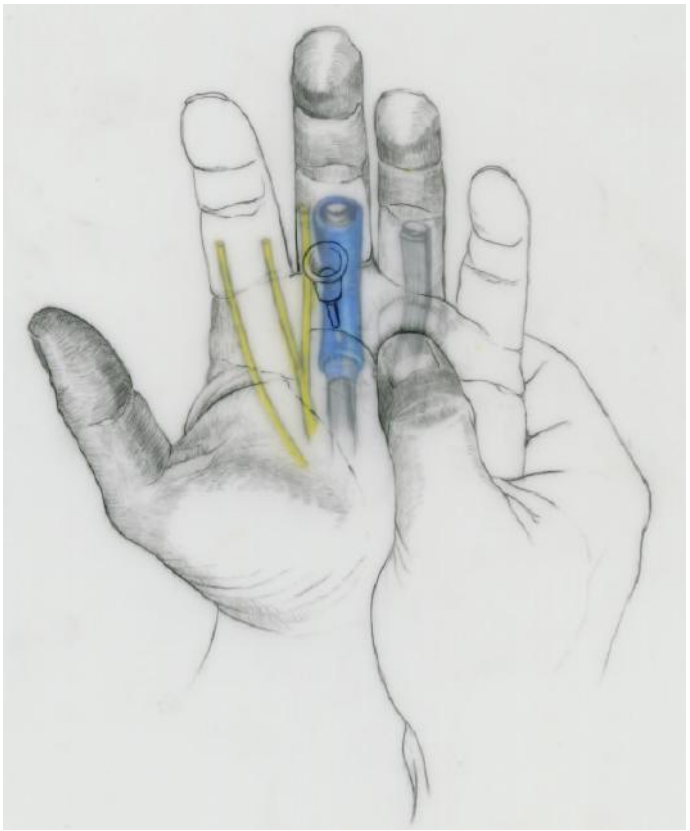

FIGURE 36-3. Transthecal (flexor tendon sheath) digital nerve block. The point of injection is in the middle of the flexor tendon sheath at the level of the distal palmar crease. A 25-gauge needle is advanced at 45 degrees, with tip directed distally until it enters the flexor tendon sheath (shown in blue) or until bone is encountered. When the needle is properly placed within the flexor tendon sheath, the anesthetic solution is injected. Diffusion out of the tendon sheath blocks adjacent palmar digital nerves. See Transthecal or Flexor Tendon Sheath Digital Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

Patient Positioning and Anatomy The hand and wrist are placed in a supine (palm up) position. The median nerve traverses between the flexor carpi radialis and the palmaris longus tendon at the proximal wrist crease. With the hand and wrist in a supine position, the flexor carpi radialis is lateral (radial direction) and the palmaris longus is medial (ulnar direction) to the nerve. When the patient makes a fist and flexes the wrist, the palmaris longus tendon is usually the more prominent of the two tendons (**Figure 36-6**, top left).

FIGURE 36-4. Hand innervation, dorsal view. Dorsal hand distribution of ulnar nerve (yellow), radial nerve (red), and median nerve (blue).

FIGURE 36-5. Hand innervation, palmar view. Palmar hand distribution of ulnar nerve (yellow), radial nerve (red), and median nerve (blue).

Technique Raise a wheal of anesthetic in the subcutaneous space between the palmaris longus and flexor carpi radialis at the level of the proximal palmar crease (**Figure 36-6**, right). Insert the needle until the "pop" of

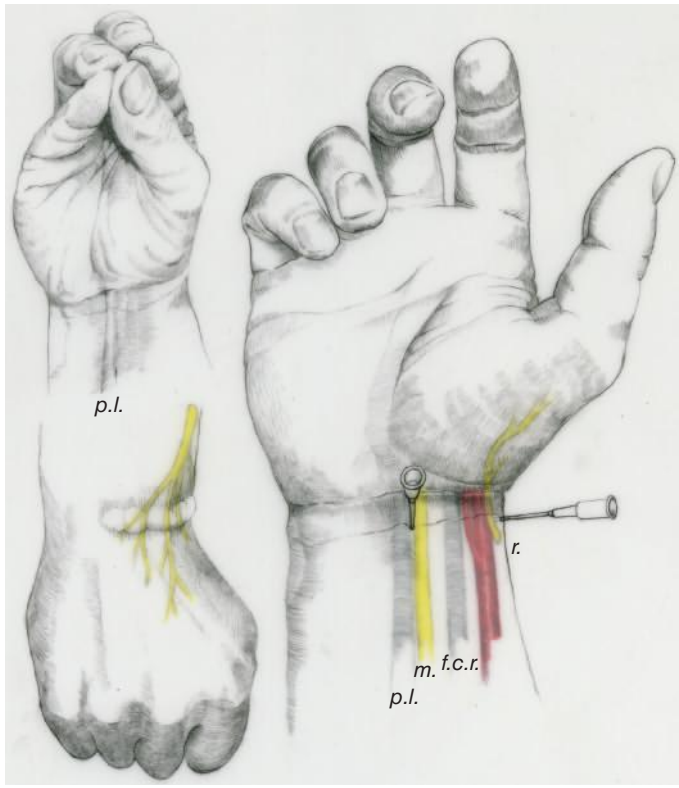

FIGURE 36-6. Median and radial nerve block. *Top left:* Technique for identification of the palmaris longus tendon (p.l.) through wrist flexion using finger and thumb opposition. *Right:* The median nerve (m.) is blocked by inserting the needle between the palmaris longus and flexor carpi radialis (f.c.r.) tendons. The radial nerve (r.) block begins with an injection over the lateral aspect of the radial styloid. *Lower left:* The radial nerve block continues dorsally as a subcutaneous field block extending to the dorsal mid wrist. See Median Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

the deep fascia can be felt, and inject 3 to 5 mL of anesthetic. If bone is contacted before the "pop" is felt, withdraw the needle 2 to 3 mm and inject the solution. To increase the probability of a successful block, withdraw the needle back to the skin and reinsert, directing the needle 30 degrees medially and laterally, and inject an additional 1 to 2 mL of anesthetic solution. The palmar branch of the medial nerve is superficial and can be blocked by withdrawing the needle to the subcutaneous space and injecting 2 to 3 mL of anesthetic solution.

Radial Nerve Block • *Purpose* A radial nerve block provides anesthesia to the dorsal lateral half of the hand and dorsal aspect of the thumb.

Patient Positioning and Anatomy The hand and wrist start in a neutral position (thumb side up) and then rotate into a prone (palm down) position. The superficial branch of the radial nerve traverses above the styloid process of the radius and provides sensation to the dorsum of the thumb, index finger, and lateral half of the middle finger (**Figures 36-4** and **36-5**). Other branches of the radial nerve traverse over the anatomic snuff box. The anatomic snuff box is formed by the extensor tendons of the pollicis brevis and longus and the radial styloid.

Technique Raise a wheal of anesthetic in the subcutaneous space just proximal to the anatomic snuffbox. Inject 5 mL of anesthetic solution into the subcutaneous tissue overlying the radial styloid (**Figure 36-6**, right). Then, reinsert the needle and direct it through the subcutaneous space in a lateral (ulnar) direction, injecting a band of an additional 5 mL of anesthetic solution to ensure blockage of the smaller branches of the radial nerve (**Figure 36-6**, lower left). The distribution of the radial nerve is less predictable; therefore, a generous amount of anesthesia should be injected.

Ulnar Nerve Block • *Purpose* An ulnar nerve block provides anesthesia to the entire fifth digit, half of the fourth digit, and the medial aspect of the hand and wrist.

Patient Positioning and Anatomy The hand and wrist are placed in a supine (palm up) position. The ulnar nerve travels with the corresponding vein and nerve and can be located underneath (deep) to the flexor carpi ulnaris. To identify the flexor carpi ulnaris, have the patient make a fist and tense the wrist. The flexor carpi ulnaris is the most prominent tendon on the ulnar side at the wrist (**Figure 36-7A**).

Technique Raise a wheal of anesthetic in the subcutaneous space just proximal (1 to 2 cm) to the most distal wrist crease. Insert the needle under the flexor carpi ulnaris tendon to an additional 5 to 10 mm past the edge of the tendon (**Figure 36-7C**). Aspirate before injection to ensure that inadvertent arterial/venous puncture has not occurred, and inject 3 to 5 mL of anesthetic solution. To block the dorsal branches of the ulnar nerve, inject 2 to 3 mL of anesthetic solution in the subcutaneous space just above the tendon of the extensor carpi ulnaris (**Figure 36-7B**). US guidance can be useful when anatomic landmarks are not easy to discern.[93]

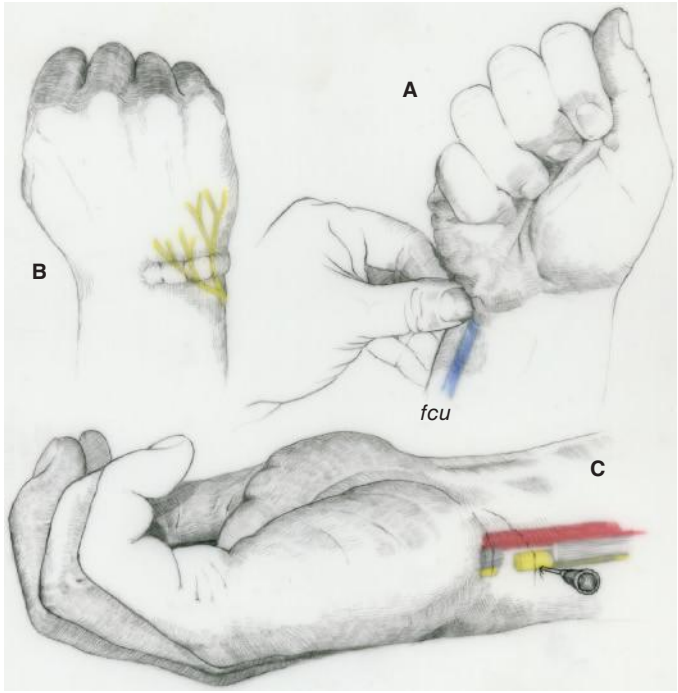

FIGURE 36-7. Ulnar nerve block. **A.** Technique for identifying the flexor carpi ulnaris tendon (fcu) by making a fist and tensing the wrist. **B.** The subcutaneous field block of the dorsal ulnar nerve branches, extending from the site of insertion of the ulnar block to the midline dorsal wrist. **C.** The needle is oriented horizontally beneath the flexor carpi ulnaris tendon and inserted to a depth of 5 to 10 mm past the tendon edge where the anesthetic solution is injected after a negative aspiration. See Ulnar Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

FOOT AND ANKLE BLOCKS

The five nerves that provide sensation to the foot are four branches of the sciatic nerve (deep and superficial peroneal, tibial, and sural nerves) and one cutaneous branch of the femoral nerve (saphenous nerve; **Figures 36-8** through **36-11**). These are excellent blocks to use alone or in combination for lacerations, fracture reductions, and exploring wounds. The deep peroneal nerve and the posterior tibial nerves are deep nerves and can be more consistently found by anatomic landmarks. The superficial peroneal, sural, and saphenous nerves are superficial and located in the subcutaneous tissue encircling the ankle. Due to the anatomic variability of these three nerves, no single injection point can reliably provide adequate anesthesia, so these nerves are blocked by depositing the local anesthetic agent as a field block in the subcutaneous space in the area through which the nerve travels. The pertinent landmarks for performing all of the ankle blocks are the extensor hallucis longus, tibialis anterior tendon, Achilles tendon, and the medial and lateral malleolus (**Figure 36-12**).

When all five blocks are used for complete foot anesthesia, the deep nerves (deep peroneal and posterior tibial) should be anesthetized before the surface anatomy is distorted by the superficial field blocks of

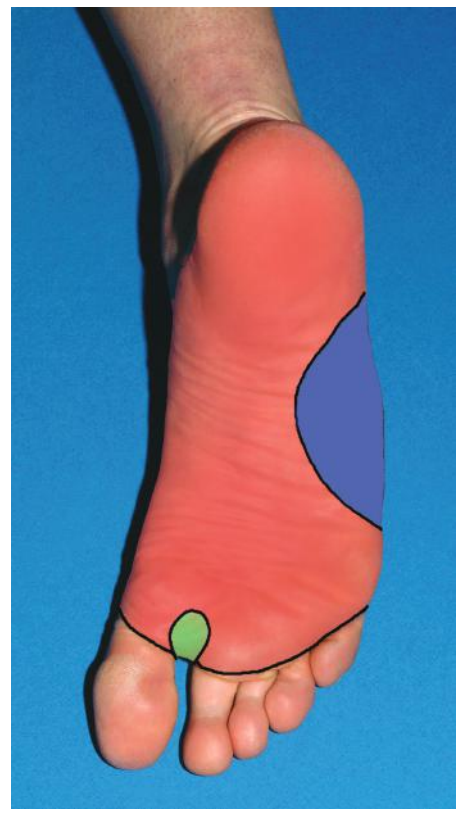

FIGURE 36-8. Foot innervation plantar view. Plantar foot distribution of deep peroneal nerve (green), posterior tibial nerve (red), and sural nerve (blue).

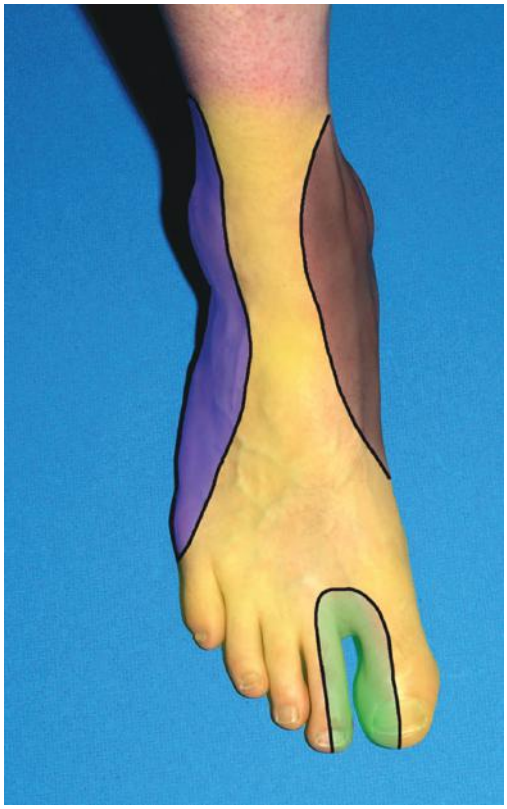

FIGURE 36-9. Foot innervation dorsal view. Dorsal foot distribution of deep peroneal nerve (green), superficial peroneal nerve (yellow), saphenous nerve (brown), and sural nerve (blue).

the other three. An additional tip is to prepare and clean the entire foot before starting so that the physician can change his or her body position and reposition the patient's foot as needed to avoid awkward reaches when accessing all five sites.

Deep Peroneal Nerve Block • *Purpose* A deep peroneal nerve block provides anesthesia to the web space between the first and second toe and a small area just proximal to the first and second toe on the plantar aspect of the foot.

Patient Positioning and Anatomy The foot is placed in a neutral position. At the level of the medial malleolus, the deep peroneal nerve can be found

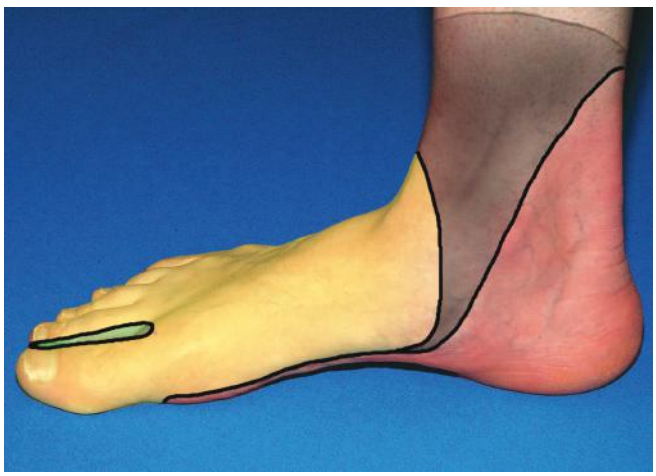

FIGURE 36-10. Foot innervation medial view. Medial foot distribution of superficial peroneal nerve (yellow), saphenous nerve (brown), and posterior tibial nerve (red).

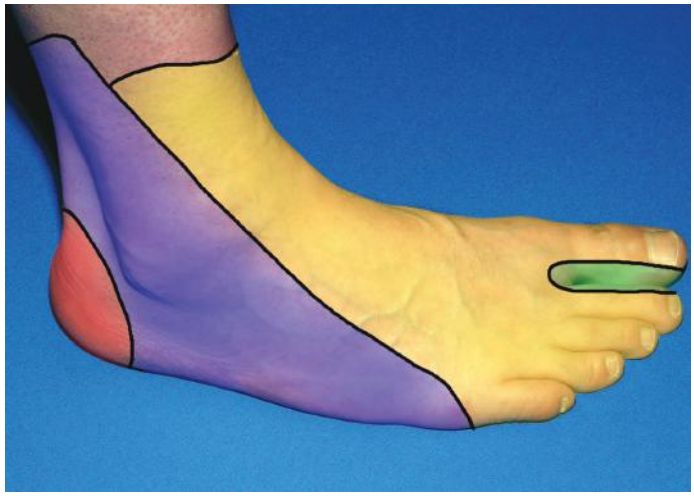

FIGURE 36-11. Foot innervation lateral view. Lateral foot distribution of deep peroneal nerve (green), superficial peroneal nerve (yellow), posterior tibial nerve (red), and sural nerve (blue).

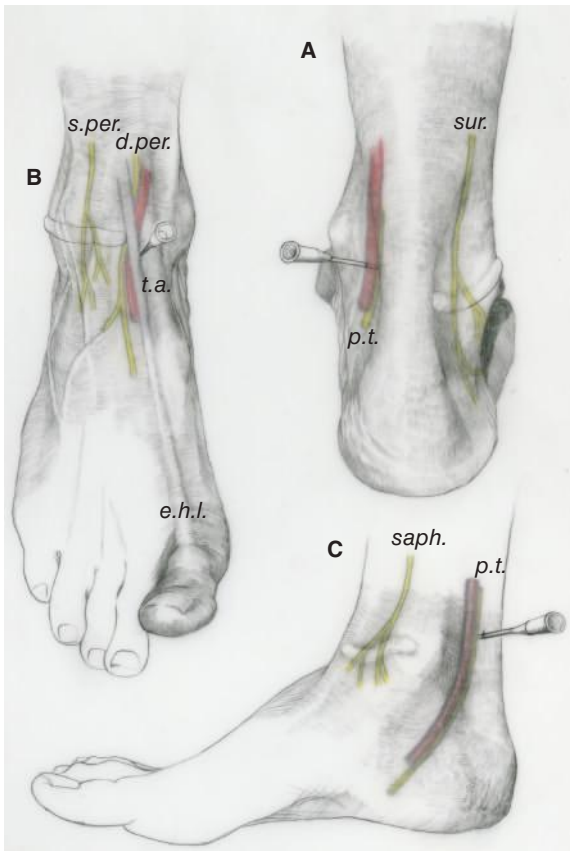

FIGURE 36-12. Ankle nerve blocks. **A.** The subcutaneous field block of the sural nerve (sur.) extends from the Achilles tendon to the lateral malleolus. The posterior tibial nerve (p.t.) is blocked just behind the posterior tibial artery. **B.** The deep peroneal nerve (d.per.) block is blocked at the level of the medial malleolus between the anterior tibial tendon (t.a.) and extensor hallucis longus tendon (e.h.l.). The subcutaneous field block of the superficial peroneal nerve (s.per.) extends from the lateral malleolus to the anterior tibial tendon. **C.** The posterior tibial nerve is blocked posteriorly to the posterior tibial artery. The subcutaneous field block of the saphenous nerve (saph.) extends from the medial malleolus to the anterior tibial tendon. See Foot and Ankle Blocks section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

between the extensor hallucis longus and the tibialis anterior tendon. Extension of the big toe against resistance will help to identify the extensor hallucis longus. Dorsiflexion and inversion of the ankle will help to identify the tibialis anterior tendon.

Technique Raise a wheal of anesthesia in the subcutaneous space between the extensor hallucis longus and the tibialis anterior tendon at the level of the medial malleolus (**Figure 36-12B**). With the syringe perpendicular to the skin, insert the needle until the extensor retinaculum is penetrated or bone is struck. If bone is struck, withdraw the needle 2 mm. After aspirating to verify that no vascular structure has been entered, inject approximately 2 to 3 mL of anesthetic solution. To increase the chance of a successful block, withdraw the needle back to the skin and reinsert, direct the needle 30 degrees medially and laterally, and deposit an additional 2 mL of anesthetic solution on each side.

Posterior Tibial Nerve Block • *Purpose* A posterior tibial nerve block provides anesthesia to the plantar aspect of the foot. This is an excellent block when repairing a laceration on the bottom of the foot.

Patient Positioning and Anatomy The patient can be either supine with the foot rotated outward or prone with the foot rotated inward. The posterior tibial nerve, artery, and vein can be found just posterior to the medial malleolus. The nerve is deep to the fascia and superficial/posterior to the artery.

Technique Raise a wheal of anesthesia posterior to the medial malleolus. Palpate the posterior tibial artery and insert the needle just posterior to the artery until it is deep to the fascia or bone is struck (**Figure 36-12A** and **C**). If bone is struck, withdraw the needle 2 mm. Inject 2 to 3 mL of local anesthetic solution after aspirating to ensure that inadvertent arterial/venous puncture has not occurred. To increase the chance of a successful block, withdraw the needle back to the skin and reinsert, directing the needle 30 degrees medially and laterally, and deposit an additional 2 mL of anesthetic solution on each side. US guidance can be used to guide the needle and increase the completeness of a posterior tibial nerve block.[94]

Superficial Peroneal Nerve Block • *Purpose* A superficial peroneal nerve block provides anesthesia to the dorsal lateral aspect of the foot.

Patient Positioning and Anatomy The patient is supine, and the foot is rotated inward. The superficial peroneal nerve traverses the lateral portion of the ankle in the subcutaneous space between the lateral malleolus and the tibialis anterior tendon.

Technique Prepare a sterile site between the superior border of the lateral malleolus and the tibialis anterior tendon. Dorsiflexion and inversion of the ankle will help to identify the tibialis anterior tendon. In the subcutaneous space, inject 5 mL of anesthetic, tracking from the tibialis anterior tendon to the superior portion of the lateral malleolus (**Figure 36-12B**). Creation of a subcutaneous wheal indicates proper anesthetic placement.

Sural Nerve Block • *Purpose* A sural nerve block provides anesthesia to the lateral aspect of the ankle with some extension of anesthesia to the plantar aspect of the foot.

Patient Positioning and Anatomy The patient can be either supine with the foot rotated inward or prone with the foot rotated outward. The sural nerve traverses the posterior lateral portion of the ankle in the subcutaneous space between the Achilles tendon and the lateral malleolus.

Technique Identify the space between the Achilles tendon and the superior border of the lateral malleolus. In the subcutaneous space, inject 5 to 6 mL of anesthetic solution in a band running from the superior portion of the lateral malleolus to the Achilles tendon (**Figure 36-12A**). Creation of a subcutaneous wheal indicates proper anesthetic placement. US guidance by injecting the local anesthetic around the lesser saphenous vein may facilitate a more complete and longer duration block.[95]

Saphenous Nerve Block • *Purpose* A saphenous nerve block provides anesthesia to the medial aspect of the ankle.

Patient Positioning and Anatomy The foot is in a neutral position. The saphenous nerve traverses the anterior medial portion of the ankle in the subcutaneous space between the tibialis anterior tendon and the medial malleolus.

Technique Identify the space between the tibialis anterior tendon and the superior border of the medial malleolus. In the subcutaneous space, inject 5 to 6 mL of anesthetic solution from the tibialis anterior tendon to the superior portion of the medial malleolus (**Figure 36-12C**). Creation of a subcutaneous wheal indicates proper anesthetic placement.

FACIAL NERVE BLOCKS

Facial nerve blocks provide excellent analgesia and little to no distortion of the forehead, cheek, and chin (**Figure 36-13**).[70,96] **Topical anesthetic applied to the mucosa should be used before the intraoral approach for infraorbital and mental nerve blocks.** It is important to assess neurovascular status before application of the block to prevent masking a primary traumatic neurovascular injury.

Supraorbital and Supratrochlear Nerve Blocks • *Purpose* Supraorbital and supratrochlear nerve blocks provide anesthesia to the entire forehead up to the vertex of the scalp and down the bridge of the nose.

Patient Positioning and Anatomy The patient is either supine or sitting. The supraorbital nerve exits the supraorbital foramen, which is in line with the pupil and above the superior orbital rim. The supratrochlear nerve exits from under the superior orbital rim 5 to 10 mm medial to the supraorbital foramen. The supraorbital nerve supplies most of the forehead, whereas the supratrochlear nerve supplies the area along the bridge of the nose (**Figure 36-13**).

Technique Raise a wheal of anesthesia in the subcutaneous space just superior to the eyebrow and in line with the pupil. Deposit 2 to 3 mL of anesthetic solution in the subcutaneous space, and then direct the needle medially to raise a horizontal wheal reaching to the medial border of the eyebrow using an additional 5 mL of anesthetic solution (**Figure 36-14**).

Infraorbital Nerve Block • *Purpose* An infraorbital nerve block provides anesthesia to the lower lid, medial cheek, ipsilateral side of the nose, and the ipsilateral upper lip (**Figure 36-13**).

Patient Positioning and Anatomy The patient is either supine or sitting. The infraorbital nerve exits the infraorbital foramen 5 to 10 mm inferior to the midportion of the orbital rim and just cranial (superior) to the

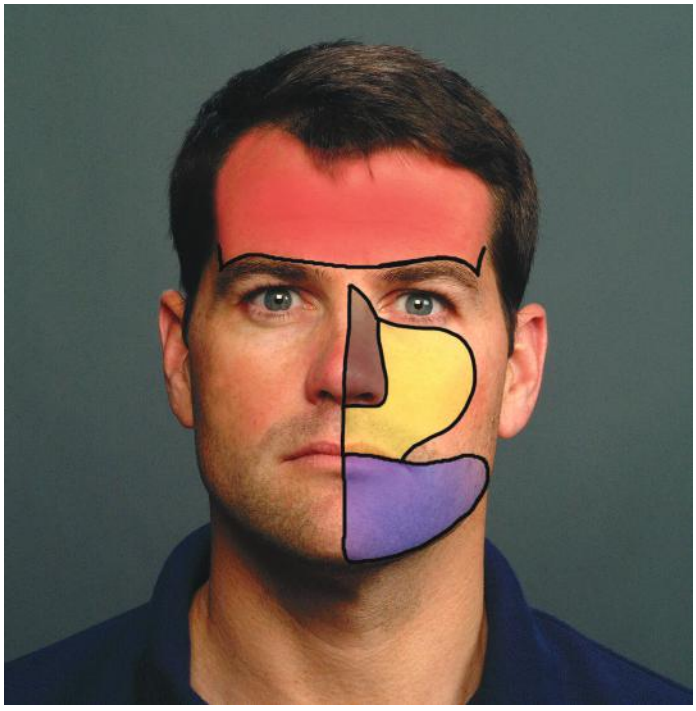

FIGURE 36-13. Face innervation frontal view. Nerve distribution to the face with supraorbital nerve (red), supratrochlear nerve (brown), infraorbital nerve (yellow), and mental nerve (blue).

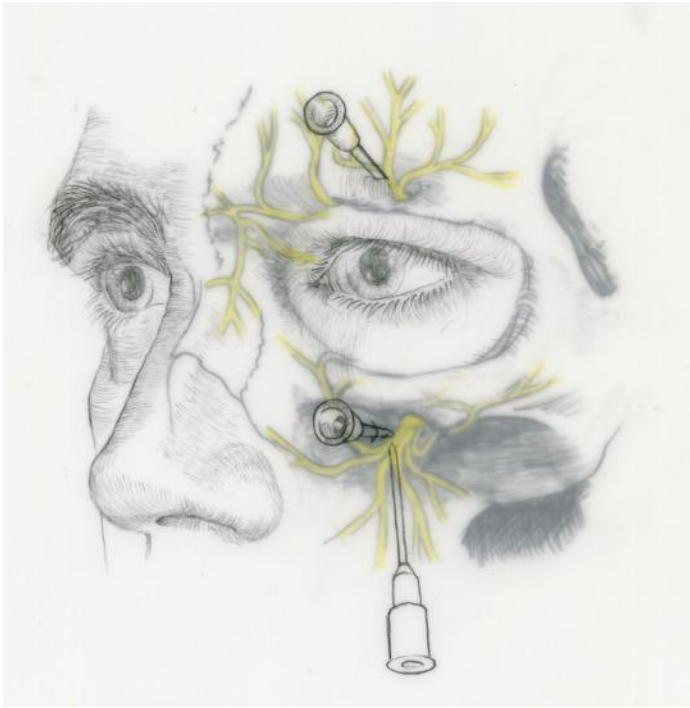

FIGURE 36-14. Supraorbital and infraorbital nerve blocks. Palpation of the subtle supraorbital foramen may be difficult, although identification is achieved when forehead paresthesias are elicited. A subcutaneous field block extending horizontally above the eyebrow is a useful addition. Palpation of the infraorbital foramen, especially via the intraoral approach, is typically easier. See Supraorbital and Infraorbital Nerve Blocks section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

FIGURE 36-15. Mental nerve block. Infiltration of anesthetic around the mental foramen from an intraoral (*right needle*) or transcutaneous (*left needle*) approach. See Mental Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

maxillary canine teeth (tooth #6 on the patient's right and #11 on the patient's left).

Technique After adequately providing topical anesthetic to the mucosa superior to the maxillary canine, dry the mucosa and retract the upper lip. The recommended technique involves placing the index finger and middle finger of the noninjecting hand on the inferior optic rim and everting the upper lip with the thumb. Insert the needle at the gingival reflection above the maxillary canine, direct the needle superiorly, advance approximately half the distance from the entry site to the orbital rim, and inject 3 to 5 mL of anesthetic solution (**Figure 36-14**). Depending on the patient's anatomy, it may be possible for the physician's index or middle finger to palpate the infraorbital foramen through the skin and direct the needle to this site.

Mental Nerve Block • *Purpose* A mental nerve block provides anesthesia to the labial mucosa, gingiva, and lower lip adjacent to the incisors and canines.

Patient Positioning and Anatomy The patient can be either supine or sitting. The inferior alveolar nerve gives rise to the mental nerve, which exits the mental foramen, located inferior to the mandibular canines and first premolars (teeth #21 and #22 on the patient's left, and #27 and #28 on the patient's right).

Technique After adequately providing topical anesthetic to the mucosa inferior to the canine and first premolars, dry the mucosa and evert the lower lip. Insert the needle at the gingival reflection at this site, direct the needle inferiorly, advance approximately 1 cm, and inject 3 to 5 mL of anesthetic solution (**Figure 36-15**). Depending on the patient's anatomy, it may be possible for the physician's finger to palpate the mental foramen through the skin and direct the needle to this site.

Auricular Block • *Purpose* An auricular block provides anesthesia to the entire ear.

Patient Positioning and Anatomy Patient can either be supine or sitting. The sensation to the ear is provided anteriorly by the auriculotemporal nerve and posteriorly by the greater auricular nerve and the mastoid branch of the lesser occipital nerve.

Technique Raise a wheal in the subcutaneous space inferior to the auricle. From this site, direct the needle in the subcutaneous space anterior and superior, and inject 2 to 3 mL of anesthetic while withdrawing the needle (**Figure 36-16**). From the original injection point, redirect the needle posteriorly and superiorly and deposit 2 to 3 mL in the subcutaneous space while withdrawing the needle. Repeat this process from the superior aspect of the ear, injecting 2 to 3 mL of local anesthetic in the subcutaneous space both anterior and posterior to the ear to complete the field block around the ear.

INTERCOSTAL NERVE BLOCK

Purpose An intercostal nerve block provides analgesia to the intercostal nerve above and below the affected rib in a band-like fashion around the chest wall. These blocks provide an alternative to parenteral analgesia for controlling pain from rib fractures that make movement and normal respiration quite painful[97,98] and for placement of tube thoracostomy.[99] Although controlled trials comparing parenteral analgesia with intercostal nerve blocks are lacking, clinical observations suggest better pain control and increased lung function associated with intercostal blocks.[100] A good intercostal block will provide anesthesia duration between 8 and 18 hours.

Patient Positioning and Anatomy Patient is sitting upright, with the ipsilateral arm raised at the shoulder and the wrist rested on top of the head. Within the subcostal groove of the rib, the intercostal nerve originates from the thoracic nerve and runs inferior to the artery and vein ("vein, artery, nerve"). Ribs 1 through 6 are difficult to block due to the position of the scapula and rhomboid muscles. With both anterior and posterior rib fractures, the optimal block site is at the "rib angle," approximately 6 cm lateral to the midline, or just lateral to the paraspinous muscles. **Blocking posterior to the midaxillary line ensures analgesia to the lateral cutaneous and anterior branch of the intercostal nerve (Figure 36-17, right).**

Technique Palpate the inferior border of the rib to be blocked with the noninjecting hand, and retract the skin cephalad at a location about

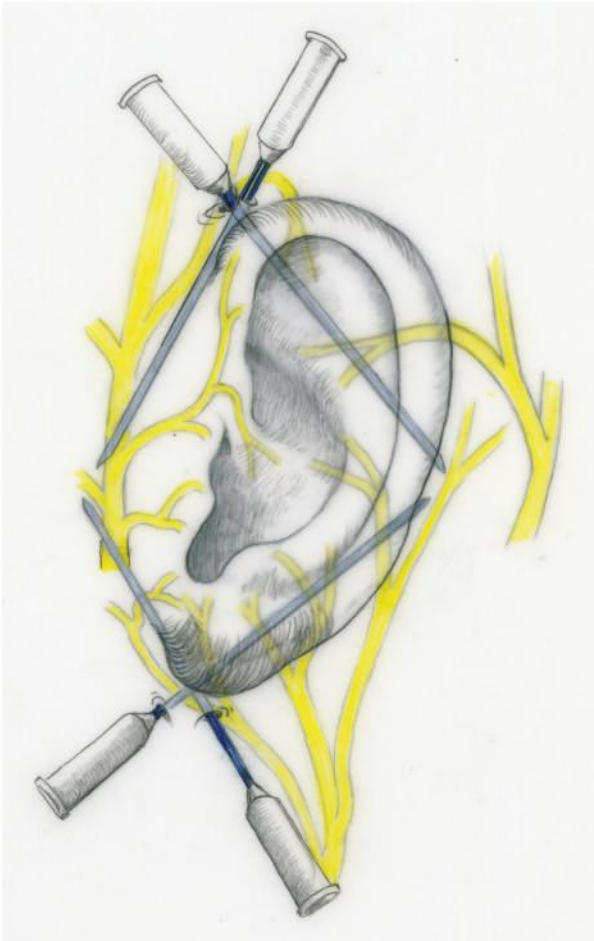

FIGURE 36-16. Auricular field block. The auricular block is a simple field block around the base of the external ear. [Illustration used with permission of Timothy Sweeney, MD.]

6 cm from the midline. Raise a wheal in the subcutaneous space, and insert the needle bevel up with the syringe lower than the entry site. The optimal angle is approximately 10 to 15 degrees off the perpendicular with the needle tip angled cephalad (**Figure 36-17**, top). Continue inserting the needle until it contacts bone. The needle should be resting at the inferior border of the rib to be blocked. Release the skin being retracted with the noninjecting hand, walk the needle caudally until it drops off the inferior edge of the rib, and advance the needle approximately 3 mm. This is the subcostal groove. Aspirate before injection, and deposit 2 to 5 mL of anesthetic.

The patient should be monitored for 30 minutes after the procedure to watch for clinical signs of pneumothorax. A postprocedure chest x-ray is not routinely indicated unless clinical signs of pneumothorax, including coughing, shortness of breath, or hypoxia, occur. Pneumothorax occurs in 8% to 9% of patients, or at a rate of about 1.4% for each individual intercostal block.[101]

FEMORAL NERVE BLOCK

Purpose Regional anesthesia in the femoral region can result in an isolated femoral nerve block or a larger block involving the femoral, obturator, and lateral femoral cutaneous nerves. These blocks provide good to excellent pain control for patients with proximal femur and hip fractures and are especially useful in the elderly.[102-105] The "three-in-one" block uses the same injection location as a femoral nerve block but applies distal pressure to promote cephalad distribution of the anesthetic agent to block the obturator and lateral femoral cutaneous nerves.[106] It is important to assess distal neurovascular status before application of the block to prevent masking a primary traumatic neurovascular injury.

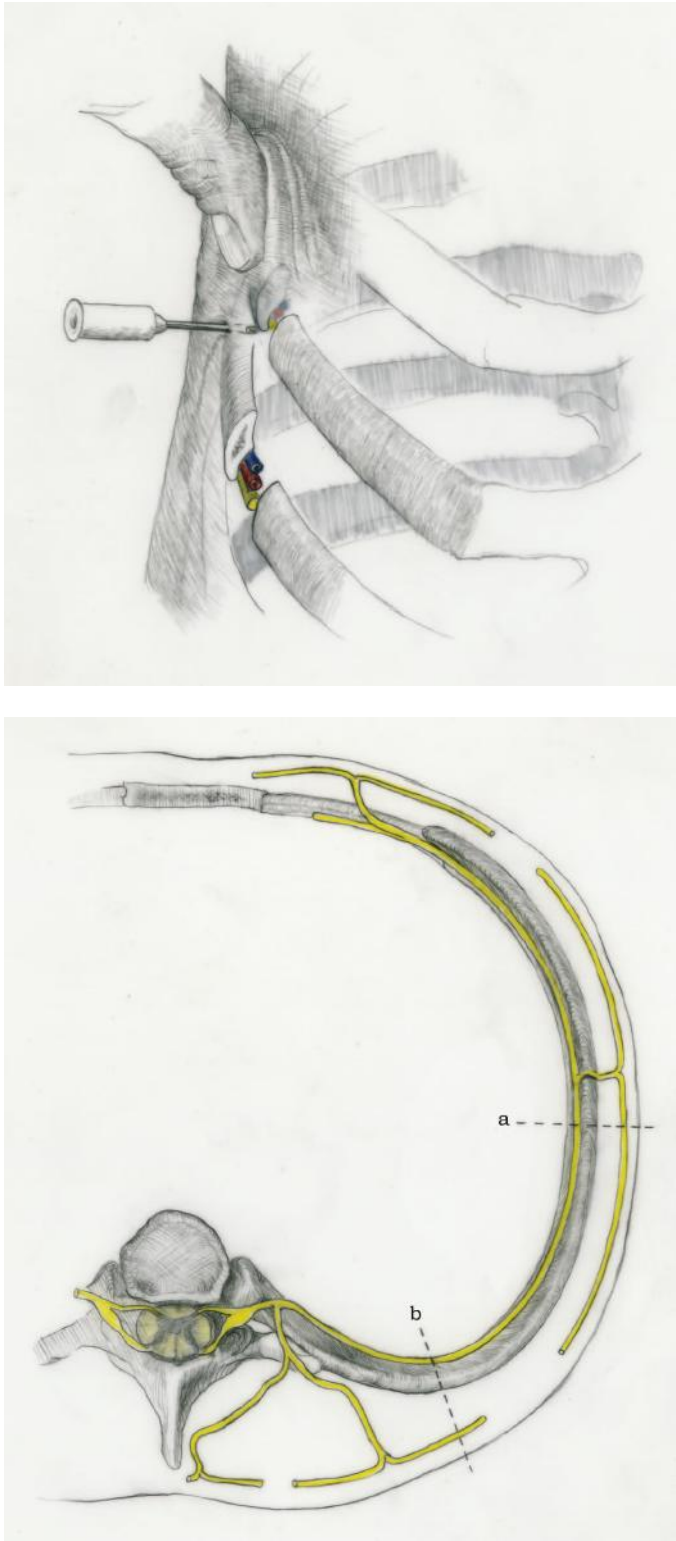

FIGURE 36-17. Intercostal block. *Top:* Cross-section of the chest shows the relevant branching of a typical intercostal nerve. Intercostal nerve blocks are commonly performed at the midaxillary line (a) or the posterior axillary "rib angle" line (b). *Bottom:* Retraction of the skin cephalad from the lower edge of the rib exposes the site of entry. The needle is inserted at a 10-degree angle off perpendicular, tip cephalad until contact is made with the lower rib edge. When the skin is released, the needle is allowed to slide caudad to the lowermost rib border. There, the needle is advanced 3 mm, aspiration is attempted, and the anesthetic solution is injected. See Intercostal Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

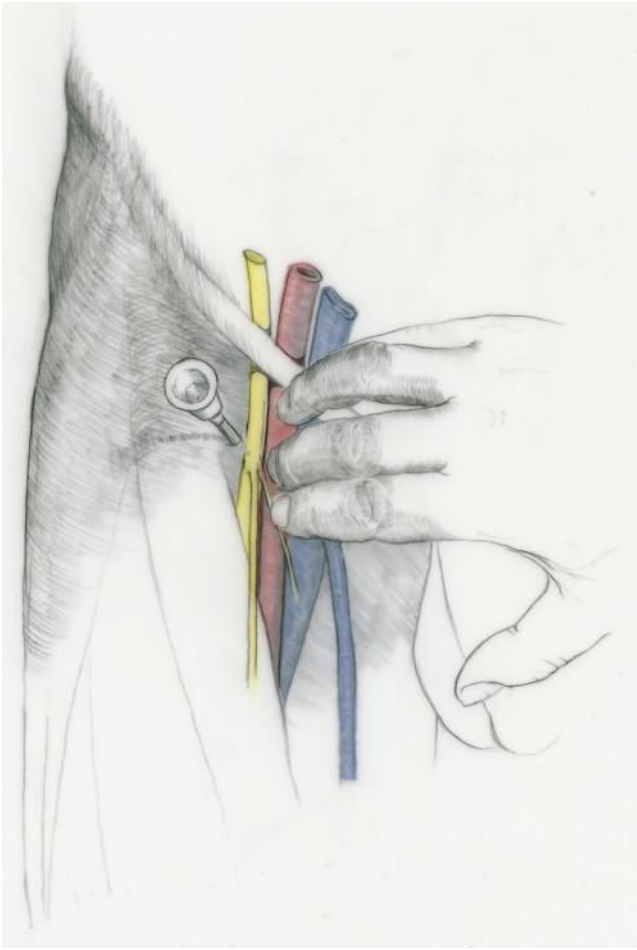

FIGURE 36-18. Femoral nerve block. The area 1 cm lateral to the femoral artery and at the level of the inguinal crease provides the point of insertion. The needle enters directly slightly cephalad and advances until paresthesia is felt. See Femoral Nerve Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

Patient Positioning and Anatomy The patient is in a supine position. In obese patients, placement of a pillow underneath the hip and retraction of the lower abdominal pannus superiorly and laterally will help expose the area. At the inguinal ligament and the inguinal (femoral) crease, the femoral nerve is positioned lateral to and slightly deeper than the femoral artery (**Figure 36-18**). The femoral nerve block will provide anesthesia to the anterior thigh and medial leg. The "three-in-one" block anesthetizes regions innervated by the obturator and the lateral femoral cutaneous nerves in addition to the anterior thigh and medial leg.

Technique **A peripheral nerve stimulator or US guidance is recommended.**[77-84,107,108] Ropivacaine is an excellent long-acting anesthetic with a relatively lower cardiac toxicity.[6,8,9]

Locate the femoral artery on the affected side at the level of the inguinal crease. Palpate the femoral artery with the noninjecting hand, and raise a wheal of anesthetic in the subcutaneous space at the level of the inguinal crease and 1 cm lateral to the femoral artery. Insert the needle at this site and directed slightly cephalad (**Figure 36-18**). The femoral nerve is a relatively superficial nerve, typically 2 to 3 cm below the skin.

If a peripheral nerve stimulator is being used, needle position is confirmed by contraction of the quadriceps muscle and subsequent patellar movement. If the sartorius muscle contracts, the needle should be repositioned slightly lateral and deeper. The sartorius muscle may mimic the quadriceps contractions, but the patella will only move with quadriceps contractions. US guidance can also be used to accurately place the anesthetic agent for a femoral nerve block.[108]

If a peripheral nerve stimulator is not being used, correct positioning of the needle is confirmed by the patient reporting paresthesia over the anterior thigh as the needle impacts the femoral nerve. Back the needle off slightly and inject approximately 20 mL of the anesthetic solution into the perineural space. If paresthesia over the anterior thigh cannot be elicited, the needle should be withdrawn to the skin, redirected 10 to 15 degrees laterally, and advanced as before. More lateral skin insertions may be required to locate the femoral nerve. Alternatively, a "blind" attempt can be made by injecting a larger quantity (30 to 40 mL) of anesthetic solution in and around the original site in an effort to spread the anesthetic through the region and reach the femoral nerve. Aspirate before each injection to avoid inadvertent arterial puncture, and do not inject if resistance is felt, as this indicates the possibility for intraneural injection.

To perform a "three-in-one" block, needle position should be confirmed by paresthesia or preferably by US.[107] Firm pressure distal to the injection site is then applied and held for 5 minutes as 20 to 30 mL of anesthetic solution is delivered. This distal pressure promotes cephalad distribution of the anesthetic solution.

An alternative to the femoral nerve block for pain control in patients with hip and femoral neck fractures is the fascia iliaca compartment block that has been recently studied in ED patients.[109,110]

HEMATOMA BLOCK

PURPOSE

Hematoma blocks are commonly performed for fracture reduction, utilizing the hematoma formation around the fracture to deliver anesthetic to the fracture site, most commonly for Colles' fractures.[111-113] This block has waned in use due to the rising popularity of procedural sedation and the misconception that hematoma blocks dramatically increase the risk of infection. The hematoma block remains a staple in the armamentarium of fracture analgesia, because it is simple, fast, and requires no special tools or personnel.

PATIENT POSITIONING

The patient is usually supine with the limb placed to access the fracture hematoma.

TECHNIQUE

Prepare a sterile block site over the bony fracture site and insert the needle directly into the hematoma (**Figure 36-19**). Positioning the needle in the hematoma can be difficult at times. Aspiration of blood aids in confirmation of needle position. Inject 5 to 15 mL of local anesthetic solution into the fracture site. **When performing this block, ensure that the maximum dose of local anesthetic is not exceeded. This procedure should not be performed through a contaminated wound or an open fracture.**

INTRAVENOUS REGIONAL ANESTHESIA (BIER BLOCK)

PURPOSE

The Bier block provides dense anesthesia in a limb for up to 60 minutes without the risks of general anesthesia. It is an excellent block for large complex lacerations, fracture reductions, and surgical procedures of <1 hour duration on the extremities[114] and does not require fasting for safe performance.[115] **Although this block is relatively easy to perform, it does require a specialized pneumatic tourniquet and provides no postprocedure pain control.** Because the local anesthetic solution is directly infused into the venous system, careful attention to technique is important to prevent systemic toxicity.[116] It is important to assess neurovascular status in the involved limb before application of the block to prevent masking a primary traumatic neurovascular injury.

TECHNIQUE

Place two IV catheters, one small gauge in the affected extremity and the other in the unaffected extremity for fluid administration and sedation,

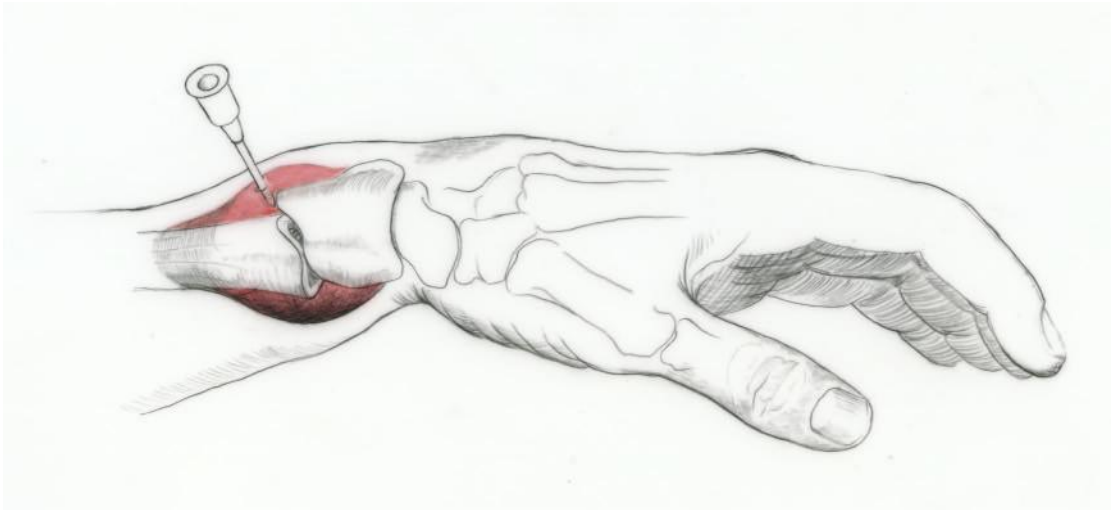

FIGURE 36-19. Hematoma block. After careful palpation for the fracture edge, the needle is inserted directly into the hematoma, with care taken to avoid regional vessels. See Hematoma Block section for further details. [Illustration used with permission of Timothy Sweeney, MD.]

if needed. Apply the specialized double-cuff pneumatic tourniquet to the affected upper arm or thigh. **The standard blood pressure cuff is not an acceptable alternative.** Provide adequate padding beneath the cuff, as this is often the site of maximal discomfort during the procedure.

Exsanguinate the affected extremity by either elevating it for 3 to 4 minutes or wrapping the extremity with a compression bandage from distal to proximal. The cuffs are then inflated in the following sequence: Inflate the distal cuff first, followed by inflating the proximal cuff and, finally, deflating the distal cuff. In the upper extremity, inflate the pneumatic tourniquet to 250 to 300 mm Hg (30 to 45 kPa) or 100 mm Hg (15 kPa) above the patient's systolic blood pressure. In the leg, cuff inflation pressures are 350 to 400 mm Hg (45 to 55 kPa). The compression bandage should be removed if used. The limb should be pale, and pulses should not be palpable.

Infuse the anesthetic via the small catheter of the affected limb. Most authors recommend diluting standard 1% lidocaine with equal parts normal saline to create a 0.5% (5 milligrams/mL) solution. The amount infused varies according to physician preference in the range of 1.5 to 3.0 milligrams/kg (3 to 6 mL of the 0.5% lidocaine solution for every 10 kg of body weight).[114] Onset of anesthesia is usually within 5 minutes. If inadequate anesthesia occurs when using a minidose (1.5 milligrams/kg), infuse additional lidocaine up to 3 milligrams/kg. If adequate anesthesia is not obtained with the maximum dose of lidocaine, infuse additional normal saline to help circulate the anesthetic.

The patient may report a sensation of warmth or cold, and the skin will become mottled. The smaller nerve fibers are affected first, causing a reduction in pain and temperature sensation followed by loss of touch, deep pressure, and, finally, motor function. An ideal Bier block will provide complete anesthesia and muscle relaxation, but patients may retain varying degrees of intact touch, deep pressure sensation, and motor function. Remove the IV in the affected extremity once adequate analgesia is obtained. Many patients will describe pain or pressure at the tourniquet site, usually within 30 minutes or so. This is handled by reinflating the previously deflated distal cuff. After ensuring that the distal cuff is inflated to the proper level and will hold pressure, the proximal cuff is slowly deflated. Dexmedetomidine mixed with the local anesthetic can also be used to control the pain of tourniquet inflation and provide postprocedure analgesia.[117]

The cuff should not be released until a minimum of 30 minutes after the initial lidocaine infusion; premature release of the cuff increases the chance of systemic toxicity from the anesthetic. Upon completion of the procedure, the pneumatic tourniquet should be cycled by lowering the cuff pressure for 5 to 10 seconds and then reinflating it for 1 to 2 minutes. This cycling should be repeated three to five times to prevent any possible bolus of anesthetic into the central circulation. Additional analgesia is usually required after completion of the procedure because anesthesia rapidly dissipates after release of the tourniquet. The patient should be monitored for approximately 30 minutes to ensure that no adverse reaction to the anesthetic has occurred.[114]

CHAPTER 37

Procedural Sedation

Chris Weaver

INTRODUCTION

Procedural sedation is the administration of sedatives or dissociative anesthetics to induce a depressed level of consciousness while maintaining cardiorespiratory function so that a medical procedure can be performed with little or no patient reaction or memory.[1] Procedural sedation and analgesia is the addition of agents to reduce or eliminate pain.[1] Levels of sedation are defined by the patient's level of responsiveness and cardiopulmonary function, not by the agents used (**Table 37-1**).[2] By definition, patients receiving procedural sedation do not require routine airway protection with endotracheal intubation or other airway adjuncts, as opposed to general anesthesia, which typically requires airway protection. Procedural sedation is commonly done for scheduled outpatient medical procedures by nonanesthesiologists[3,4] and is an accepted technique in emergency medicine.[5-8] Procedural sedation performed in the ED presents different issues to the practitioner than scheduled outpatient sedation (**Table 37-2**).[1,7,8]

SEDATION LEVEL

There are several key principles that must be followed to safely perform procedural sedation and analgesia (**Table 37-3**).[1,2,7,8] Despite careful planning and performance, the depth of sedation needed or achieved cannot always be predicted. It is therefore important to prepare for managing deeper levels of sedation than anticipated. Most of the agents used can produce variable levels of sedation, so pay particular attention to dosing and to the patient's responses to the medications.

TABLE 37-1 Levels of Sedation and Analgesia

	Responsiveness	Airway	Breathing	Circulation
Minimal sedation (aka "anxiolysis")	Normal but slowed response to verbal stimulation	Unaffected	Unaffected	Unaffected
Moderate sedation (aka "conscious sedation")	Purposeful response to verbal or physical stimulation	Usually maintained	Usually adequate	Usually maintained
Deep sedation	Purposeful response after repeated or painful physical stimulation	May be impaired	May be suppressed	Usually maintained

Minimal sedation is characterized by anxiolysis but with normal, although sometimes slowed, response to verbal stimuli. Minimal sedation is typically used for procedures that require patient cooperation and those in which pain is controlled by local or regional anesthesia. Minimal sedation procedures might include abscess incision and drainage, lumbar puncture, simple fracture reductions, and laceration repair. During minimal sedation, ventilatory function is usually maintained with a low risk of hypoxia or hypoventilation. Agents typically used for minimal sedation in adults include nitrous oxide, midazolam, fentanyl, pentobarbital, and low-dose ketamine.

Moderate sedation is characterized by a depressed level of consciousness and a slower but purposeful motor response to simple verbal or tactile stimuli. Moderate sedation most closely matches the formerly used term "conscious sedation." Patients at this level generally have their eyes closed and respond slowly to verbal commands. Moderate sedation can be used for procedures in which detailed patient cooperation is not necessary, and muscular relaxation with diminished pain reaction is desired. During moderate sedation, the patient is usually able to maintain a patent airway with adequate respirations.[9] Depending on the agent, the incidence of hypoxia and/or hypoventilation during moderate sedation is 10% to 30%.[10-12] Procedures performed using moderate sedation include reduction of dislocated joints, thoracostomy tube insertion, and synchronized cardioversion. Agents used for moderate sedation in adults include propofol, etomidate, ketamine, methohexital, and the combination of fentanyl and midazolam.

Dissociative sedation is a type of moderate sedation. Dissociation is a state in which the cortical centers are prevented from receiving sensory stimuli, but cardiopulmonary activity and responses are preserved. Ketamine is the agent most commonly used for dissociative sedation.[13]

Deep sedation is characterized by a profoundly depressed level of consciousness, with a purposeful motor response elicited only after repeated or painful stimuli. Deep sedation may be required with procedures that are painful and require muscular relaxation with minimal patient reaction. The risk of losing airway patency or developing hypoxia or hypoventilation is greater with deep sedation than with moderate or minimal sedation.[10,14,15] Examples of ED procedures sometimes requiring deep sedation are reducing fracture dislocations, open fracture reductions, and burn wound care. Deep sedation generally is achieved in the ED with the same agents as moderate sedation, but with larger or more frequent doses.

RISK ASSESSMENT AND PATIENT SAFETY

Complications are primarily determined by the interaction of the depth of sedation and the patient's current medical condition. A common tool for assessing the patient's underlying medical condition is the American Society of Anesthesiologists' physical status classification system.[16] The risk of a significant complication from ED procedural sedation and analgesia in American Society of Anesthesiologists class I (healthy normal patient) and II (patient with mild systemic disease) is low, usually less than 5%.[1,5-8] The risk of an adverse procedural sedation and analgesia event is correspondingly higher in patients with an American Society of Anesthesiologists class of III (patient with severe systemic disease) or IV (severe systemic disease that is a constant threat to life).[17,18]

PATIENT EVALUATION

To prepare for procedural sedation, perform a focused history and physical examination.[1,3,4,8] The focused history should determine the fasting state, prior experiences with sedation or anesthesia, current medications, and allergies. The focused physical examination identifies a potentially difficult airway or cardiorespiratory problems. A potentially difficult airway should be anticipated when the following findings or conditions are present: short neck, micrognathia, large tongue, trismus, morbid obesity, a history of difficult intubation, or anatomic anomalies of the airway and neck. The implications of these individual factors vary,[19-21] partially due to the weak interobserver reproducibility.[22] Additionally, studies on the association between these findings and difficult intubation are usually done on patients going to the operating room for general anesthesia, and these findings may not be entirely relevant to the ED patient.[23] If time allows and an anesthesiologist is available, consultation may be advisable before undertaking procedural sedation in a patient with a potentially difficult airway. At a minimum, difficult airway equipment should be present and available.

Cardiorespiratory conditions increase the complication rate. Most agents can cause vasodilatation and hypotension, particularly in patients with preexisting hypovolemia. Clinically active obstructive pulmonary disease and active upper respiratory infections may predispose the patient to heightened airway reactivity during the procedure and promote hypoventilation. Drug or alcohol intoxication or reduced level of consciousness increases the risk of hypoxemia and hypoventilation. If possible, delay procedural sedation in intoxicated patients until mental status improves.

Routine laboratory studies are not necessary in otherwise healthy patients. Directed ancillary testing may be useful in patients with conditions such as airway abnormalities, infections, advanced age, hepatic or renal disease, dehydration, fever, or hypovolemia. Such conditions may increase the risk of hypotension, prolonged sedation, or hypoxemia. These should be corrected if possible. If correction before procedural sedation is not possible, either delay the procedure or use the lowest possible level of sedation.

The need for sedation is sometimes more urgent than a full preprocedure evaluation. Emergent indications include cardioversion for life-threatening arrhythmias, neuroimaging for head trauma, reduction of

TABLE 37-2 Comparison of Outpatient and ED Procedural Sedation

	Outpatient	ED
Occurrence	Scheduled	Unpredictable
Timing	Not time dependent, can be rescheduled	More time dependent, sometimes emergent
Gastric state	Fasting	Variable
Preprocedure pain	Minimal to none	Often moderate to severe
Patient selection	Preselected for little to no systemic disease to reduce sedation risk	Unselected, may have moderate systemic disease

fractures or dislocations with soft tissue or vascular compromise, care of contaminated wounds, or intractable pain. Stable fractures, abscess incision and drainage, care of clean wounds, foreign body removal, and laceration repair require less urgent procedural sedation. Nonurgent indications for sedation include the removal of a soft tissue foreign body, placing splints on fractures that require minimal manipulation, or changing splints on fractures that have already been reduced.

RISKS AND PRECAUTIONS

FASTING STATE

There is no primary evidence that the risk of aspiration during procedural sedation is increased with recent oral intake.[24-26] Current guidelines regarding the safe fasting period prior to procedural sedation were developed by expert consensus,[27] and the American Society of Anesthesiologists guidelines for fasting prior to general anesthesia are of limited relevance to the risk of aspiration with ED procedural sedation.[25] Thus recent food intake is not a contraindication.[27] If the risk of aspiration is concerning, waiting 3 hours after the last oral intake before performing procedural sedation is associated with a low risk of aspiration, regardless of the level of sedation.[27]

NUMBER OF PHYSICIANS NEEDED

The anesthesia model for procedural sedation consists of two physicians, one to perform sedation and monitor the patient and the other to perform the procedure. In theory, if one physician is dedicated to administering procedural sedation, it should be possible to monitor the level of sedation, titrate the medication carefully, and identify adverse events earlier. Despite such potential benefits, clinical experience indicates that one emergency physician—providing sedation and performing the procedure—may achieve the same low risk of adverse events as having two physicians.[1,28] Thus, for minimal and moderate levels of sedation, one emergency physician simultaneously administering sedation and performing the procedure with a nurse monitoring the patient appears to be an appropriate practice. If available, a clinical pharmacist can provide useful information and assist during procedural sedation, with the potential to reduce the likelihood for medication errors.[29]

EQUIPMENT

The sedation area should include all necessary size-appropriate equipment for airway management and resuscitation, including oxygen, a bag-mask ventilation device, suction, oral/nasal airway(s), and intubation equipment.[1,3,4,8] A defibrillator should be available. Reversal agents, such as opioid receptor and benzodiazepine receptor antagonists, should also be readily available.

PROCEDURAL SEDATION MONITORING

Two types of monitoring are used for ED procedural sedation: interactive monitoring by dedicated observers and electronic monitoring with equipment connected to the patient. The recommended extent of monitoring is determined by the level of sedation (**Table 37-4**). **No matter which method is used, patients must be checked after each dose of medication to assess the response, determine the need for further doses, and make appropriate interventions if adverse events arise.**

INTERACTIVE MONITORING

Interactive monitoring is the direct observation of the patient to assess the depth of sedation and observe for hypoventilation or apnea, upper airway obstruction, laryngospasm, vomiting, or aspiration. Thus interactive monitoring requires an unobstructed view of the patient's face, mouth, and chest wall.

For minimal sedation, the risk of adverse events is so low that observation by the physician performing the procedure is usually adequate. For moderate and deep sedation, a dedicated observer—typically a nurse in the one-physician model—should continuously monitor the patient while the physician oversees drug administration and performs theprocedure.

ELECTRONIC MONITORING

Electronic monitoring uses equipment to assess arterial oxygenation, ventilation, blood pressure, and cardiac rate and rhythm. Moderate and deep sedation require constant observation and continuous monitoring. Cardiac monitoring is particularly recommended for patients with preexisting cardiac disease or dysrhythmias or during procedures in which the cardiac rhythm is of interest, such as during cardioversion. Arterial oxygen saturation is monitored with pulse oximetry. For almost all patients undergoing minimal sedation and many undergoing moderate sedation, pulse oximetry is adequate as the sole mechanical monitoring modality. However, pulse oximetry is not a substitute for monitoring ventilation, as hypoventilation or apnea develop before oxygen saturation decreases, especially in patients who receive supplemental oxygen.[30-33]

Ventilation can be electronically monitored using capnography, the measurement of the partial pressure of carbon dioxide in exhaled breath.[32,33] Many experts suggest that capnography should be used to monitor procedural sedation.[34-36] The capnography device uses an infrared carbon dioxide detector placed at the nares to sample inhaled and exhaled gases. The partial pressure of carbon dioxide detected at the nares during the respiratory cycle is represented by the carbon dioxide waveform (capnogram) that can be displayed on the monitor (**Figure 37-1**). A value commonly reported on the capnography device is the end-tidal carbon dioxide: the maximum carbon dioxide concentration at the end of each tidal breath. The end-tidal carbon dioxide correlates with arterial partial pressure of carbon dioxide so that an end-tidal car-

TABLE 37-4 Recommendations for Procedural Sedation and Analgesia Monitoring by Target Sedation Level

Target Level of Sedation	Level of Consciousness	Heart Rate	Respiratory Rate	Blood Pressure	Oxygen Saturation	Capnography End-Tidal CO_2
Minimal	Observe frequently	Measure every 15 min	Measure every 15 min	Measure every 15 min and after sedative boluses	Monitor continuously	No recommendation
Moderate or dissociative	Observe constantly	Monitor continuously	Continuous direct observation	Record every 5 min and after sedative boluses	Monitor continuously	Consider continuous monitoring
Deep	Observe constantly	Monitor continuously	Continuous direct observation	Record every 5 min and after sedative boluses	Monitor continuously	Recommend continuous monitoring for prolonged procedures

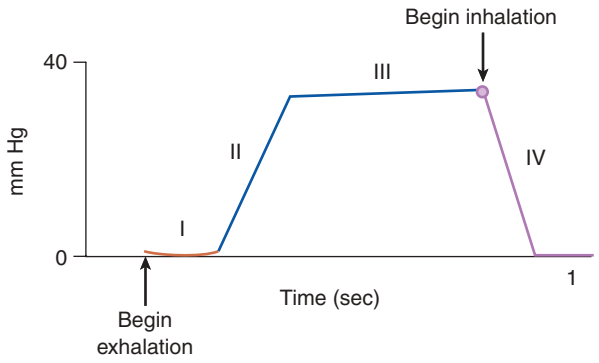

FIGURE 37-1. Normal capnogram. Phase I: At the start of exhalation, carbon dioxide concentration in the exhaled gas is essentially zero, representing gas from the anatomic dead space that does not participate in gas exchange. Phase II: As the anatomic dead space is exhaled, carbon dioxide concentration rises as alveolar gas exits the airway. Phase III: For most of exhalation, carbon dioxide concentration is constant and reflects the concentration of carbon dioxide in alveolar gas. Phase IV: During inhalation, carbon dioxide concentration decreases to zero as atmospheric air enters the airway. [Reproduced with permission from Krauss B, Hess DR: Capnography for procedural sedation and analgesia in the emergency department. *Ann Emerg Med* 50: 172, 2007 (Table 1, p. 176). Copyright Elsevier.]

bon dioxide above 50 mm Hg or an increase in end-tidal carbon dioxide >10 mm Hg indicates hypoventilation. Capnography can assess the severity of ventilatory abnormalities and the response to interventions. Most importantly, capnography can detect changes in ventilation before clinical observation.[32,33]

Variations in the capnogram can identify specific conditions, such as apnea, upper airway obstruction, laryngospasm, bronchospasm, and respiratory failure.[32] A flat-line capnogram can be due to apnea, upper airway obstruction, or complete laryngospasm. Normalization of the waveform after airway alignment maneuvers (chin lift, jaw thrust, or oral airway placement) confirms that apnea was due to upper airway obstruction.

Capnography during procedural sedation allows the early recognition of adverse events.[1,32,33] Because the risk of respiratory depression increases with the depth of sedation, capnography should be considered for moderate sedation and is recommended for prolonged deep sedation.

FREQUENCY OF MONITORING

Vital signs (pulse, blood pressure, and respiratory rate) and oxygen saturation should be obtained and recorded before the procedure, after each dose of medication, upon completion of the procedure, at the beginning of the recovery period, and before discharge.[1,3,4,8] For mild sedation, intermittent measurements are sufficient. For moderate and deep sedation, it is recommended that blood pressure be assessed every 5 minutes and heart rate and pulse oximetry be continuously monitored. Patients are at the highest risk of hypoxia and hypoventilation during the period immediately after IV medication administration (until the peak effect of the medication has been reached) and during the immediate postprocedure period (when external stimuli are discontinued and the stimulating pain of the procedure has subsided).

DOCUMENTATION

Predesigned documentation forms are a good practice because such forms can guide the providers through the procedure, improve the quality of the documentation of the procedure,[37] and better tabulate sedation-related events for quality-auditing purposes.[38]

SCALES FOR MONITORING DEPTH OF SEDATION

The level of sedation can be assessed using structured scoring techniques, such as the Ramsay Sedation Scale© and the Observer's Assessment of Alertness/Sedation Scale©. However, regular patient monitoring is more important than the application of scales. Specific central nervous system monitoring, such as the bispectral index scale that uses processed electroencephalogram signals to measure the depth of sedation, is primarily a research tool for procedural sedation.[11,15,39,40]

STEP-BY-STEP TECHNIQUE

PREPROCEDURE PAIN MANAGEMENT

The administration of morphine or fentanyl for pain control before the start of procedural sedation will provide the patient with analgesia during the procedure. Pain should be controlled so the patient is comfortable, but if preprocedure pain is intractable and if the procedure itself will result in pain relief, do not wait for complete pain control to begin.

Begin procedural sedation after the last dose of analgesic has reached its peak effect (3 to 5 minutes for IV morphine and 2 to 3 minutes for IV fentanyl). The administration of propofol or etomidate concurrently with analgesics may increase the likelihood of adverse events, so these medications should be titrated separately.[18,41]

The opioid dose needed before a procedure is typically more than the amount required after the procedure. Shorter-acting agents are preferred to drugs with a longer duration of action to minimize postprocedure respiratory depression. (See chapter 35, Acute Pain Management, for further discussion).

SUPPLEMENTAL OXYGEN

The incidence of oxygen desaturation during ED procedural sedation ranges from 6% to 40% without supplemental oxygen.[10-12,30,42,43] Supplemental oxygen reduces the incidence of hypoxemia[30,31,42,43] and has no adverse clinical effects. However, the administration of supplemental oxygen can delay the recognition of respiratory suppression, because oxygen saturation is maintained despite rising carbon dioxide noted by capnography.[32,33,42] In morbidly obese patients, bilevel positive airway pressure may be useful to facilitate adequate sedation while averting hypoventilation.[44]

SEDATION MANAGEMENT

After the patient has been evaluated, the appropriate sedation target level is selected, the monitoring modalities are applied, and preparations are made for possible adverse events, then procedural sedation can begin (**Table 37-5**). Observe and monitor the patient until the peak effect of the initial sedative dose has been reached. If necessary, titrate with additional medications to the desired sedation level. Once the patient has achieved the target sedation level, the actual procedure may begin. If the

patient begins to regain alertness before completion of the procedure, additional sedative doses may be required. However, additional sedative doses given to extend procedural sedation are associated with an increased risk of respiratory depression. As larger cumulative doses of the drug are given, the half-life of each bolus will increase. After the patient recovers from sedation, analgesics are administered as needed, for patient comfort.

SEDATION AGENTS

NITROUS OXIDE

Nitrous oxide is typically supplied in a 50:50 mixture with oxygen (**Table 37-6**). Nitrous oxide can be used alone for minimal sedation or as an adjunct with IV medications for moderate sedation (**Table 37-6**).[45,46] Technical aspects of nitrous oxide administration include the use of a demand delivery system triggered by the patient's inspiratory force and a disposal or scavenger system to prevent accumulation of nitrous oxide in the room. Nitrous oxide has a rapid onset (1 to 2 minutes) and a rapid recovery (3 to 5 minutes) when inhalation of the gas is discontinued.

Nitrous oxide has few adverse side effects.[47] Nitrous oxide is a mild cardiac depressant and pulmonary vasoconstrictor so it is relatively contraindicated in patients with pulmonary hypertension. Nitrous oxide is an inhibitor of folate metabolism and is therefore contraindicated in pregnant women. Nitrous oxide may promote expansion of internal gas-filled structures and should be avoided in patients with pneumothorax, pneumocephalus, and vascular air embolism.

MIDAZOLAM

Midazolam is a short-acting benzodiazepine commonly used as a sole agent for minimal sedation.[48] After IV administration, peak effect is seen within 2 to 3 minutes, and duration of retrograde amnesia is 20 to 30 minutes (**Table 37-6**). Midazolam can be combined with an opioid for moderate or deep procedural sedation, but when given with an opioid, there is an increased risk of respiratory depression.

Midazolam causes mild cardiovascular depression, and hypotension can result when this agent is given to hypovolemic patients. Paradoxical agitation has been reported with the use of midazolam in 1% to 15% of patients, and flumazenil can be given for reversal.[48]

Midazolam can be administered IV, PO, IM, PR, or intranasally. The IV route has the most predictable onset and duration of action. The PO route can result in unreliable levels of sedation as a result of first-pass hepatic metabolism. Because the agent has a low pH and benzyl alcohol is added as a preservative, intranasal midazolam irritates the nasal mucosa, which can be painful and provoke anxiety. Buffering the solution does not decrease the irritation. Both the PR and IM routes have unreliable onset and depth of sedation, but can be easier to administer in some patients.

FENTANYL AND ALFENTANIL

Fentanyl is a potent, relatively short-acting opioid. A single IV dose has rapid onset of <1 minute, peak effect in 2 to 3 minutes, and duration of 30 to 60 minutes. It is easily titratable when used alone for minimal sedation and can be used in combination with midazolam for moderate and deep procedural sedation and analgesia.

Rigid chest syndrome, a rare complication characterized by spasm of the respiratory muscles leading to respiratory depression or apnea, is seen when high doses (>5 micrograms/kg) of fentanyl are given by rapid IV bolus. In small children, this syndrome may be precipitated by rapidly flushing the IV line. Rigid chest syndrome is not reversible with opioid receptor antagonists. Intubation with rapid-sequence induction and pharmacologic paralysis is usually required to ventilate the patient in this situation. **Slow administration of fentanyl (1 to 3 micrograms/kg over 5 minutes) followed by slow and careful flushing of the IV line can prevent rigid chest syndrome.**

Alfentanil is an effective agent but is associated with a 30% to 40% rate of airway and respiratory adverse effects,[49,50] a rate typically higher than that seen with fentanyl or propofol alone.

METHOHEXITAL

Methohexital is an ultra-short-acting barbiturate that produces sedation within 1 minute of IV administration and has an effective duration of

TABLE 37-6 Sedation Agents for Adult Procedural Sedation and Analgesia

Medication	Recommended Dosage	Route of Administration	Peak Effect	Approximate Duration	Use
Nitrous oxide	50:50 mixture with oxygen	Inhalational	1–2 min	3–5 min	Minimal sedation
Midazolam	0.05–0.1 milligram/kg. May repeat 0.05 milligram/kg every 2 min until adequately sedated	IV	2–3 min	20–30 min	Minimal or moderate sedation
	0.1 milligram/kg	IM	15–30 min	1–2 h	Minimal sedation
Fentanyl	1–3 micrograms/kg, can be titrated up to 5 micrograms/kg	IV	2–3 min	30–60 min	Minimal sedation
Fentanyl and midazolam	1–2 micrograms/kg fentanyl plus 0.1 milligram/kg midazolam	IV	2–3 min	1 h	Moderate and deep sedation
Methohexital	1 milligram/kg	IV	1 min	3–5 min	Moderate or deep sedation
Pentobarbital	2.5 milligrams/kg followed by 1.25 milligram/kg, as needed, up to two times	IV rate should be <50 milligrams/min	3–5 min	15 min	Minimal and moderate sedation. Frequently used for radiologic procedures.
Ketamine	1 milligram/kg	IV	1–3 min	15–30 min	Dissociative sedation
	2–5 milligrams/kg	IM	5–20 min	30–60 min	Dissociative sedation
Ketamine and midazolam	Ketamine as above plus midazolam, 0.03 to 0.05 milligram/kg	IV	1–3 min	30–60 min	Dissociative sedation
Etomidate	0.15 milligram/kg, followed by 0.1 milligram/kg every 2 min, if needed	IV	15–30 s	3–8 min	Moderate and deep sedation
Propofol	0.5–1.0 milligram/kg, followed by 0.5 milligram/kg every 3 min, if needed	IV	30–60 s	5–6 min	Moderate and deep sedation
Ketamine and propofol "ketofol"	Ketamine 0.125–0.5 milligram/kg and Propofol 0.5 milligram/kg	IV	30–60 s	15 min	Moderate and deep sedation

3 to 5 minutes. Methohexital is best used for brief moderate and deep sedation, such as that needed for joint dislocation reduction. The major adverse effect of methohexital is respiratory depression; the risk increases if additional boluses are given after the initial dose.[12]

PENTOBARBITAL

Pentobarbital is a short-acting barbiturate that is useful when the procedure itself is painless, but the associated circumstances may cause anxiety (e.g., radiologic procedures). Pentobarbital produces sedation within 3 to 5 minutes of IV administration and lasts approximately 15 minutes, and complete recovery occurs in 30 to 40 minutes.

KETAMINE

Ketamine produces a state of dissociation characterized by profound analgesia, sedation, and amnesia. Unlike other agents used for procedural sedation, ketamine possesses both analgesic and anxiolytic properties.[13] Ketamine is an effective agent for ED procedural sedation[13,51-55] and for prehospital analgesia and sedation when used by physicians.[55]

Ketamine does not have a typical dose-response continuum with progressive titration. At doses lower than a threshold, analgesia and sedation occur. Once a critical dosing threshold is exceeded (about 1.0 to 1.5 milligrams/kg IV or 3 to 4 milligrams/kg IM), the characteristic dissociative state abruptly appears. This dissociation has no observable levels of depth. The only value of additional ketamine is to prolong the dissociative state for extended procedures.

Ketamine can be given either IV or IM. The IM route allows for approximately 40 minutes of sedation, compared with 10 minutes by the IV route. **Ketamine is the only sedative agent that typically preserves a patient's ventilatory effort and has minimal effect on blood pressure.** Ketamine can induce hypersalivation. Anticholinergics, such as atropine 10 micrograms/kg IV or glycopyrrolate 4 micrograms/kg IV, are often administered to counter this effect. However, studies evaluating this practice of coadministering anticholinergics fail to demonstrate tangible benefit or harm. Thus anticholinergics can be reserved for the treatment of clinically significant hypersalivation or for patients with an impaired ability to mobilize secretions.[13] Other adverse effects also include laryngospasm, vomiting (most often in the late recovery phase), and emergence reactions. Laryngospasm has been reported primarily in children, with reported rates of occurrence of <1.0% to 2.5%. It is typically transient and responds to positive pressure ventilation with a bag-valve mask. Children with significant upper respiratory tract infectious symptoms and patients who will undergo major stimulation of the oropharynx (e.g., endoscopy) should not receive ketamine due to a possible increased risk of laryngospasm.[13]

Emergence reactions are common with ketamine and range from mild agitation to recurrent nightmares and hallucinations.[53,54] Midazolam can be given along with ketamine to blunt the occurrence of emergence reactions.[56,57] However, the overall clinical benefit of such prophylaxis has not been demonstrated.[13] It is sufficient to give ketamine without midazolam and then treat patients who develop emergence reactions with midazolam as they occur. Because of these emergence reactions, ketamine should not be used in patients with schizophrenia and psychosis.[13]

It is commonly stated that ketamine increases intracranial pressure, which potentially limits its use in many emergent situations.[58] The experimental data from animal studies and human observations are conflicting, depending on the specific circumstances.[58,59] Thus there is no clear evidence that ketamine is harmful as an induction or sedation agent in patients with potential head injury. Ketamine does increase intraocular pressure and should be avoided in patients with eye injuries or glaucoma.[60]

ETOMIDATE

Etomidate is a nonbarbiturate sedative-hypnotic with a rapid onset (15 to 30 seconds) and a short duration of effect (3 to 8 minutes). Compared with the other sedative agents, etomidate causes less cardiovascular depression but a similar degree of respiratory depression. Etomidate is an effective agent for ED procedural sedation, with a reported complication rate of 10% to 15%, most complications being minor.[61-64]

Myoclonic jerking occurs in up to 20% of patients and can interfere with the procedure for which the patient was sedated.[64] Etomidate causes suppression of the adrenal-cortical axis, and when used for rapid sequence induction in critically ill patients, it is associated with adrenal insufficiency and increased mortality.[65-68] However, no clinically significant adverse event related to adrenal suppression has been detected from etomidate used during ED procedural sedation in stable patients.

PROPOFOL

Propofol is frequently used for moderate and deep procedural sedation in the ED.[18,69-77] Propofol is associated with fewer complications than etomidate or methohexital in patients who received multiple doses and is much easier to titrate.[12,64] Because of the short duration of action, propofol results in a shorter recovery time and ED length of stay.[76-79]

The most serious adverse effect of propofol is sudden respiratory depression and apnea,[24,41] so ventilatory support equipment should be at the bedside when using propofol. Propofol can produce hypotension as a result of both negative inotropy and vasodilatation. Hypotension is more common in hypovolemic patients and those with American Society of Anesthesiologists physical status scores of III or IV.[70] **Hypovolemia should be corrected before propofol administration.**

Sedation from propofol occurs within 30 to 60 seconds after injection and lasts for about 5 to 6 minutes. Propofol is rapidly distributed into tissues, and once tissues are saturated, subsequent doses will have a greater effect than the initial bolus. The recommended dose for ED procedural sedation in healthy nonelderly adults is 0.5 to 1.0 milligram/kg IV, followed by 0.5 milligram/kg IV every 3 minutes if needed. Higher doses are associated with more respiratory depression.

Propofol is formulated in a soybean oil, glycerol, and egg lecithin emulsion and is contraindicated in patients who are allergic to eggs or soy protein. Propofol causes local pain at the IV site during administration. Methods to reduce the pain of propofol administration include placing a tourniquet proximal to the IV and injecting 0.05 milligram/kg of lidocaine through the IV approximately 60 seconds before injecting the propofol, mixing the propofol with lidocaine, or coadministering the short-acting opioid alfentanil at 10 micrograms/kg.[80,81]

KETAMINE AND PROPOFOL

The combination of ketamine and propofol for ED procedural sedation has a well-documented safety and efficacy profile.[82,83-92] Propofol is an excellent sedative, but respiratory depression and hypotension are its principal adverse events. The sympathomimetic properties of ketamine may mitigate these, in addition to adding analgesia. Ketamine causes emergence reactions and vomiting as adverse events, whereas propofol has antiemetic and hypnotic properties. This combination is safe and effective for ED procedural sedation and analgesia.[83-92] Published "ketofol" ED procedural sedation studies have used a variety of combinations, from equal mixtures of propofol and ketamine to normal doses of propofol with sub-dissociative doses of ketamine for its analgesic properties. Adding ketamine to propofol promotes hemodynamic stability, which is reassuring in patients with known or potentially reduced cardiac function.[88] There is also evidence of synergism between the two drugs, and data indicate that ketofol provides less erratic sedation depth than propofol alone.[87] The analgesic properties of ketamine preclude the need for and risks of opioids administered with propofol.[84,88] When the total dose of ketamine administered during ketofol use is less than the reliable dissociative dose (<1.5 milligram/kg), clinical observation suggests that recovery time is longer than that for full doses of propofol (1.6 to 1.8 milligrams/kg) alone[82,86] but shorter than that of full dissociative doses of ketamine (1.0 to 1.5 milligrams/kg) alone.[82] However, despite the theoretical benefit for decreasing complications, studies to date have failed to demonstrate a consistent difference in complications between ketofol (mixtures of ketamine and propofol from 1:1 to 1:4) compared with propofol alone.[89,90] The advantage of ketofol is that it may be able to achieve adequate sedation with lower total doses compared with when either drug alone is used, and ketofol prolongs the

duration of sedation more than propofol alone, which is useful for procedures anticipated to take more time, and without the need for additional doses of propofol.

OUTCOME ASSESSMENT/COMPLICATIONS

Reported complication rates for ED procedural sedation range from 2.3% to 11%.[28,69,93-95] Most of these are minor. Factors associated with an increased rate of complications include age >65 years,[93,94] level of sedation,[94,95] premedication with fentanyl,[94] use of short-acting agents,[94] and procedural sedation and analgesia performed at night, when procedural sedation and analgesia could be administered by physicians with varying levels of training and experience and when consultant-level supervision is not always physically present.[95] Serious adverse events include the need for assisted ventilation, endotracheal intubation, or treatment of hypotension or cardiac dysrhythmias. Minor adverse events resolve spontaneously and include sedation to a deeper level than intended, transient hypoxia, or emesis. Complications can occur unexpectedly, so careful preparation, appropriate procedural monitoring, and careful selection of the target sedation level will minimize the rate of occurrence and severity of adverse events.

Failure to successfully complete a procedure during ED procedural sedation occurs in about 5% and is more common with some joint reductions (hips, mandibles) and with patient body weight >100 kg.[96]

FOLLOW-UP AND PATIENT INSTRUCTIONS

At the completion of sedation and the procedure, patients should be monitored until they return to baseline mental status and cardiopulmonary function. A structured assessment, such as the Aldrete Score©,[97] can be used to assess the patient's recovery and safety for discharge. Such assessment tools are typically part of procedural sedation documentation forms.

The duration of observation before discharge is variable. It depends on the quantity of sedatives given, the patient's response, the duration of the procedure, and the occurrence of any adverse events. Generally, patients who have returned to a baseline level of consciousness are unlikely to have further negative changes in level of consciousness. Most adverse events occur during procedural sedation itself, typically within a few minutes of sedative administration. The occurrence of adverse events >5 minutes after completion of the procedure is rare (<1%).[98] The occurrence of adverse events after discharge of an ED patient who has undergone procedural sedation has not been reported. Patients should be instructed to return if they develop respiratory complaints or nausea or vomiting. The follow-up interval required for patients who undergo ED procedural sedation is usually related to the procedure rather than the sedation itself.

SPECIAL CIRCUMSTANCES

PROCEDURAL SEDATION AND ANALGESIA IN CRITICALLY ILL PATIENTS

Etomidate might arguably be the drug of choice for hypotensive patients who require sedation for an emergency procedure because it produces less cardiovascular suppression than other agents.[17] However, etomidate suppresses the adrenal-cortical axis, and when used for rapid-sequence induction in critically ill patients, it is associated with adrenal insufficiency and increased mortality.[65-68] Thus other sedation agents should be used in critically ill patients. Patients undergoing extended complex procedures are likely to require sedation longer than can be achieved with a single bolus of methohexital or propofol, or etomidate, and are at a higher risk of complications.[12,17,64] Critically ill patients who require prolonged sedation should be referred for general anesthesia in the operating room.

PROCEDURAL SEDATION AND ANALGESIA IN THE ELDERLY

Procedural sedation in the elderly is associated with increased technical and pharmacologic adverse events.[93,94] Ventilatory drive and the ability to maintain a patent airway are reduced. Remove false teeth or partial dentures before sedation to prevent aspiration of the devices. Risk of pulmonary aspiration increases as a result of reduced gag reflex and gastroesophageal sphincter incompetence. Underlying comorbidities or hepatic or renal insufficiency affect the response to sedatives. The risk of respiratory depression from all agents is increased. All these factors indicate a need for more planning, monitoring, and slow titration of sedative agents in the elderly. With such preparation, procedural sedation of the elderly is safe.[93]

Etomidate is a good sedative agent in the elderly because of its minimal cardiovascular effects.[63] For painful procedures, opioids may be necessary, as etomidate has no analgesic effect. In elderly patients with underlying clonus, etomidate should be avoided, as it can exacerbate that symptom.

Propofol produces greater peak plasma concentrations after a specific IV bolus dose in the elderly, therefore producing a greater risk of respiratory depression and apnea. **To counteract this, the initial and subsequent doses should be 50% (0.25 to 0.5 milligrams/kg) of those recommended for younger adults, and more cautious titration is needed.** Lower dosing of the sedative with increased age and American Society of Anesthesiologists score may lead to similar complication rates as those for younger patients.[93]

The elderly, especially those with underlying cerebral disease or dementia, are more sensitive to the neurologic side effects of benzodiazepines and barbiturates. These agents should be used with caution, particularly if opioid analgesics are also given.

PROCEDURAL SEDATION AND ANALGESIA FOR EMERGENCY ENDOSCOPY

Procedural sedation is a standard part of outpatient endoscopy. If an ED patient requires emergency endoscopy, the emergency physician may be asked to perform procedural sedation. Ideally, a protocol during emergency endoscopy should be jointly developed by emergency medicine and gastroenterology. Sedation during endoscopy presents some unique challenges related to the medications used and the performance of the procedure itself.[99-101]

Endoscopy increases the risk for vasovagal reactions, with bradycardia and hypotension. These reactions can occur with upper gastrointestinal endoscopy during passage of the endoscope through the pharynx or gaseous distention of the small bowel, or with colonoscopy during gaseous distention of the colon. Most reactions are transient, and treatment with atropine should be reserved for rare cases of persistent bradycardia.

Passage of the endoscope through the pharynx into the stomach can exacerbate the risks for hypoxia, apnea, and aspiration. The endoscope can interfere with ventilation and can induce vomiting. Topical agents (benzocaine, lidocaine) are used for pharyngeal anesthesia. The occurrence of methemoglobinemia after benzocaine topical spray can interfere with pulse oximetry monitoring.

Antiemetic agents used during the procedure, such as promethazine or droperidol, can cause complications during the performance of procedural sedation. Promethazine exerts an α-adrenergic blocking effect and may produce hypotension. In addition, the sedative effect of promethazine may last >2 hours, so a prolonged recovery should be anticipated. Droperidol, which is occasionally used, increases the risk of transient hypotension and may also prolong the recovery phase (up to 3 to 6 hours). Ondansetron is an antiemetic without these potential effects and is a reasonable alternative.

CHAPTER 38

Chronic Pain

David M. Cline

CHRONIC PAIN

INTRODUCTION

Chronic pain is a painful condition that lasts >3 months, pain that persists beyond the reasonable time for an injury to heal, or pain that persists 1 month beyond the usual course of an acute disease. Chronic pain lacks the essential function of acute pain. Whereas acute pain is a vital biologic signal to stop the individual from a potentially injurious activity or to pursue medical care, chronic pain serves no obvious biologic function. Complete pain relief is unrealistic in cases of chronic pain. Rather, the goal of therapy is pain reduction and return to functional status. Chronic pain syndromes discussed in this chapter are divided into neuropathic and nonneuropathic conditions. Aberrant drug-related behavior, also called drug-seeking behavior, is discussed.

Chronic pain is a common problem affecting 30.7% of the U.S. population and is more prevalent in women (34.3%) than in men (26.7%).[1] Back pain is the most common site for chronic pain, followed by the knee and neck.[1] The prevalence of neuropathic pain is 6.9% to 10% of the population.[2] Risk factors for chronic pain include increasing age, female gender, higher body mass, and chronic illness.[3] An exacerbation of chronic pain is part of the presentation of 11% to 15% of ED visits.[4] Compared to patients with acute pain, chronic pain patients are more likely to report their pain as severe and more likely to be frequent visitors to the ED.[5]

PATHOPHYSIOLOGY

The pathophysiology of chronic pain is incompletely understood. Many chronic pain syndromes follow nerve or tissue injury, producing nerve dysfunction secondary to the mechanical injury or in response to chemical mediators released from adjacent cell injury. Peripheral nerves, the CNS, or both become abnormally sensitive and develop pathologic spontaneous activity through upregulation of sodium channels and receptors.[6] Neuroplastic changes in the central descending pain modulatory systems, inhibitory or facilitatory, may lead to further hyperexcitability. These changes lead to **hyperalgesia** (exaggerated response to a normally painful stimulus) and **allodynia** (pain from a normally nonpainful stimulus). In several disorders, a history of injury may be lacking, such as for fibromyalgia, where central sensitization is thought to play a key role.[7] Psychological factors frequently precede or follow the onset of chronic pain and frequently predispose individuals to physiologic changes, through the fear-avoidance model. The fear of pain may lead to disuse disability, which leads to nerve hyperexcitability and dysfunction, and ultimately, may result in a chronic pain syndrome.[8]

CLINICAL FEATURES

The nonneuropathic syndromes share certain characteristics, the most common feature being muscle-related pain (**Table 38-1**). A feature common to most neuropathic syndromes is allodynia (**Table 38-2**).

Clinical assessment should be appropriate to the circumstances, and can be focused or comprehensive. A comprehensive evaluation starts with assessing the quality and character of the patient's current pain, including initiating, exacerbating, or relieving factors. Compare and quantify prior episodes to the current episode. Determine sources, modes, and success or failure of prior treatment, including medications and dosages for physician-prescribed, over-the-counter, or alternative medications. Determine the patient's functional status across the course of the illness and treatment. Treatments that have provided pain relief yet have led to disability cannot be considered a success. Assess any history of alcohol or drug addiction, need for prior detoxification, or psychiatric illness that may impact decisions about choice of medication. A review of systems should assess for potential life- or limb-threatening conditions.

Objective findings of acute pain include tachycardia, hypertension, diaphoresis, and muscle spasms on stimulation. Objective evidence of chronic pain includes muscle atrophy in the distribution of pain due to disuse and skin temperature changes due to the effects of the sympathetic nervous system after disuse or secondary to nerve injury. Trigger points, another objective sign, are focal points of muscle tenderness and tension that, when stimulated with pressure, provoke referred pain, typically in the distribution of the involved muscle. Trigger points are differentiated from simple focal tender portions of the muscle, as trigger points provoke referred pain throughout the affected muscle. Trigger points lack a biologic basis and interexaminer agreement, yet they remain an essential feature of the diagnosis of myofascial pain syndromes.[9] Objective evidence of pain is not observed for the pain to be factual. For ED patients, there is no observed correlation between numeric pain scores and vital signs.[10]

CLINICAL FEATURES OF SELECTED CHRONIC PAIN SYNDROMES

Further discussion including treatment of chronic back pain, neck pain, and sciatica is found in chapter 279, Neck and Back Pain. Migraine headaches and tension headaches are discussed in chapter 165, Headache.

Transformed migraine is a syndrome in which classic or common migraine headaches change over time and develop into a chronic pain syndrome, most commonly from medication overuse.[11] Chronic migraine (15 or more migraine days a month) is a precursor to transformed migraine. Medications implicated in this transition are barbiturates taken 5 or more days per month, opioids taken 8 or more days per

TABLE 38-1 Symptoms and Signs of Nonneuropathic Pain Syndromes

Disorder	Pain Symptoms	Signs
Myofascial headache	Constant dull pain, occasionally shooting pain	Trigger points on scalp, muscle tenderness and tension
Chronic tension headache	Constant dull pain	Diffuse tenderness of the scalp and associated tension
Transformed migraine	Initially migraine-like, becomes constant, dull; nausea, vomiting	Muscle tenderness and tension, normal neurologic exam
Myofascial neck pain	Constant dull pain, occasionally shooting pain; pain does not typically follow nerve distribution	Trigger points in area of pain, usually no muscle atrophy, poor ROM in involved muscle
Chronic neck pain	Constant dull pain, occasionally shooting pain; pain does not follow nerve distribution	No trigger points, poor ROM in involved muscle due to pain
Chronic back pain	Constant dull pain, occasionally shooting pain; pain does not follow nerve distribution	No trigger points, poor ROM in involved muscle due to pain
Myofascial back pain syndrome	Constant dull pain, occasionally shooting pain; pain does not typically follow nerve distribution	Trigger points in area of pain, usually no muscle atrophy, poor ROM in involved muscle

Abbreviation: ROM = range of motion.

TABLE 38-2 Symptoms and Signs of Neuropathic Pain Syndromes

Disorder	Pain Symptoms	Signs
Painful diabetic neuropathy	Symmetric numbness and burning or stabbing pain in lower extremities; allodynia may occur	Sensory loss in lower extremities
Phantom limb pain	Variable: aching, cramping, burning, squeezing, or tearing sensation	May have peri-incisional sensory loss
Trigeminal neuralgia	Paroxysmal, short bursts of sharp, electric-like pain in nerve distribution	Tearing or red eye may be present
HIV-associated sensory neuropathy	Symmetric pain and paresthesias, most prominent in toes and feet	Sensory loss in areas of greatest pain symptoms
Postherpetic neuralgia	Allodynia; shooting, lancinating pain	Sensory changes in the involved dermatome
Fibromyalgia	Widespread muscular pain and stiffness, fatigue, sleep disturbance, and cognitive dysfunction (forgetfulness, inability to concentrate or recall simple words or numbers, confusion)	Muscle tenderness in >6 body areas out of 19 total regions
Poststroke pain	Same side as weakness; throbbing, shooting pain; allodynia	Loss of hot and cold differentiation
Sciatica (neurogenic back pain)	Constant or intermittent, burning or aching, shooting or electric shock–like pain; may follow dermatome; leg pain > back pain	Possible muscle atrophy in area of pain, possible reflex changes
Complex regional pain type I	Burning persistent pain, allodynia, associated with immobilization or disuse, not associated with nerve injury	Early: edema, warmth, local sweating Late: above alternates with cold, pale, cyanosis, eventually atrophic changes
Complex regional pain type II	Burning persistent pain, allodynia, associated with peripheral nerve injury, associated with nerve injury, usually more painful and difficult to control than Type I	Early: edema, warmth, local sweating Late: above alternates with cold, pale, cyanosis, eventually atrophic changes

Abbreviation: HIV = human immunodeficiency syndrome.

month, and triptans or nonsteroidal anti-inflammatory drugs (NSAIDs) taken 10 or more days per month.[11] Patients with chronic migraine may have more symptoms similar to tension headache with tenderness and tension of scalp musculature. Nausea and vomiting or failure of an oral antimigraine medication often prompts an ED visit. In addition to increased headache frequency, headache duration is longer in chronic migraine.

Fibromyalgia is widespread muscular pain involving greater than six body areas out of 19 total regions and a symptom severity score of 5 or more, rating four areas: fatigue, sleep disturbance, and cognitive dysfunction (e.g., forgetfulness, inability to concentrate or recall simple words or numbers, confusion and associated non-muscle pain symptoms).[12,13] Prevalence is thought to be 5.4% of the population.[14]

The symptoms of **painful diabetic neuropathy** are symmetric numbness associated with burning, electrical, or stabbing pain in lower extremities. Patients may have hyperesthesia, dysesthesias, and/or deep aching pain. Pain may be provoked with a gentle touch to the skin in the areas of abnormal sensation.

Postherpetic neuralgia may follow the course of an acute episode of herpes zoster in 5% to 30% of cases; pain lasts more than 1 year for 30% of patients.[15] Pain is characterized by allodynia and shooting, lancinating (tearing or sharply cutting) pain. Often, patients have hyperesthesia in the involved dermatome. Occasionally there are pigmentation changes in the distribution of the involved dermatome, but this is not unique to postherpetic neuralgia.

Typical symptoms of **trigeminal neuralgia** include paroxysmal, short bursts of sharp, electric shock–like pain in the nerve distribution of the trigeminal nerve. Pain is often triggered by chewing, speaking, washing, brushing teeth, or something touching the face. Tearing of the eyes or red eye may be present.

Phantom limb pain is quite variable in presentation but is more frequent in patients who had pain in the extremity before amputation. Pain may be aching, cramping, burning, tearing, or squeezing. Phantom limb pain occurs in 30% to 81% of amputations and changes over years, becoming less "knife-like" and more "burning" in character.[16]

There are two types of **complex regional pain syndrome**: type I, from prolonged immobilization or disuse, as after stroke; and type II, from a peripheral nerve injury (e.g., due to fracture or gunshot). Symptoms include allodynia and a persistent burning or shooting pain on the affected side or limb. Associated signs early in the course of the disease include edema, warmth, and localized abnormal sweating. It may be difficult to distinguish this stage from an underlying wound infection or osteomyelitis. Later signs include periods of edema and warmth that alternate with cold, pale, cyanotic skin, and, eventually, atrophic changes.

Patients with **acquired immunodeficiency syndrome** can develop distal sensory polyneuropathy characterized by shooting pain, numbness, and burning sensations primarily on the soles, dorsum of the feet, and toes. This human immunodeficiency virus–associated sensory neuropathy is associated with antiretroviral therapy, but not with low CD4 counts.[17] Sensory loss is common in the areas of greatest pain symptoms. As the neuropathy progresses, walking becomes difficult, and quality of life is diminished.

DIAGNOSIS

The most important task is to distinguish an exacerbation of chronic pain from a life- or limb-threatening condition. The history and physical examination should either confirm the chronic condition or point to the need for further evaluation when unexpected signs or symptoms are elicited. Because patients with chronic pain may be frequent visitors to the ED, the entire staff may prejudge complaints as simply chronic or even factitious. Follow routine procedures, including a standard triage assessment and a complete set of vital signs.

After eliminating potential conditions that require emergent treatment, clinical judgment determines if focused management of pain is an appropriate course of action in the ED. The principles of focused management are to identify that symptoms are an exacerbation or continuation of a chronic pain pattern, provide appropriate rescue therapy for pain relief, and reinforce the need for a single provider (physician or clinic) for ongoing pain management.

Rarely is a provisional diagnosis of a chronic pain condition made for the first time in the ED. Definitive assessment for chronic pain conditions is difficult and requires expert opinion and often advanced procedures such as MRI, CT, and thermography. Furthermore, abnormal results do not confirm with certainty the cause of pain. For example, abnormalities on MRI of the spine and extremities are common in both asymptomatic and symptomatic patients. Therefore, referral back to the primary source of care is warranted to confirm the diagnosis.

TREATMENT

OPIOIDS FOR CHRONIC PAIN

In 1986, Portenoy and Foley[18] reported a case series of 38 patients treated with long-acting opioids for chronic, noncancer pain claiming that this therapy was safe and effective and that the risk of addiction was less than 1%, citing unrelated data. Without randomized controlled trials to support their assertions, the use of opioids to treat chronic, noncancer pain rapidly gained popularity with physicians who were twice as likely to prescribe an opioid for chronic pain in 2000, compared to 1980, and with prescriptions for strong opioids (oxycodone compared to codeine) quadrupled.[19] From 2001 to 2010, the percentage of patients receiving an opioid prescription at ED discharge increased from 20.8% to 31.0%, while the percentage of visits for painful conditions increased only 4.0%.[20] ED visits for nonmedical use of opioids (adverse events including nonfatal overdose) increased 111% from 2004 to 2008.[21] The age-adjusted rate for opioid-analgesic poisoning deaths nearly quadrupled from 1.4 per 100,000 in 1999 to 5.4 per 100,000 in 2011;[22] poisoning is now the most common cause of injury-related death in the United States, surpassing motor vehicle–related death.

In response to the dramatic increase in opioid-analgesic poisoning, state agencies created statewide prescription drug monitoring programs accessible by the Internet for registered medical providers to view controlled substance prescriptions that a patient has received.[23] As of June 2014, 48 states had operational prescription drug monitoring programs.[24] Many state medical boards have issued guidelines for the prescription of controlled substances by physicians licensed in that state with specific recommendations for emergency care providers, including Arizona, Arkansas, California, New York, North Carolina, Ohio, Oklahoma, and Washington State;[25] additional state guidelines are pending. The American College of Emergency Physicians issued a policy on the prescription of opioids for patients discharged from the ED.[26] **Table 38-3** summarizes key guideline statements from the American College of Emergency Physicians policy[26] and Washington State guidelines.[25]

TABLE 38-3 Guidelines for Prescribing Opioids for Adults in the ED

*For the treatment of back pain, given a lack of demonstrated evidence of superior efficacy of either opioid or nonopioid analgesics, and the individual and community risks associated with opioid use, misuse, and abuse, opioids should be reserved for more severe pain or pain refractory to other analgesics rather than routinely prescribed.
*If opioids are indicated, the prescription should be for the lowest practical dose for a limited duration (e.g., <1 week), and the prescriber should consider the patient's risk for opioid misuse, abuse, or diversion.
*Avoid the routine prescribing of outpatient opioids for a patient with an acute exacerbation of chronic noncancer pain seen in the ED.
*Honor existing patient-physician pain contracts/treatment agreements.
*Consider past prescription patterns from information sources such as prescription drug monitoring programs.
†The administration of intravenous and intramuscular opioids in the ED for the relief of acute exacerbations of chronic pain is discouraged.
†Do not provide replacement prescriptions for controlled substances that were lost, destroyed, or stolen.
†Long-acting or controlled-release opioids (such as OxyContin®, fentanyl patches, and methadone) should not be prescribed from the ED.
†Prescriptions for controlled substances from the ED should state that the patient is required to provide a government-issued picture identification (ID) to the pharmacy filling the prescription.
†Do not provide replacement doses of methadone for patients in a methadone treatment program.
†If opioids are prescribed to a patient with chronic pain, prescribe only enough pills to last until the office of the patient's primary opioid prescriber opens.

†Washington State Opioid Prescribing Guidelines

TREATMENT OF CHRONIC NONNEUROPATHIC PAIN SYNDROMES

Evidence-based treatment for chronic nonneuropathic pain syndromes is divided into primary and secondary treatment modalities (**Table 38-4**).[27-33] For management in the ED, an acute exacerbation of a chronic migraine can be treated like an exacerbation of episodic migraine.[27] When selecting a standard NSAID, adding a proton pump inhibitor reduces GI complications, and the combination is less expensive than daily use of the cyclooxygenase-2 inhibitors.[34]

Treatment in the ED should never be regarded as definitive, and follow-up care is essential. Many emergency providers will elect to prescribe short-acting nonspecific pain medications (**Table 38-3**) for patients with chronic pain, deferring initiating of more specific therapy for the primary care physician or pain specialist. Specialty referral may provide optimization of therapy, trigger point injections, and novel treatments, such as onabotulinumtoxinA injections.

TREATMENT OF CHRONIC NEUROPATHIC PAIN SYNDROMES

Evidence-based treatment for chronic neuropathic pain syndromes is divided into primary and secondary treatment modalities (**Table 38-5**).[35-44]

There is no convincing unbiased evidence to support the use of opioids (specifically oxycodone) in the treatment of neuropathic pain including fibromyalgia.[45] Duloxetine is favored over pregabalin and gabapentin in the treatment of painful diabetic neuropathy.[40] Human immunodeficiency syndrome–related neuropathy is resistant to many therapies commonly used for neuropathic pain; although topical capsaicin is effective,[38] it is best directed by a specialist because pain increases at first application and pretreatment with topical lidocaine may be required.

Tramadol reduces pain in most neuropathic pain syndromes but is considered secondary treatment because it is less effective than the primary treatments (**Table 38-5**).[40,46] Complex regional pain syndrome is the most resistant to pharmacotherapy of all neuropathic pain conditions.[44] An IV infusion of ketamine may reduce pain for up to 12 weeks,[44] but does not improve function. Corticosteroids (prednisone, 60 milligrams PO once a day) have been recommended at the time of first diagnosis when signs of inflammation are present,[44] but steroids do not affect the course of illness. Patients should be informed that NSAIDs and strong opioids are generally ineffective in neuropathic pain. Although considered second line, cyclic antidepressants are effective therapy for most patients with neuropathic pain, except spinal cord injury pain, phantom limb pain, human immunodeficiency syndrome–related neuropathy, and chronic regional pain syndrome. Amitriptyline can be started at 25 milligrams PO nightly, and escalated by the follow-up clinician. Complete relief of pain is an unrealistic goal for patients with chronic pain, both for the ED visit and for follow-up care; patients should be informed of this limitation early in their ED course.

DISPOSITION AND FOLLOW-UP

Referral to an appropriate specialist is one of the most productive means of aiding in the care of chronic pain patients who present to the ED. Chronic pain clinics have been successful in changing the lives of patients by eliminating opioid use, decreasing medication use, reducing pain levels, and increasing work hours. Patients' compliance with pain clinics may improve if these benefits are explained. Admission to the hospital is rarely indicated. However, occasionally patients may be admitted for pain control, possibly using self-controlled analgesic administration.

SPECIAL POPULATIONS

ELDERLY PATIENTS

The prevalence of chronic pain increases with age.[1] Opioid analgesic alternatives, such as NSAIDs, have side effects that may limit their use in the elderly who are prone to GI and renal complications; however, when compared to opioids, NSAIDs have fewer side effects overall and are less likely to lead to premature death in the elderly.[47] GI bleeding rates are similar for patients treated with opiates or nonselective NSAIDs and lower

TABLE 38-4 Management of Nonneuropathic Chronic Pain Syndromes

Disorder	Primary Treatment	Secondary Treatment	Possible Referral Outcome
Myofascial pain syndromes	Nonsteroidal anti-inflammatory drugs orally, topical diclofenac patch for single site of pain	Amitriptyline	Trigger point injections or dry needling, US treatments, optimization of medical therapy, recommendations for exercise
Chronic migraine headache	See chapter 165 for treatment of acute exacerbations	Prophylaxis with sodium valproate or topiramate	Optimization of medical therapy, evaluation for use of prophylactic onabotulinumtoxinA
Transformed migraine/medication overuse headache	Stop prior medications	Celecoxib or prednisone taper during withdrawal period	Optimization of medical therapy, withdrawal of prior medications, evaluation for use of prophylactic onabotulinumtoxinA

Note: Medication dosing for above indications: **amitriptyline**, 25 milligrams at bedtime; **celecoxib**, 400 milligrams/d for the first 5 days, then decreased at a rate of 100 mg every 5 days; **diclofenac**, 1.3% patch every 12 hours over single site of focal pain; **prednisone**, 60 milligrams/d orally for the first 5 days, then taper down dose by 20 milligrams every 5 days; **sodium valproate**, 250 milligrams two times daily; **topiramate**, 25 milligrams at bedtime in first week, 25 milligrams two times daily in second week, and further dose adjustments at follow-up.

for those treated with cyclooxygenase-2 inhibitors.[47] NSAIDs should not be given to patients with renal dysfunction. Topical analgesics (lidocaine 5%, capsaicin 8%) are effective[48] and can be given alone or as adjuncts. Topical NSAIDs provide excellent joint and tissue levels with low plasma levels and are available as diclofenac gel, patch, or topical solution.[48]

Cognitively and mentally impaired adults with chronic pain are at risk for inadequate pain control due to barriers in communicating the nature and intensity of their pain. Be alert to these potential barriers and look for nonverbal signs of pain: agitation, irregular breathing, facial expressions of pain, stiffened body positioning, and reports of irregular sleep patterns. The ability to monitor undesired side effects, such as sedation, may limit the use of certain pain medications in this population.

ABERRANT DRUG-RELATED BEHAVIOR

INTRODUCTION AND EPIDEMIOLOGY

The term *drug-seeking behavior* is imperfect, and its definition varies among clinicians. A more accurate term is *aberrant drug-related behavior*, which raises concern for addiction and opioid misuse (**Table 38-6**). The spectrum of people seeking controlled drugs includes those who have chronic pain and have been prescribed limited opioids, the drug addict who is trying to supplement a habit, and the "hustler" who is obtaining prescription drugs to sell on the street. However, the ability of the physician to correctly identify individuals in any of these three categories is difficult and imperfect.

The prevalence of aberrant drug-related behaviors is not known; however, there is considerable indirect evidence of the problem. A systematic review of the literature found that the only consistent predictor of aberrant drug-related behaviors in chronic pain patients is a personal history of illicit drug and alcohol abuse.[49] A separate systematic review of chronic nonmalignant pain patients exposed to chronic opioid analgesic therapy found that 20.4% of patients had negative urine tests for prescribed opioids despite filling regular prescriptions, and 14.5% tested positive for illicit drugs.[50] In 2012, 17% of the teens trying illicit drugs for the first time used prescription opioids, second only to marijuana.[51]

Individuals attempting to secure opioids from emergency providers are successful through persistence. A 1996 study found that the average aberrant drug-related behavior patient presented to an ED 12.6 times per year, visited 4.1 different hospitals, and used 2.2 different aliases.[52] Patients who were refused opioids at one facility were successful in obtaining opioids at another facility 93% of the time and were later successful at obtaining opioids from the original facility 71% of the time.[52]

CLINICAL FEATURES

Because of the spectrum of aberrant drug-related behaviors, the history given may be factual or fraudulent. Patients may be demanding, intimidating, or flattering. The most common complaints of patients who attempt to obtain opioids from the ED are (in decreasing order): back pain, headache, extremity pain, and dental pain.[52] Patients may complain of panic disorder or drug withdrawal symptoms and request benzodiazepines. In some cases, observation of vital signs and physical examination findings will help the physician identify factitious illness, but even experienced clinicians are frequently misled.

TABLE 38-5 Management of Neuropathic Chronic Pain

Disorder	Primary Treatment	Secondary Treatment	Possible Referral Outcome
Fibromyalgia	Pregabalin	Duloxetine	Exercise program, optimization of medical therapy
Trigeminal neuralgia	Carbamazepine	Oxcarbazepine	Optimization of medical therapy, consideration for surgery or radiation
Human immunodeficiency virus neuropathy pain	Topical capsaicin	Gabapentin	Optimization of medical therapy
Spinal cord pain	Pregabalin	Tramadol	Optimization of medical therapy
Painful diabetic neuropathy	Duloxetine	Gabapentin or Pregabalin	Optimization of medical therapy
Postherpetic neuralgia	Pregabalin or gabapentin	Tramadol	Optimization of medical therapy, regional nerve blockade
Phantom limb pain	Gabapentin	Tramadol	Optimization of medical therapy, ketamine infusion
Poststroke pain	Pregabalin	Gabapentin	Optimization of medical therapy
Complex regional pain syndrome types I and II (reflex sympathetic dystrophy and causalgia)	Acute phase: prednisone	Chronic: intermittent infusions of low-dose ketamine by specialist	Physical therapy, individualized therapy based on neurologic testing

Note: Dosing for above indications can be started as follow: **capsaicin** is best started at follow-up because pain increases before it decreases; **carbamazepine**, 100 milligrams PO two times daily; **duloxetine**, 30 to 60 milligrams daily; **gabapentin**, 300 milligrams PO, once on day 1, two times on day 2, then three times daily, eventually increasing to 1200 milligrams/d guided by follow-up clinician; **oxcarbazepine**, 300 milligrams PO two times daily for 3 days, 300 milligrams in morning and 600 milligrams in evening for 3 days, then 600 milligrams two times daily; **prednisone,** 60 milligrams daily for 7 days to be adjusted by follow-up physician; **pregabalin**, 50 milligrams three time per day; **tramadol**, 50 milligrams every 6 hours as needed.

TABLE 38-6 Aberrant Drug-Related Behaviors

Forges/alters prescriptions*
Sells controlled drugs*
Uses aliases to receive opioids*
Current illicit drug use*
Factitious illness, requests opioids
Conceals multiple physicians prescribing opioids
Abusive when refused
Conceals multiple ED visits for opioids

*Unlawful behaviors in many states.

Patients should be examined for signs of injection drug use, including needle marks, and the heart should be examined for evidence of a regurgitant murmur indicative of valve damage from prior endocarditis. Look for key characteristics of patients attempting to falsify illness (**Table 38-7**). Patients most commonly have completely normal physical examination findings. Widespread anecdotal experience of ED personnel has indicated that such patients will relate an allergy to alternative pharmacotherapy and insist that only one or two specific opioids are effective.

DIAGNOSIS

The diagnosis of drug-seeking behavior may not be possible in the ED. The medical record can provide a wealth of information about the patient, including documentation proving that the patient is supplying false information. Often the diagnosis is suspected in the ED but cannot be confirmed. In such cases, the clinical impression should be documented in the chart listing the provider's concerns, but physicians should be careful when using terms such as *drug-seeking behavior* without solid evidence. A listing or card file at the nurses' desk of "drug-seekers" violates confidentiality between patient and physician unless it is part of the patient's permanent medical record and subject to the same controls restricting access. However, electronic medical records can be programmed to flag charts with alerts for patient safety; accidental overdose is always a concern in such patients.

Do not miss a true emergency in patients suspected of aberrant drug-related behaviors because the negotiation over pain medicine can distract the entire team from a subtle yet life-threatening medical or surgical illness.

Prescription drug monitoring programs and other computerized tracking systems may help identify patients who are abusing or overusing prescription drugs. Practitioners are encouraged to review the prescription drug monitoring program database before prescribing a discharge medication, because that information is likely to change the intended discharge plan.[53]

TREATMENT, DISPOSITION, AND FOLLOW-UP

The treatment of definite aberrant drug-related behavior is to refuse the controlled substance, consider the need for alternative medication or treatment, and refer for drug counseling (**Table 38-7**). The patient who complains of multiple drug allergies can be difficult. Occasionally the medical record will show previous administration of the drug in question (usually an opioid substitute) with no adverse reaction. When confronted, patients hoping to acquire opioids may become verbally abusive, and hospital security may be required to control the situation and, if necessary, escort the patient out of the ED. A nonjudgmental attitude facilitates communication; avoid using labels such as "narcotics addict" or "drug-seeker." Stick to the facts, inform the patient that you are not able to prescribe or administrate the medication they seek, and offer a substitute.

When aberrant drug-related behavior is confirmed or suspected in the ED, it should be documented in the chart, stating only the facts. Concerns about opioid overuse can be documented without diagnosing the patient with "drug-seeking behavior," which may not be appropriate without evidence of illegal behavior. When physicians are notified by a pharmacist of forged or altered prescriptions, law enforcement authorities should be called, and physicians should cooperate with the legal investigation. The prosecution of fraudulent behaviors, such as using

TABLE 38-7 Recommendations to Manage Fraudulent Techniques Used by Patients Attempting to Obtain Narcotics for Illicit Use

Technique	Characteristics	Management
Lost prescription	Calls or returns stating that opioid prescription was lost before being filled.	Establish a policy: no lost opioid prescriptions refilled. Notify patients of policy at discharge as they receive prescriptions.
"Stolen" prescription or pill bottle	Police have not been called.	Inform patient this is a police issue and recommend calling police to rectify matter. Establish a policy: no stolen opioid prescriptions refilled.
Impending surgery	Wants temporizing opioids, doctor "unavailable," previous surgery, patient from out of town.	Use Internet and phone calls to check validity of information. Check medical records. Offer substitute for opioid.
Carries own records and x-rays	Suspicious or forged records, doctor's written permission to receive opioids, patient from out of town.	Use Internet and phone calls to check validity of information. Check records. Offer substitute for opioid.
Factitious hematuria with complaint of kidney stones	Appears comfortable or overacting, pricked finger dipped in urine, lip/cheek bitten and blood spitted into the urine.	Examine fingers and mouth. Obtain witnessed urinalysis. Offer nonopioid pain medicine. Obtain confirmatory test before giving opioid.
Self-mutilation	Done with dominant hand, requests opioids for pain.	Use bupivacaine for local block. Do not prescribe opioids without indications. Offer substitute for opioids.
Dental pain	Dental caries only.	Give local nerve block with bupivacaine. Refer to dentist.
Factitious injury	Old injury, old deformity, self-massaged to produce erythema, patient from out of town.	X-ray before treatment. Check records. Check for erythema that dissipates over time.

aliases to obtain opioids, requires the involvement of the state bureau of investigation or a similar state agency.

SPECIAL CONSIDERATIONS: LEGAL ISSUES

The U.S. Drug Enforcement Agency (in addition to state agencies) licenses physicians to administer or dispense controlled substances. However, state law determines most prescribing regulations. Physicians should be aware of state laws regulating controlled substances prescribed in their practice setting. The prescribing of opioids to a known drug addict could result in restriction of the physician's medical license in some states, although this is rarely prosecuted for isolated incidents. If a patient refuses to acknowledge an addiction, the physician cannot be held accountable unless medical records at the facility where the patient presents document the addiction. In all states, it is illegal for patients to forge or alter prescriptions. In some states, it is illegal for patients to use aliases or factitious illness to obtain opioids. Furthermore, in some states, concealing previous or recent prescriptions for opioids when requesting opioids from a new practitioner is illegal.

SECTION 6

Wound Management

CHAPTER 39

Wound Evaluation

Adam J. Singer
Judd E. Hollander

PRINCIPLES OF INITIAL EVALUATION

Evaluation of the patient with a traumatic wound begins with overall patient assessment.[1,2] Less obvious but more serious life-threatening injuries need care before directing attention to wound management. Determine the patient's past medical history and circumstances surrounding the injury.[1,2] Remove rings or other circumferential jewelry as soon as possible so they do not act as constricting bands when swelling progresses. Remove clothing over the injured area to reduce the potential for contamination.

External bleeding can usually be controlled by direct pressure over the bleeding site. When possible, replace skin flaps to their original position before applying pressure in order to avoid exacerbating vascular compromise. Tourniquet application may be necessary to stop life-threatening exsanguination or when needed for a short period to create a "bloodless" field for wound inspection.[3-5] Amputated fingers or extremities should be wrapped with a moist, sterile, protective dressing, placed in a waterproof bag, and then placed in a container of ice water for preservation and consideration for future reattachment. Before wound exploration, cleansing, and repair, most patients will need some form of anesthesia.[6] Systemic analgesia or procedural sedation may be required (see chapter 35, Acute Pain Management, and chapter 37, Procedural Sedation).

RISK ASSESSMENT

Proper wound management begins with a pertinent patient history (**Table 39-1**).[1,2] A variety of patient factors have adverse effects on wound healing and increase the rate of wound infection—extremes of age, diabetes mellitus, chronic renal failure, obesity, malnutrition, the use of immunosuppressive medications, the presence of connective tissue disorders, and protein and vitamin C deficiencies.[1] Predictive factors for infection are the wound characteristics of location, age, depth, configuration, and contamination.[7,8]

Ascertain the tendency of patients to form hypertrophic scars or keloids by both history and examination, as past experience may predict poor scar formation. Black and Asian patients are more prone to keloid formation than whites. Hypertrophic scars are due to tissue tension during wound healing, and these scars stay within the original wound boundaries and tend to undergo partial spontaneous regression within 1 to 2 years. Keloids are genetically linked variations in wound healing, resulting in the production of excess collagen beyond the original wound boundaries (**Figure 39-1**). Once they form, keloids rarely decrease in size.

Obtain a detailed history of allergies or prior adverse reactions to anesthetic agents or antibiotics. **Review any prior allergies to latex.**[9] **Determine the status of prior tetanus immunization and the need for further tetanus vaccination** (see chapter 156, Tetanus).

Review the mechanism of injury to identify the presence of potential wound contaminants and foreign bodies. Bite wounds are at high risk for infection and are generally managed differently than other lacerations (see chapter 46, Puncture Wounds and Bites). Foreign bodies are common in puncture wounds, wounds associated with broken glass, and motor vehicle collisions.[10-13] Ask about the presence of a foreign body sensation. In adults, those reporting a foreign body sensation are more likely to have a retained foreign body than those who do not (positive likelihood ratio = 2.49 and negative likelihood ratio = 0.69).[14] This question has little utility in children.[15]

Both foreign body retention and visible contamination increase the risk of infection.[7,8] Organic and inorganic components of soil can cause infection even from very small doses of bacterial inoculum. Clay is the major inorganic soil component responsible for infection. Conversely, sand grains and black dirt from roadways are relatively inert.

The likelihood of wound infection varies according to the forces applied at the time of injury.[7,8] The most common mechanism for traumatic wounds is blunt force. The skin is crushed against underlying bone and tears or splits from the subsequent tension. Sharp objects produce shear forces that cut skin cleanly. Crush injuries produce more tissue devitalization and are more susceptible to infection than wounds from shear forces.

Low-energy impact injuries may not result in lacerations, but instead may disrupt vessels, leading to ecchymosis or hematoma formation. Some hematomas spontaneously resorb. Those that become encapsulated may eventually require aspiration or incision and drainage.

Determine the time that the injury occurred. Although the growth of the bacterial inoculum is directly related to the time interval from injury to laceration repair,[1,7] **there is no clearly defined relationship of time to closure to clinical infection[16-18] (Table 39-2). Therefore, time from injury until presentation is only one element to be considered, in addition to the wound etiology, location, degree of contamination, host risk factors, and the importance of cosmetic appearance, before determining whether or not to perform primary wound closure.** Wounds that are not closed primarily because of a high risk of infection should be considered for delayed primary closure after 4 days. The clinical consensus of wound care experts is that after 4 days of open wound management, the risk of infection after closure substantially decreases, although this approach has not been subjected to randomized controlled trials.[19]

Determine whether the wound was the result of an intentional, unintentional, or workplace event. Most states have regulations that require the reporting of intentional injuries, and patients with self-inflicted injuries may need psychiatric evaluation. Occupational injuries may require alternative follow-up arrangements.

The anatomic location of the injury helps predict the clinical outcome, both in terms of infection risk and cosmetic result[7,8,15,20] (**Table 39-3**). The risk of infection is determined largely by the interplay between baseline bacterial colonization and vascular blood supply. With respect to bacterial colonization, the density of the bacterial population is low on the upper arms, legs, and torso. Conversely, moist areas of the body, such as the axilla, perineum, toe webs, and intertriginous areas, harbor millions of bacteria per square centimeter, including anaerobes. Obviously, any wounds with human or animal fecal contaminants run a high risk of infection, even with therapeutic intervention.

Wounds located on highly vascular areas, such as the face or scalp, are less likely to be infected than wounds located in less vascular areas.[7,8,15,17,20] The increased vascularity of the area more than offsets the high bacterial inoculum found in the scalp, and lacerations of the scalp and face have a very low infection rate regardless of the intensity of cleansing.[21] While prophylactic oral antibiotics have traditionally been considered as warranted for intra-oral lacerations, there is inconclusive evidence to support their use.[22]

TABLE 39-1 Pertinent Medical History

Symptoms
Pain, swelling, paresthesias, muscle weakness
Type of force causing injury
Crush (blunt) or shear (sharp)
Bite or puncture
Elements of contamination
Time elapsed from injury until initial cleansing
Time elapsed from injury until presentation
Wound care performed prior to ED arrival
Object that caused injury (glass, wood, etc.)
Cleanliness of body and environment at time of injury and afterward
Factors resulting in injury
Intentional or unintentional
Occupation or nonoccupation related
Assault or self-inflicted
Foreign body potential
Did the object break or shatter?
Foreign body sensation
Removal of portion of object
Function
Occupation and handedness
Allergies
Anesthetics, analgesics, antibiotics, and latex
Medications
Chronic medical conditions that increase risk of infection
Chronic medical conditions that increase likelihood of poor wound healing
Previous scar formation (hypertrophic scars or keloids)

WOUND EXAMINATION

Thorough wound examination should be conducted when the patient is calm and cooperative and positioned appropriately, with optimal lighting conditions, and with little or no residual bleeding (**Figure 39-2**).

Cursory examination under poor lighting or when the depths of the wound are obscured by blood will occasionally result in poor detection of foreign bodies and tendon, nerve, and vascular injuries. If bleeding is a problem, epinephrine-containing anesthetic solutions may be helpful, when not contraindicated. **Tourniquets may be used to obtain a bloodless field, but they should not be used for more than 30 minutes.**[3-5] Lacerations over joints may have penetrated the joint capsule, and sometimes it is necessary to inject the joint to ensure that there is no communication between the joint space and the laceration. Evaluate the wound in neutral position and also in the position present during injury. Chain-saw knee wounds, for example, are often sustained with the knee in flexed position. **Repositioning the joint or extremity in the position assumed during injury can better reconstruct the mechanism of injury and identify injured structures.** Lacerations over the metacarpophalangeal joints are suspicious for having occurred during a fight (clenched fist injury) and should be treated as though they are human bites.

FIGURE 39-1. A large keloid extending beyond the original wound margins. IMAGING

Although most lacerations will not require any diagnostic testing, on occasion, wound imaging for detection of foreign bodies may be necessary (see chapter 45, Soft Tissue Foreign Bodies). Most foreign bodies commonly found in wounds are much denser than the surrounding tissue and are readily apparent on plain radiographs. Metal, bone, teeth, pencil graphite, certain plastics, glass, gravel, sand, some fish bones, some painted wood, and most aluminum are visible on plain radiographs.

CT and MRI are useful for identifying and locating objects that have densities similar to soft tissue. US may also be useful, particularly for wooden foreign bodies, although the sensitivity of US is inadequate to reliably exclude small (<2.5 mm) wood fragments.

PATIENT EDUCATION

Patients should be carefully educated regarding the expected cosmetic outcome. They should be informed that there will be some scarring and, if predisposed, possible keloid formation.[1] Some indication of the maximal width of the scar can be predicted based on wound location,

TABLE 39-2 Risk of Wound Infection as Function of Time From Injury to Closure

Reference	Comments	Distinction Between Early and Late Closure (h)	Infection Rate/Inadequate Healing With Early Closure	Infection Rate/Inadequate Healing With Late Closure	Percent age Difference (95% CI)
Morgan et al., 1980[16]	Hand and forearm; all patients received IM penicillin and half received PO clindamycin	4	10/148 (7%)	14/69 (21%)	13.5% (3.2% to 23.9%)
Baker and Lanuti, 1990[18]	Children, 59% head and neck location	6	32/2665 (1.2%)	2/147 (1.3%)	0.16% (−1.76% to 2.08%)

	Head	19	2/44 (5%)	1/36 (3%)	−1.8% (−9.9% to 6.4%)
	Trunk and extremities	19	6/53 (11.3%)	24/71 (33.8%)	22.5% (8.6% to 36.4%)

TABLE 39-3 Risk of Wound Infection After ED Closure

Location	Risk of Infection (%)
Head and neck	1–2
Upper extremity	4
Lower extremity	7

FIGURE 39-2. This deep antecubital laceration could involve arterial, venous, nerve, and tendon injury. Such wounds require careful and complete exploration. Proximal arterial control is important for visual inspection in a "bloodless" field. [Image used with permission of J. Stephan Stapczynski, MD.]

whether the laceration is aligned parallel or perpendicular with lines of minimal tension, and how gaping the wound is while at rest (static tension) or when put through a range of motion (dynamic tension).[20,23] Lacerations over joints (which have more dynamic tension) will have wider scars than similar lacerations subject to less tension. Wounds that deviate from the lines of skin tension will also be prone to greater scar formation after suturing than wounds that are more closely aligned with skin tension.[23] The most important determinant of cosmetic outcome under control of the treating physician is meticulous wound repair with approximation of viable wound edges under little tension. Patients should be clearly educated that all lacerations result in some scarring.

CHAPTER 40

Wound Preparation

Aleksandr M. Tichter
Wallace A. Carter
Susan C. Stone

INTRODUCTION

The common methods of wound care are reasonably effective, resulting in a good outcome for the vast majority of cutaneous wounds treated in the ED.[1-3] Wound preparation is the most important step in restoring tissue integrity and function, minimizing infection risk, and achieving the best possible cosmetic result. However, there is surprisingly little scientific validation for most of these methods.[4-7] With some patient and wound characteristics (**Table 40-1**), the risk of improper healing increases, and the importance of careful wound preparation becomes more important.[4,5,8-10]

TABLE 40-1 Risk Factors for Poor Wound Repair Outcome

Patient Factors	Wound Factors
Immunosuppression: diabetes, chemotherapeutic agents, chronic steroid therapy, chronic renal failure, hematologic malignancies, congenital immunodeficiencies	Crush injuries
Tissue ischemia: peripheral vascular disease, anemia, vasculitis	Tissue loss
Poor wound healing: elderly, cigarette smoking, malnourished, connective tissue disorders	Contamination
	Foreign bodies
	Peripheral location

ANESTHESIA

Thorough cleansing and meticulous wound evaluation and repair can be painful procedures, so adequate anesthesia is important for patient comfort and cooperation. Choice of anesthetic agent and route varies according to wound location and size (see chapter 36, Local and Regional Anesthesia). The sensory, motor, and vascular examination should be performed at and distal to the wound site prior to the administration of local or regional anesthetic.

Sensory examination should include evaluation of pain or touch. If a wound involves the hand or fingers, additional assessment for digital nerve injury using **two-point discrimination (normal <6 mm)** on the volar pads should be performed prior to local or regional anesthesia administration. Motor examination should assess movement and strength of tendons and muscles around the wound site as well as muscles that are innervated by nerves traversing the site. Vascular examination should assess distal perfusion by noting skin color, temperature, capillary refill time, and quality of pulses. Comparison of the systolic blood pressure in the injured extremity with the noninjured one (using a Doppler stethoscope and pneumatic cuff) assesses for hemodynamically significant arterial compromise. While performing the sensory examination prior to the administration of an anesthetic is important, adequate motor examination can be occasionally limited by pain, with improved strength testing following achievement of pain control.

IRRIGATION

Wound irrigation is widely considered to be the most important step in the management of acute wounds; it decreases bacterial count and helps to remove debris and foreign bodies, thereby reducing the risk of wound infection.[1,3,11] Choices in the performance of wound irrigation include solution composition, temperature of the irrigant, pressure with which it is applied, and the total volume used.

In most medical settings, wound irrigation is performed with sterile normal saline, but potable tap water is as effective and may be superior when taking into account time, resources, cost, and the potential for occupational exposures during clinician-performed irrigation techniques.[12-17] Limited studies indicate that dilute solutions containing povidone-iodine or hydrogen peroxide do not appear to confer greater benefit than water alone.[18-20] **Polyhexanide** (a chlorhexidine polymer) is an antiseptic that, when used for wound irrigation of dirty and contaminated soft tissue wounds, reduced the rate of postrepair wound infections compared to Ringer's lactate, povidone-iodine, or hydrogen peroxide irrigation.[21-23] One small clinical trial suggests that warmed solution may be more comfortable than room temperature irrigant.[24]

High-pressure irrigation is defined as approximately 7 psi (50 kPa) or greater, and is achieved using any combination of a 30- to 65-mL syringe and a 19-gauge catheter or needle hub, or commercially available splashguard, with forceful depression of the syringe piston.[3,25-28] **Low-pressure irrigation** is defined as approximately 0.5 psi (3.5 kPa) or lower, and is achieved with a slow, gentle wash.[29] Low-pressure irrigation may be sufficient for cleansing simple, nonbite, uncontaminated wounds in highly vascular areas such as the scalp and face.[30]

However, high-pressure irrigation is generally regarded as more effective for clearance of debris and reduction of infection.[11,16,31]

Wound soaking is not effective in cleansing contaminated wounds and may actually increase wound bacterial counts.[32] Routine scrubbing of traumatic wounds with a sponge is also ineffective, inflicting trauma and impairing resistance to infection.

Many wounds and lacerations seen in the ED have little visible contamination, and there is no strong evidence regarding the amount of irrigation effective to minimize postrepair infection. Common sense dictates that the higher the volume of irrigation, the more thoroughly cleansed the wound and the less likely infection will ensue. Typical recommendations by wound care experts range from 25 to 100 mL/cm of wound length for "clean"-appearing wounds.[11] Additional volumes should be based on anatomic location, mechanism of injury, degree of contamination, and patient factors that lower resistance to infection.

High-pressure wound irrigation risks mucous membrane exposure of the healthcare worker to contaminated body fluids. Irrigation shields provide some measure of safety,[28] but universal precautions, including barrier protection with face mask/shield, should be employed as a matter of routine.

SKIN DISINFECTION

A common practice is to disinfect intact skin around the wound with either a povidone-iodine–based or chlorhexidine-containing agent. These agents suppress bacterial growth on intact skin and are thus favorable antiseptics prior to surgical incision,[33-35] but within the environment of an already open wound, they can impair host defenses and promote bacterial growth. Both povidone-iodine[36,37] and chlorhexidine[38] can produce chemical burns on intact skin and in the eyes. Apply disinfectants from the wound edges outward in order to avoid cytotoxic exposure of nonintact skin.[10,11,20]

STERILE TECHNIQUE

Although observing sterile technique has been well demonstrated to have a beneficial effect on patient outcomes in several settings, the extent to which its routine employment in the ED treatment of traumatically contaminated wounds reduces infection rates is unclear. Adherence to full aseptic methods (cap, gown, mask, and gloves) does not appear to be of substantial benefit,[39] nor does hand antisepsis prior to initiation of wound repair.[40] Although recommendations exist for the use of sterile gloves in the repair of uncomplicated lacerations, supportive evidence is lacking, if not refutative.[41] These findings suggest that aspects of the sterile technique may be curbed, leading to time and cost savings per laceration by using common-sense cleanliness.

HEMOSTASIS

To adequately evaluate a wound, hemostasis is needed to prepare a clear visual field. The most common sources of wound-related bleeding are the subdermal plexus and superficial veins. Oozing from these sources can usually be controlled with the application of direct pressure using saline-soaked sponges or gauze.

In the event of continual bleeding, the next step is typically an attempt at chemical hemostasis using **epinephrine mixed with local anesthetics** in concentrations of 1:100,000 or 1:200,000 and injected into the wound area. Local epinephrine induces vasoconstriction that will additionally allow a longer duration of anesthesia and a larger total local anesthetic dose due to the depot effect of the vasoconstriction.[42-45] Despite the theoretical risk of end-organ ischemia (i.e., fingers, nose, ears, toes), when mixed with local anesthetics, the safety of epinephrine use in these regions has been well documented.[46-52] Use caution in patients with small vessel disease, where end-organ epinephrine injection remains ill advised. Although epinephrine interferes with wound healing in experimental animal models,[4,5] no increase in wound infection has been observed with the addition of epinephrine to local anesthetics used in the ED.

Physical means of applying pressure to bleeding include the use of **gelatin**, **cellulose**, or **collagen** sponges placed directly into the wound.

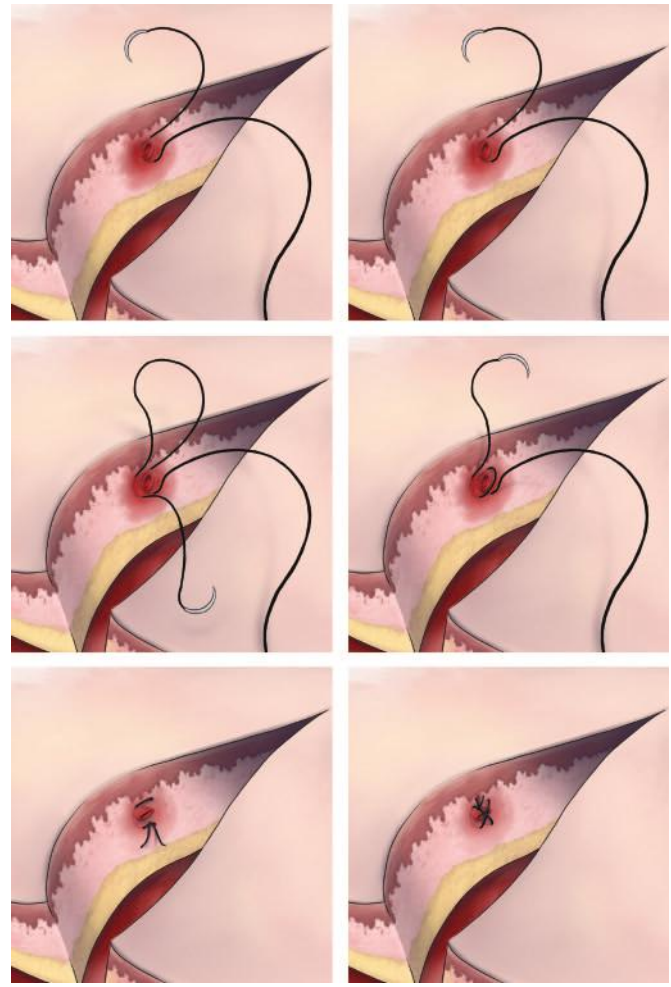

FIGURE 40-1. Suture to control bleeding wound edges where the involved vessel is not visible. **Left column:** Standard horizontal mattress suture. **Right column:** Figure-of-eight suture. [Image used with permission of Nicholas Hatch, MD.]

Denatured gelatin (Gelfoam®; Pfizer, Inc., New York, NY) has no intrinsic hemostatic properties and works by the pressure it exerts as it expands. A cellulose derivative (Oxycel®; Becton Dickinson Infusion Therapy Systems, Inc., Sandy, UT) or a collagen (Actifoam®; MedChem Products, Inc., Woburn, MA) sponge reacts with blood, forming an artificial clot. These products are not particularly effective for actively bleeding wounds, as the blood flowing into the wound can wash them out.

If the source of bleeding is a small vessel that has been lacerated but can be easily visualized, control may be achieved through direct pressure applied with a gloved fingertip directly on the vessel. Once bleeding has ceased, more permanent control can be obtained by clamping the vessel, isolating a short length, and ligating it with absorbable synthetic suture (typically 5-0). Take care to avoid clamping or ensnaring adjacent structures (i.e., nerves and tendons), particularly when working with wounds of the face.

For bleeding wound edges where the involved vessel is not visible, a figure-of-eight or horizontal mattress suture (**Figure 40-1**) applied adjacent to the site of bleeding will sometimes achieve control. However, this technique may impair blood flow and leave nonviable tissue in the wound.

Bipolar **electrocautery** can achieve hemostasis in blood vessels <2 mm in diameter, but if improperly or too extensively applied, it can result in tissue necrosis. Electrocautery units are not routinely available in many EDs. Battery-powered, hand-held cautery devices (**Figure 40-2**), although more accessible, do not generate sufficient heat to produce coagulation in vessels larger than capillaries. Low-temperature units, identified where the wire loop does not glow when heated, are recommended for ED use.

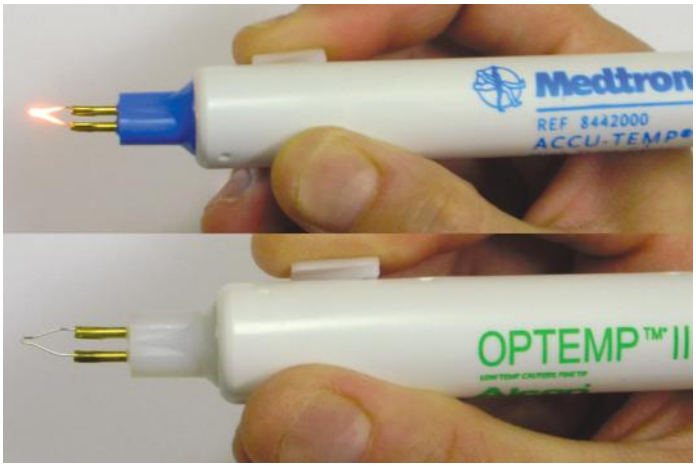

FIGURE 40-2. Battery-powered, hand-held thermal cautery units commonly used in the ED. **Top:** High-temperature unit (1200°C); wire loop glows when heated. **Bottom:** Low-temperature unit (690°C); wire loop does not glow when heated. [Image used with permission of J. Stephan Stapczynski, MD.]

Scalp lacerations can bleed extensively from the wound edges due to the highly vascular subcutaneous layer. If traditional methods of hemostasis fail, scalp bleeding can be controlled by the use of specially designed clips applied along the wound edges (**Figure 40-3**). If the source of bleeding is determined to be a major artery, do not ligate the vessel. Maintain direct pressure on the vessel and obtain surgical consultation.

Extremity wounds that are refractory to direct pressure, ligation, or cautery may require an arterial tourniquet.[53] **Tourniquets** may compress and damage underlying blood vessels and nerves, reducing tissue viability, and therefore should not be left in place for greater than 20 to 30 minutes at a time. The simplest tourniquet to use in an ED is a blood pressure cuff placed proximal to the wound and inflated to 20 to 30 mm Hg (2.7 to 3 kPa) above the patient's systolic pressure. Elevating the extremity to reduce venous blood volume prior to cuff inflation may be useful. If an extremity tourniquet is needed to control bleeding, the best course of action is exploration and repair in the operating room.

FOREIGN BODY REMOVAL

Retained foreign bodies are a frequent concern in the management of traumatic wounds. The risk for retained foreign bodies is increased in patients with head or foot wounds, wounds sustained in motor vehicle collisions, and puncture wounds. Clinical clues to their presence include foreign body sensation, point tenderness, or increased pain on range of motion.

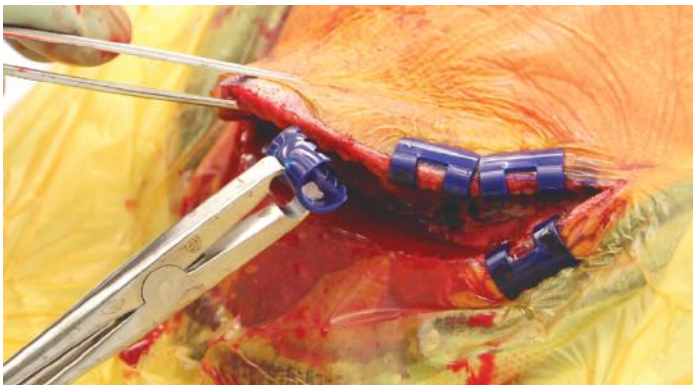

FIGURE 40-3. **Raney clips** are used to control bleeding from the wound edges of scalp lacerations. An applicator is used to apply the open clip. When the applicator is released, the clip closes and pinches onto the wound edges. [Image used with permission of J. Stephan Stapczynski, MD.]

Visual wound inspection, down to the full depth and along the full course of the wound, is the most important method of detection. Carefully remove obvious foreign debris, using forceps to avoid injury to the physician from sharp edges or points. Probing wounds with a gloved fingertip to detect foreign bodies by palpation is discouraged. Despite thorough exploration, some reports suggest that up to 4% of superficial wounds have retained foreign bodies missed on exam.[54]

Imaging modalities may be used as a diagnostic adjunct. These include plain radiographs, which are most sensitive for radiopaque foreign bodies (e.g., metal, gravel), and high-frequency US, which is most sensitive for radiolucent foreign bodies (e.g., rubber, wood), as well as CT and MRI (see chapter 45, Soft Tissue Foreign Bodies).[55]

HAIR REMOVAL

Although the presence of hair around a wound can interfere with wound closure, obstruct field of view, become entangled in sutures or staples, and complicate the application of adhesive dressings following repair, routine hair removal does not appear to have an effect on the rate of skin and soft tissue infections following neurosurgery[56-63] or scalp laceration repair.[64] Rather, shaving may increase the rate of postoperative skin and soft tissue infection.[65,66] Hair removal prior to wound repair may also result in irregular and cosmetically undesirable regrowth in certain anatomic locations (e.g., eyebrows and hairline). In the event that hair is interfering with wound care, it is best removed by clipping it 1 to 2 mm above the skin with scissors.[1,3,11] An alternative method to clipping is to use ointment or saline to allow the hair to be parted away from the wound edges.

DEBRIDEMENT

Nonviable tissue in the wound increases the risk of infection and delays healing by simultaneously acting as a culture medium and inhibiting host defenses.[1,3,8] Debridement serves the dual purposes of removing foreign matter, bacteria, and devitalized tissue, and creating a clean wound edge that is easier to repair.[67]

Excisional debridement targets tissue that has a narrow base, has irregular devitalized edges, or lacks capillary refill, and is performed using a standard surgical blade or scissors (**Figure 40-4**), with the goal of converting a contaminated wound into a clean surgical edge and

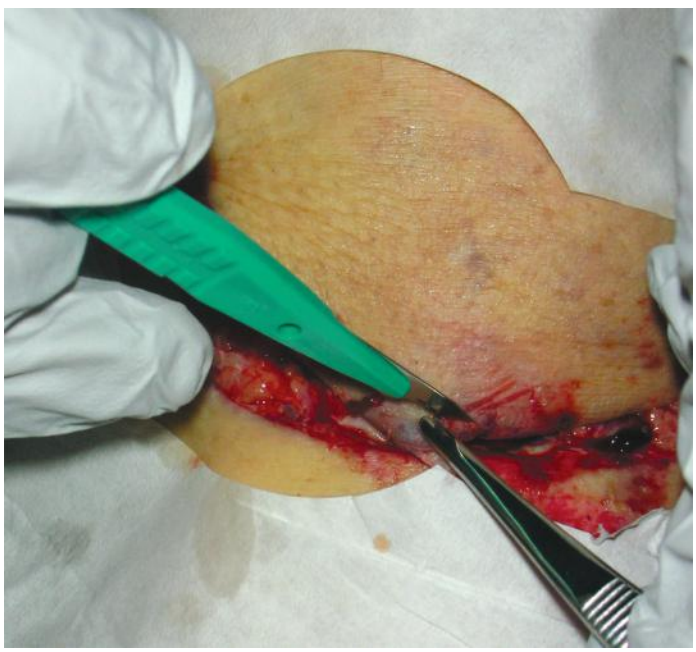

FIGURE 40-4. Sharp debridement of the contused and jagged edge of a 10-cm infrapatellar knee laceration sustained from a fall onto gravel. [Image used with permission of J. Stephan Stapczynski, MD.]

re-establishing a margin of normal healthy tissue.[67] The easiest technique for excisional debridement is to mark an elliptical area around the sides of the wound and then use a scalpel to cut only through the epidermis. Relaxed skin tension lines should be respected, and extensive excision should be avoided. Certain types of wounds with devitalized tissue (e.g., low-velocity civilian gunshot wounds to the extremities) can be successfully managed without debridement, using conservative wound care techniques (irrigation and cleaning) alone.[68,69]

Wounds with an extensive amount of nonviable tissue or heavy contamination are more problematic. They may require operative debridement and need more delayed wound closure or grafting. In general, a surgeon should be consulted to assist in their management.[11]

PROPHYLACTIC ANTIBIOTICS

Infections occur in approximately 2% to 5% of traumatic wounds repaired in EDs, although this rate varies widely according to mechanism, location, and patient factors (**Table 40-1**).[2,9] Less vascular, moist (axilla and perineum), and exposed areas (feet and hands) tend to be at higher risk for infection. Crush or puncture wounds are more prone to infection due to the tensile and compressive forces generated that increase the potential for devitalized tissue. With current methods for ED wound care, **the time from injury until wound closure for simple lacerations does not have much influence on the occurrence of postrepair infection**.[70-72] The most important step in the prevention of a wound infection is adequate irrigation and debridement.

There is no clear evidence that routine antibiotic prophylaxis prevents infections in most patients whose wounds are closed in the ED (see chapter 47, Postrepair Wound Care).[9,73-76] Certain types of injuries that have historically been considered high risk, specifically, uncomplicated hand lacerations[77] and mammalian bites,[78-82] appear to have no clear benefit from routine prophylaxis either.

If antibiotic prophylaxis is chosen, the principles learned from the surgical literature suggest that effectiveness requires the achievement of antimicrobial blood levels prior to, or rapidly after, wound contamination.[82-85] Antibiotic prophylaxis for traumatic wounds in an ED should be (1) initiated before significant tissue manipulation is done, (2) performed with agents that are effective against predicted pathogens, and (3) administered by routes that rapidly achieve desired blood levels. There are no studies that compare the common practice of IV administration of the initial dose of prophylactic antibiotics with PO administration. Based on the above principles, the PO route may be as effective if administered before manipulation using an agent with an appropriate spectrum and rapid PO absorption.

Most nonbite wound infections are due to staphylococci or streptococci, and despite the increase in methicillin-resistant *Staphylococcus aureus* skin infections, prophylactic coverage with a β-lactam remains adequate (see chapter 47).[86] The duration for adequate antibiotic prophylaxis is unknown; most experts recommend only 3 to 5 days.[87] Patients with established wound infections require longer treatment.

Prophylactic antibiotics are recommended for all human bites to the hands and feet, as well as to those overlying joints or cartilage.[80] *Eikenella* is the target organism, and adequate prophylaxis can be attained with amoxicillin-clavulanate.

Prophylactic antibiotics are recommended for all mammalian bites to the hand.[78,79,81] The studies of mammalian bites have not been of adequate size to draw conclusions regarding the benefit of antibiotic prophylaxis in locations other than the hand. *Pasteurella* is the target organism, and adequate prophylaxis can be attained with amoxicillin-clavulanate.

Wounds contaminated by fresh water or plantar puncture wounds through athletic shoes carry the theoretical risk of *Pseudomonas* infection, and although there is little evidence for prophylactic antibiotics, agents should be chosen whose spectrum includes this pathogen (see chapter 46, Puncture Wounds and Bites).

CHAPTER 41

Wound Closure

Adam J. Singer
Judd E. Hollander

INTRODUCTION

The major goal of wound closure is to restore the skin's integrity in order to reduce the risk of infection, scarring, and impaired function. This may be achieved by one of three methods: primary, secondary, and delayed closure. With **primary closure**, the wound is immediately closed by approximating its edges, with the main advantage being a reduction in healing time in comparison with other closure methods. Primary wound closure also may reduce bleeding and discomfort often associated with open wounds. **Secondary wound closure**, in which the wound is left open and allowed to close on its own, is particularly well suited for highly contaminated or infected wounds as well as in patients at high risk of infection. Although this method may reduce the risk of infection, it is relatively slow and uncomfortable and leaves a larger scar than primary closure. With **delayed (or tertiary) closure**, the wound is initially cleansed and then packed with dry sterile gauze covered by a sterile covering. The dressing is left undisturbed unless signs of infection—fever, purulent exudate, or spreading cellulitis—develop. After 4 to 5 days, the dressing is removed, and the wound edges can be closed if no infection has supervened. This approach may be useful for highly contaminated wounds and animal bites, and while commonly described and recommended, there is little evidence documenting the effectiveness for traumatic wounds seen in the ED.[1]

OVERVIEW OF WOUND CLOSURE METHODS

Lacerations may be closed by one of five commonly available methods or devices: sutures, staples, adhesive tapes, tissue adhesives, and hair apposition. Each method has advantages and disadvantages (**Table 41-1**). Choice of the wound closure method and timing should take into account both patient and wound characteristics.[2] Cosmetic outcome is more closely related to practitioner technique and the patient's own healing characteristics than to any specific closure method or device. Many of the principles discussed in this chapter are based on experience and observation rather than on controlled trials.

One of the most important considerations when choosing a wound closure method is the amount of tension on the wound, both *static* (at rest) and *dynamic* (with motion). *Linear lacerations subject to little tension* can usually be closed by any one of the five closure methods. For low-tension lacerations, consider patient characteristics and preferences such as compliance, the availability to return for follow-up and device removal, and overall level of patient anxiety. *With low-tension irregular lacerations,* sutures may be the best alternative, allowing the greatest degree of precision for accurate wound edge approximation. Conversely, some small lacerations that would typically be closed may not actually benefit from primary closure. For example, simple (**<2 cm**) uncomplicated hand and finger lacerations, when treated with antibiotic ointment and gauze dressing, heal as fast and with no notable differences in appearance or function as those closed primarily with sutures.[3] But note that this technique is limited to small, superficial hand lacerations; it cannot be recommended for larger lacerations and in other sites.

With *lacerations subject to high tension* (static and/or dynamic) one can relieve the amount of tension on the wound in order to avoid early dehiscence or gradual widening of the scar. Relief of tension is best achieved by careful undermining, placement of deep dermal sutures, and wound immobilization (when appropriate). After placement of deep, tension-relieving sutures, the superficial epidermal layer may be closed by any of the aforementioned closure methods. Reinforcement with adhesive skin tape is useful when the skin is thin, as in pretibial lacerations.[4-6]

TABLE 41-1 Advantages and Disadvantages of Wound Closure Techniques

Technique	Advantages	Disadvantages
Sutures	Time honored Meticulous closure Greatest tensile strength Lowest dehiscence rate	Requires removal (if using nonabsorbable material) Requires anesthesia Risk of needle stick to physician Greatest tissue reactivity Highest cost Slowest application
Staples	Rapid application Low tissue reactivity Low cost Low risk of needle stick	Less meticulous closure May interfere with some imaging techniques (CT, MRI) Requires removal
Tissue adhesives	Rapid application Patient comfort Resistant to bacterial growth No need for removal Low cost No risk of needle stick Microbial barrier Occlusive dressing	Lower tensile strength than 5-0 or larger sutures Dehiscence over high-tension areas (joints) Not useful on hands Cannot bathe or swim (can shower)
Adhesive tapes	Least reactive Lowest infection rates Rapid application Patient comfort Low cost No risk of needle stick	Frequently fall off Lower tensile strength than sutures or tissue adhesives Highest rate of dehiscence Often requires use of toxic adjuncts Cannot be used in areas with hair Cannot get wet
Hair apposition	Simple Low cost No foreign body placed in wound No risk of needle stick	Can only be used on the scalp Can only approximate simple nongaping lacerations

With patients at risk of **keloid** formation, it makes logical sense to relieve tension and minimize the amount of foreign material introduced into the wound. Skin tapes or tissue adhesives, instead of sutures, can minimize the amount of foreign material and inflammation that may increase the likelihood of excessive scar formation.

SUTURES

Sutures are the strongest of all the closure devices and allow the most accurate approximation of the wound edges, regardless of their shape or configuration. However, sutures are the most time-consuming and operator dependent of all wound closure methods and have the risk of inadvertent needle-stick injury. Using forceps to handle the needle during suturing can reduce this risk. A needle-catcher device is reported to be useful in reducing needle-stick injury during skin suturing.[7-9]

Sutures may be classified as absorbable and nonabsorbable. ***Nonabsorbable sutures*** **retain their tensile strength for at least 60 days.** They are most often used to close the outermost layer of the skin (where they can be removed) or for repair of tendons (where prolonged strength is necessary due to very high tension). In general, nonabsorbable sutures are avoided in deep vascularized tissues where their presence stimulates a foreign body response with fibroblastic proliferation. Nonabsorbable sutures are differentiated by their origin and structure (**Table 41-2**). Due to their strength, handling, and relatively low tissue reactivity, synthetic monofilament sutures (such as nylon or polypropylene) are preferred. Polybutester sutures have the ability to elongate in response to external forces and possess elasticity to return to the original size once the load is removed. This property may be useful in wounds where swelling is anticipated. Less distensible sutures, such as nylon or polypropylene, cannot expand, and instead may lacerate the wound edges as the tissue swells.

Absorbable sutures **lose most of their tensile strength in less than 60 days.** As a result, they are well suited for closure of deep structures such as the dermis and fascia (**Table 41-3**). Poliglecaprone 25 has handling characteristics that are similar to nonabsorbable sutures (such as nylon) and is particularly useful for intracuticular or subcuticular closure. Due to its rapid absorption, poliglecaprone 25 should probably be limited to relatively low-tension wounds. With high-tension wounds, a suture with more sustained tensile strength is preferred. Absorbable sutures that incorporate the antibacterial agent triclosan are also available and may be especially indicated in contaminated wounds.[10,11] Rapidly absorbing sutures can also be used to close the superficial skin layers, especially when avoidance of suture removal is desirable.[12-15]

For most ED use, the choice between absorbable and nonabsorbable material for percutaneous sutures is clinically irrelevant.[12-15] The cosmetic outcomes and complications of traumatic lacerations and surgical incisions closed with absorbable or nonabsorbable sutures have similar short- (infection, dehiscence) and long-term (cosmesis) outcomes.[16] Absorbable sutures, like rapidly absorbing gut, are especially useful for skin closure in children who are not candidates for wound repair with skin tapes or tissue adhesives.

Suture material is categorized by the U.S. Pharmacopeia gauge size. The larger the suture size number, the thinner the suture, so that, for example, a 6-0 suture is thinner than a 5-0 suture. **A general principle is that larger-diameter material produces more damage to the tissues and leaves larger holes in the skin, so generally thinner suture material is used**

TABLE 41-2 Nonabsorbable Suture Characteristics

Suture	Structure	Raw Material	Tensile Strength Retention Profile	Tissue Reactivity	Common ED Uses
Silk	Braided	Organic protein fibroin	Degradation of fiber results in loss of strength over many months	Significant inflammatory reaction	Intraoral mucosal surfaces for comfort
Nylon (Ethilon®, Dermalon®)	Braided and monofilament	Polyamide polymer	Hydrolysis results in 20% loss in strength per year	Minimal	Soft tissue and skin reapproximation
Polypropylene (Prolene®, Surgipro®)	Monofilament	Polypropylene polymer	Indefinite	Least	Soft tissue and skin reapproximation
Polyester (Mersilene®, Ti-Cron®)	Braided and monofilament	Polyethylene terephthalate polymer	Indefinite	Minimal	Tendon repair using undyed (white) color
Polybutester (Novafil®)	Monofilament	Copolymer of butylene terephthalate and polytetramethylene ether glycol	Indefinite	Minimal	Soft tissue approximation

TABLE 41-3 Absorbable Sutures

Suture	Structure	Raw Material	Tensile Strength Retention Profile	Absorption Rate	Tissue Reactivity	Common ED Uses
Surgical gut	Monofilament	Collagen derived from beef serosa or sheep submucosa	7–10 d	Absorbed by proteolytic processes in 70 d	Moderate reactivity	Intraoral wounds
Chromic gut	Monofilament with chromic salt coating	Collagen derived from beef serosa or sheep submucosa	21–28 d	Absorbed by proteolytic processes in 90 d	Moderate reactivity	Subcutaneous approximation and intraoral wounds
Fast-absorbing gut	Monofilament heat treated to facilitate absorption	Collagen derived from beef serosa or sheep submucosa	5–7 d	Absorbed by proteolytic processes in 21–42 d	Moderate reactivity	Facial wounds and skin grafts
Polyglycolic acid (Dexon®)	Braided	Glycolic acid polymer	65% at 14 d and 35% at 21 d	Absorbed by hydrolysis, complete by 60–90 d	Minimal	Subcutaneous approximation and ligation of vessels
Coated polyglactin 910 (Vicryl®)	Braided	Copolymer of lactide and glycolide, coated with polyglactin 370 and calcium stearate	75% at 14 d and 40% at 21 d	Absorbed by hydrolysis, complete by 56–70 d	Minimal	Subcutaneous approximation and ligation of vessels
Coated polyglactin 910 with triclosan (Vicryl PLUS®)	Braided	Copolymer of lactide and glycolide, coated with polyglactin 370 and calcium stearate; incorporates antibacterial agent triclosan	75% at 14 d, 50% at 21 d, and 25% at 28 d	Absorbed by hydrolysis, complete by 56–70 d	Minimal	Subcutaneous approximation and ligation of vessels, especially useful in contaminated wounds
Coated polyglactin 910 rapid absorption (Vicryl Rapide®)	Braided	Copolymer of glycolide and lactide, coated with polyglactin 370 and calcium stearate	50% by 5 d and 0% at 14 d	Absorbed by hydrolysis, complete by 42 d	Minimal to moderate	Skin approximation when absorbable sutures are used
Coated glycolide and lactide (Polysorb®)	Braided	Copolymer of glycolide and lactide, coated with mixture of caprolactone, glycolide copolymer, and calcium stearoyl lactylate	80% at 14 d and 30% at 21 d	Absorbed by hydrolysis, complete by 56–70 d	Minimal	Subcutaneous soft tissue approximation
Polydioxanone (PDS II®)	Monofilament	Polyester polymer	70% at 14 d, 50% at 28 d, and 25% at 42 d	Absorbed by hydrolysis, complete at 180–210 d	Slight	Subcutaneous soft tissue approximation where more prolonged strength is needed
Poliglecaprone 25 (Monocryl®)	Monofilament	Copolymer of glycolide and epsilon-caprolactone	50–70% at 7 d and 20–40% at 14 d	Absorbed by hydrolysis, complete by 91–119 d	Minimal	Subcutaneous soft tissue approximation
Poliglecaprone 25 with triclosan (Monocryl PLUS®)	Monofilament	Copolymer of glycolide and epsilon-caprolactone; incorporates antibacterial agent triclosan	50–70% at 7 d and 20–40% at 14 d	Absorbed by hydrolysis, complete by 91–119 d	Minimal	Subcutaneous soft tissue approximation; especially in contaminated wounds
Glycomer 631 (Biosyn®)	Monofilament	Polyester composed of glycolide, dioxanone, and trimethylene carbonate	75% at 14 d and 40% at 21 d	Absorbed by hydrolysis, complete by 90–110 d	Slight	Subcutaneous soft tissue approximation where extended strength is not needed
Polyglyconate (Maxon®)	Monofilament	Copolymer of glycolic acid and trimethylene carbonate	80% at 7 d, 75% at 14 d, 65% at 21 d, 50% at 28 d, and 25% at 42 d	Absorbed by hydrolysis, complete by 180 d	Slight	Subcutaneous soft tissue approximation where more prolonged strength is needed

whenever possible. Because smaller-diameter material has less strength, the trade-off is that more individual sutures closer together are sometimes needed to close a wound. Where cosmetic appearance is important, as on the face, smaller-diameter material is preferred (**Table 41-4**).

Improper tissue handling further traumatizes the tissues and results in an increased risk of infection and poor scarring.[17] Gentle tissue handling using either skin hooks or the open limb of fine forceps is encouraged (**Figure 41-1**). Magnifying lenses such as surgical loupes can assist in accurate placement of sutures. While there are many types of **surgical loupes** available, a version useful in the ED is a magnifying power of 2.5× with the Keplerian lens system, which will provide a bright, clear image out to a field of view of 10 cm. Hemostasis is best achieved by direct pressure. Topical vasoconstrictors (such as epinephrine) applied to the wound edges and bed or mixed with the local anesthetic injected into the wound may help control bleeding in traumatic lacerations treated in the ED. With bleeding from vessels >2 mm in diameter, careful and selective placement of a ligature tie is often necessary. Electrocautery increases the risk of wound infection and scarring.[17] The technique requires training and policies for its use, to ensure patient and healthcare professional safety.

The best cosmetic outcome is achieved by carefully matching each layer of the wound with its corresponding counterpart on the opposite side, ensuring eversion of the wound edges and minimizing the amount of tension on the wound. As the wound heals and the swelling subsides, the wound will eventually flatten, becoming flush with the surrounding skin surface. Inadvertent inversion of the wound edges may result in an

TABLE 41-4 Recommended Suture Size Based on Laceration Location

Location	Suture Size
Scalp	3-0 or 4-0
Face	6-0
Trunk	4-0
Extremities	4-0
Digits	5-0

unsightly depressed scar. A variety of suture techniques can be used to handle wounds of nearly all shapes, irregularities, and depths (**Table 41-5**).

SIMPLE INTERRUPTED PERCUTANEOUS SUTURES

Individual simple interrupted percutaneous sutures are the most basic and most commonly used approach to close lacerations. Introduce the needle through the outer layer of the skin, and exit at the level of the dermis on one side of the wound. Then, reinsert the needle through the opposite wound edge starting at the level of the dermis and exit superficially (**Figure 41-2**). In order to ensure proper wound edge eversion, the needle should enter and exit the skin at equal distances from the wound and at an angle of 90 degrees. Wound edge eversion is achieved by taking a larger bite through the depth of the wound than through the more superficial layers (**Figure 41-3**).

The entrance and exit of the suture should be close enough to the wound edges that they are not puckered when the knot is tied but far enough away to allow the suture material a firm hold on the tissue. **Sutures are tied using square knots, and, generally, the number of knot ties should correspond to the suture size** (i.e., four ties for a 4-0 suture, five ties for a 5-0 suture, etc.). Additional ties do not increase the strength of a properly tied square knot; they only add to its bulk. The extra ties are to increase knot security and prevent unraveling. Once the knot is completed, it should be moved to one side of the wound so as to not rest directly over the edges. For simple linear lacerations, a useful approach is to place the first suture in the middle of the wound, creating

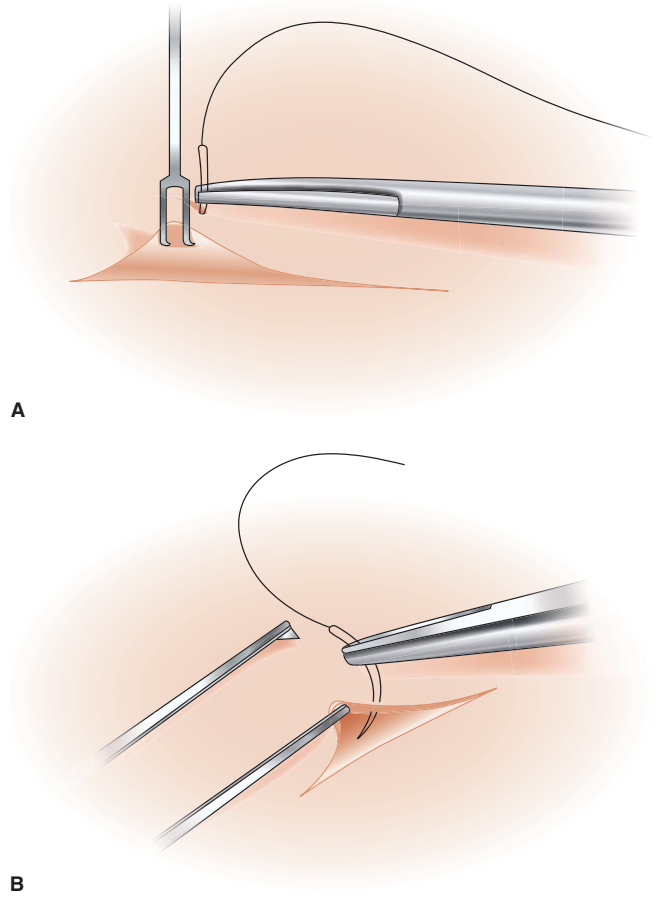

FIGURE 41-1. The skin hook (A) or one limb of a tissue forceps with teeth (B) is used to elevate the wound edge to facilitate placement of the percutaneous suture.

TABLE 41-5 Suture Techniques Based on Wound Type

Suture Type	Advantages	Disadvantages	Frequent Uses
Interrupted percutaneous	Excellent approximation for irregular and complex lacerations	Time-consuming May strangulate tissues	Low-tension wounds May be used with deep sutures for high-tension wounds
Continuous percutaneous	Rapid closure Accommodates edema	Less meticulous closure than interrupted sutures Wound may dehisce if a single knot unravels and no deep sutures were placed	Percutaneous closure in conjunction with deep sutures
Deep dermal	Reduces tension on wound surface Allows early removal of percutaneous sutures, avoiding hatch marking May reduce scar width	May increase infection in contaminated wounds	High-tension wounds Closure of dead space
Continuous subcuticular	Rapid Reduces tension on wound surface Reduces or eliminates need for percutaneous sutures May reduce scar width	Technically difficult Less accurate approximation than interrupted sutures Wound may dehisce if a single knot unravels	Cosmetically visible areas to reduce scarring
Vertical mattress	Excellent wound edge eversion Combines advantages of deep and superficial sutures	May cause tissue strangulation	Thin or lax skin with little dermal or fascial tissue High-tension areas (e.g., extremities)
Horizontal mattress	More rapid than simple interrupted sutures Avoids punctures close to wound edges that may impair perfusion Accommodates wound swelling	Requires skill to achieve wound edge eversion	Volar wounds of the hands Initial approximation of high-tension wounds
Half-buried horizontal mattress	Less compromising to flap tip perfusion and stellate lacerations	Technically difficult	Corner stitches and flaps Stellate lacerations

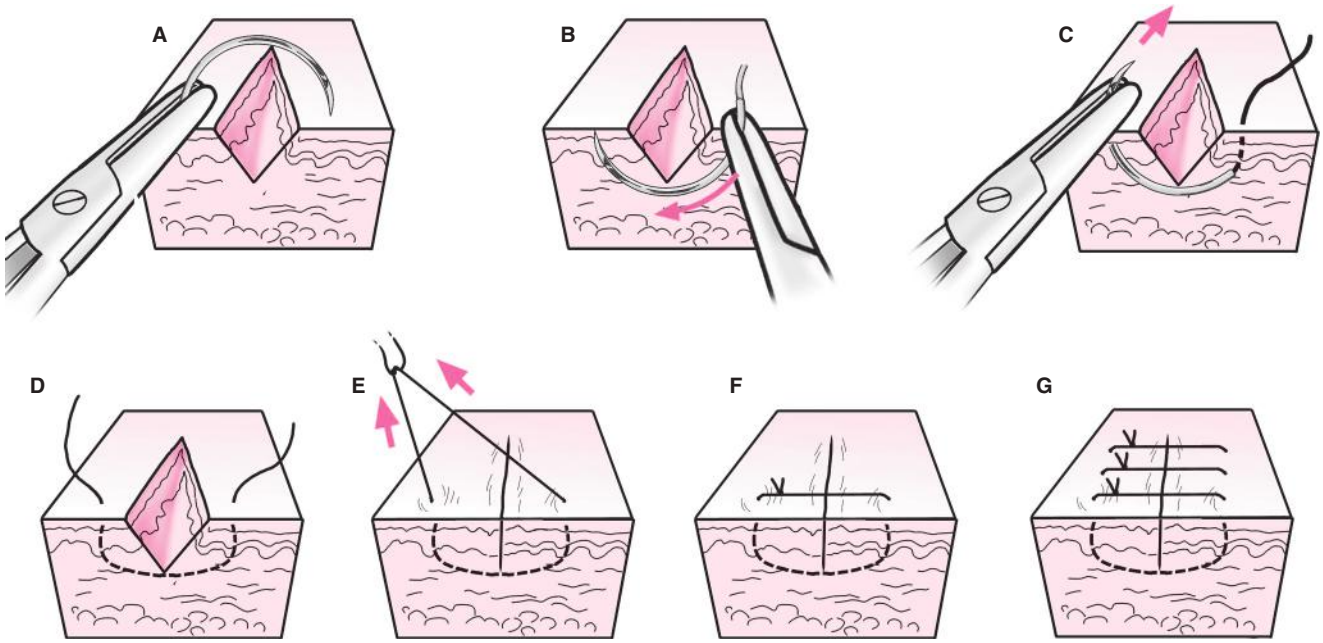

FIGURE 41-2. Placement of simple interrupted percutaneous sutures. **A.** Insert the needle at a 90-degree angle to the skin. **B.** Drive the needle through the tissue until the tip exits the skin. **C.** Grasp the needle behind the tip and pull it through the wound. **D.** The suture should enter and exit the skin equidistant from the wound edges. **E.** Pull the suture to oppose the wound edges and cinch down the knot. **F.** Complete the knot to one side of the laceration. **G.** Apply additional sutures equidistant from each other until the wound is closed. Printed in the United States of America, Figure 78-6. By The McGraw-Hill Companies, Inc.]

two smaller segments that are sequentially bisected into smaller segments until adequate coaptation of the edges is achieved.

CONTINUOUS (RUNNING) PERCUTANEOUS SUTURES

The major advantage of this method is its rapidity, as the entire wound is closed before any of the suture material is cut. This technique is most appropriate for long linear lacerations. Because it does not allow for precise wound edge apposition, it should be avoided in irregularly shaped lacerations. With this method, the first suture is placed at one end of the laceration similarly to an interrupted percutaneous suture. After the knot is tied, the suture material is not cut, and the needle is reintroduced into the skin on the opposite side, pulling the suture across the wound at a 65-degree angle (**Figure 41-4**). The needle then crosses the depth of the wound in a circular motion perpendicular to the wound, exiting on the opposite side approximately 3 to 5 mm from the wound edge. This process is repeated as needed until the entire wound is approximated and a second knot is tied.

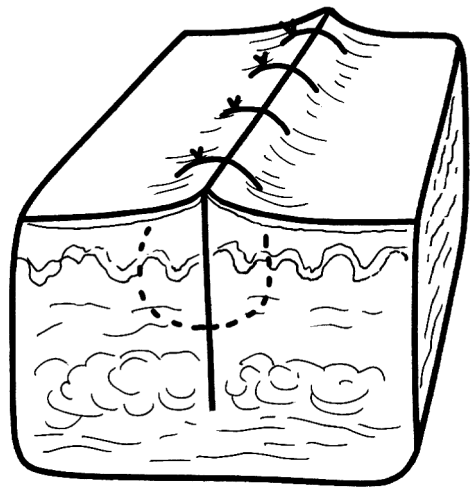

FIGURE 41-3. Wound edge eversion. The distance of the suture from the wound edge is greater at the depth of the wound than at the surface, promoting wound edge eversion when tightened. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 41-77-8. By The McGraw-Hill Companies, Inc.]

BURIED DERMAL SUTURES

Deep dermal sutures are used to reduce tension on the wound and to close dead spaces. Placement of buried dermal sutures requires judgment because the benefits for nongaping small wounds are unproven and their presence may increase the risk of infection in contaminated wounds.[18,19] Sutures through adipose tissue do not hold tension, are unnecessary in clean surgical cases, and only promote infection in contaminated wounds.[19,20]

With buried dermal sutures, the needle is first inserted at the level of the mid dermis on one side of the wound and then exits more superficially below the dermal–epidermal junction (**Figure 41-5**). The needle is then introduced below the dermal–epidermal junction on the opposite wound side and exits at the level of the mid dermis. Thus the knot becomes buried in the depth of the tissue when tying of the suture is completed. The first suture is placed at the center of the laceration, followed by additional sutures that sequentially bisect the wound. The number of buried sutures should be minimized.

CONTINUOUS SUBCUTICULAR SUTURES

The continuous subcuticular suture is one of the more complex methods of wound closure. The major advantage of this method is that it results in fairly good wound approximation, often without requiring any percutaneous sutures. For this technique, after anchoring the absorbable suture at one end of the wound, sequential, horizontally oriented "bites" are taken immediately below the dermal–epidermal junction, working toward the other end until the wound is adequately

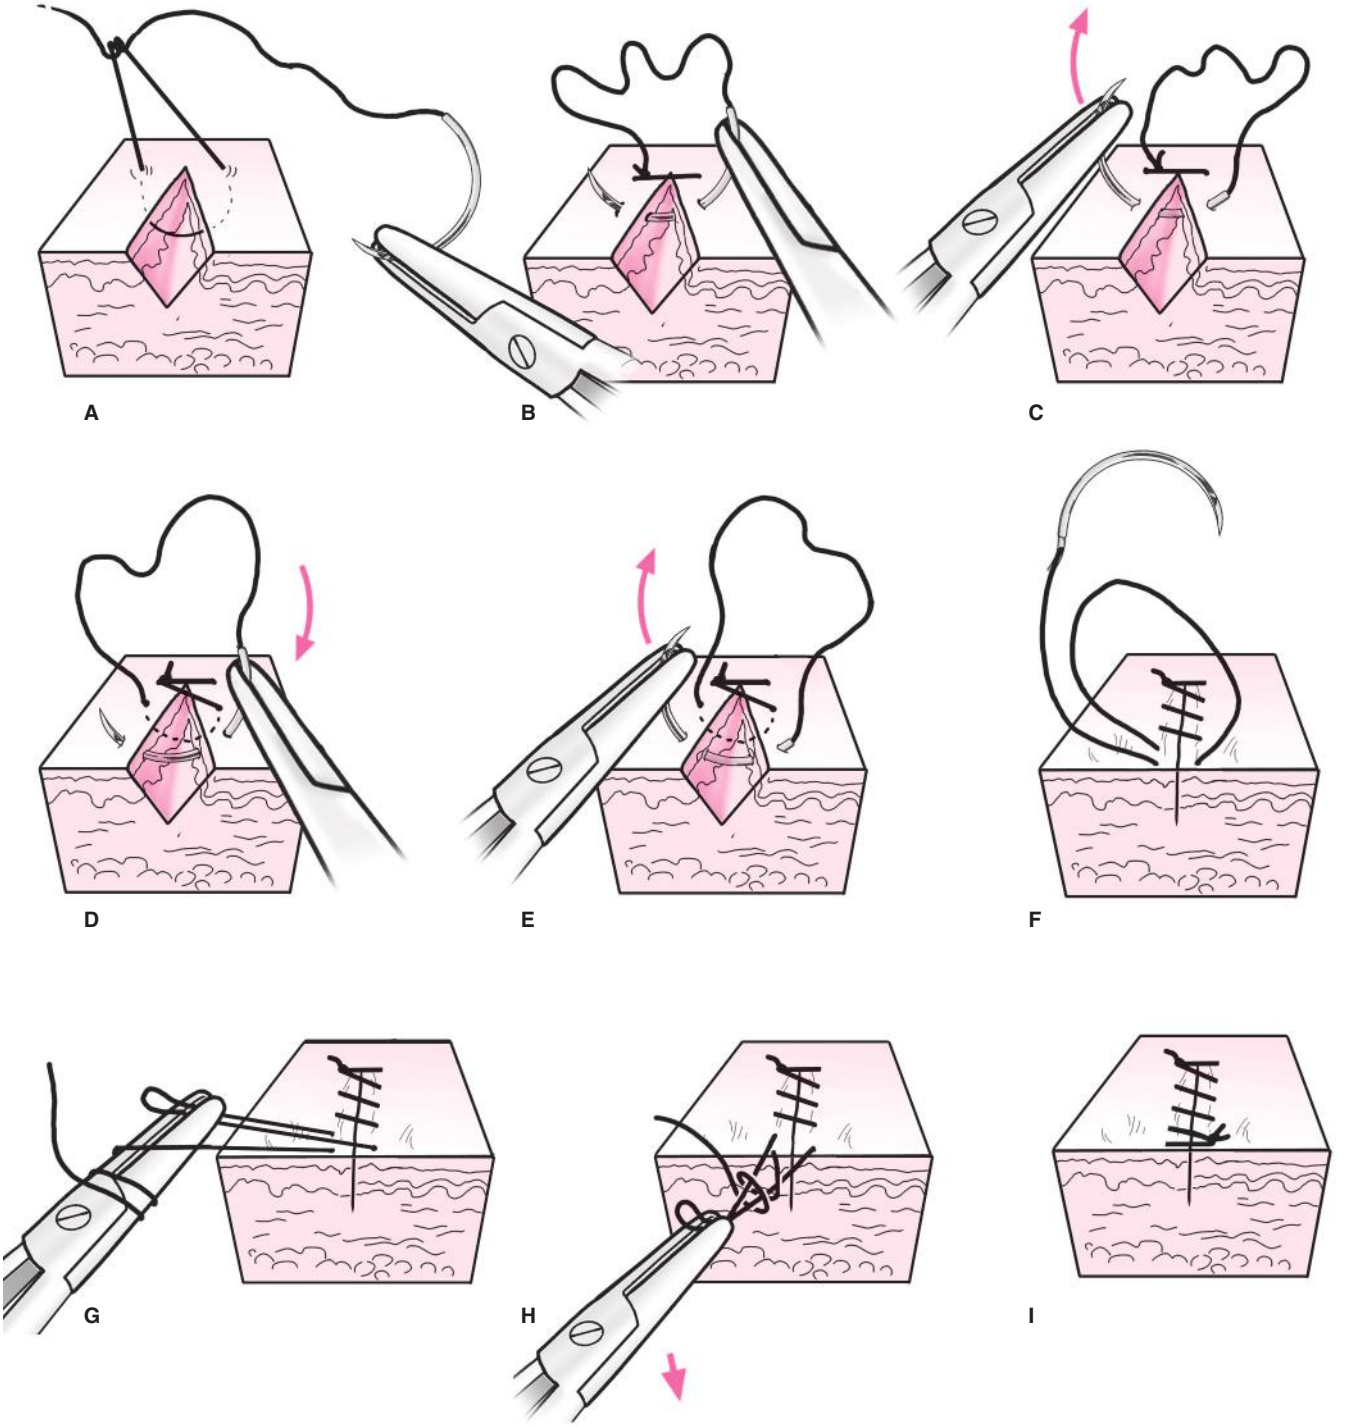

FIGURE 41-4. Continuous or running percutaneous suture. **A.** Place the initial stitch as a simple interrupted stitch, but do not cut the suture after the knot is securely tied. **B** and **C.** Place a second stitch 3 to 5 mm from the first stitch as if placing another simple interrupted stitch. **D** and **E.** Place a third stitch 3 to 5 mm from the second stitch and continue to place additional stitches until the end of the laceration is reached. **F.** Do not pull the last throw taut against the skin; the loop will act as the tail end of the suture for knot tying. **G.** Loop the needle end of the suture twice around the tip of the needle driver and grasp the last throw with the tips of the needle driver. **H.** Pull the last throw through the loops until the knot is against the skin. **I.** Perform three to five more instrument ties to secure the knot, and then cut off the excess suture. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-9. By The McGraw-Hill Companies, Inc.]

approximated (**Figure 41-6**). The second knot is tied with the tails cut short so as to remain buried.

VERTICAL MATTRESS SUTURES

Vertical mattress sutures combine some of the advantages of deep and percutaneous sutures. They also result in excellent wound edge eversion. Vertical mattress sutures are particularly useful in very thin or lax skin and in areas where the deep subcutaneous tissues are too fragile to be used for anchoring tension-reducing sutures (e.g., over the shin). After taking a large, deep bite from both sides of the wound ("far to far"), the direction of the needle is reversed, and a smaller superficial bite is taken from both sides ("near to near") of the laceration (**Figure 41-7**). Vertical mattress sutures may result in excessive tension on the more superficial

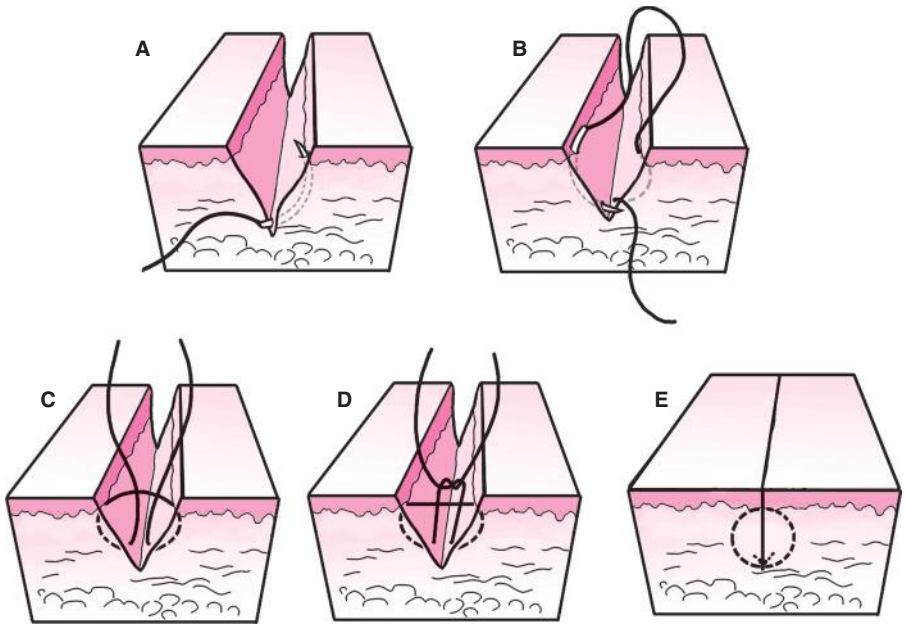

FIGURE 41-5. Buried dermal suture. **A.** Insert the needle into one side of the base of the wound, and drive the needle from deep to superficial and exiting at the dermal–epidermal junction. **B.** Insert the needle through the dermal–epidermal junction on the opposite side of the wound and drive it through the base of the wound. The suture should exit the base of the wound across from and level with the entrance site of the first throw. **C.** Pull both free ends of the suture up and out through the laceration. **D.** Tie a knot in the suture. **E.** Pull both free ends of the suture to lower the knot to the base of the wound and oppose the tissue. Tie two additional knots to secure the suture. Cut off any excess suture. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-19. By The McGraw-Hill Companies, Inc.]

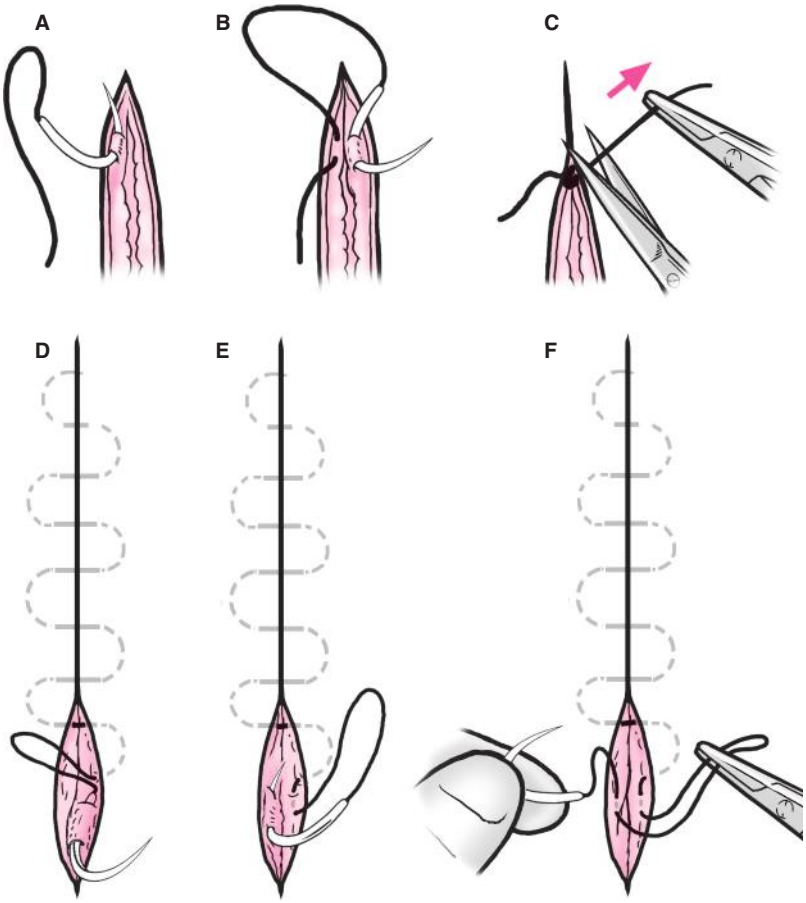

FIGURE 41-6. Continuous subcuticular sutures. **A, B,** and **C.** Place the first stitch into the dermis, just inside the laceration edge, as a buried knot. **D.** Place the continuous suture until the opposite end of the laceration is reached. **E.** The final throw should be left lax with a trailing loop of suture. **F.** The loop should be used as the "tail end" to perform an instrument tie. Tie three or four knots in the suture. Lift the free ends of the suture and cut them just above the knot. Apply adhesive tape across the laceration to help maintain the apposition of the wound. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-18. By The McGraw-Hill Companies, Inc.]

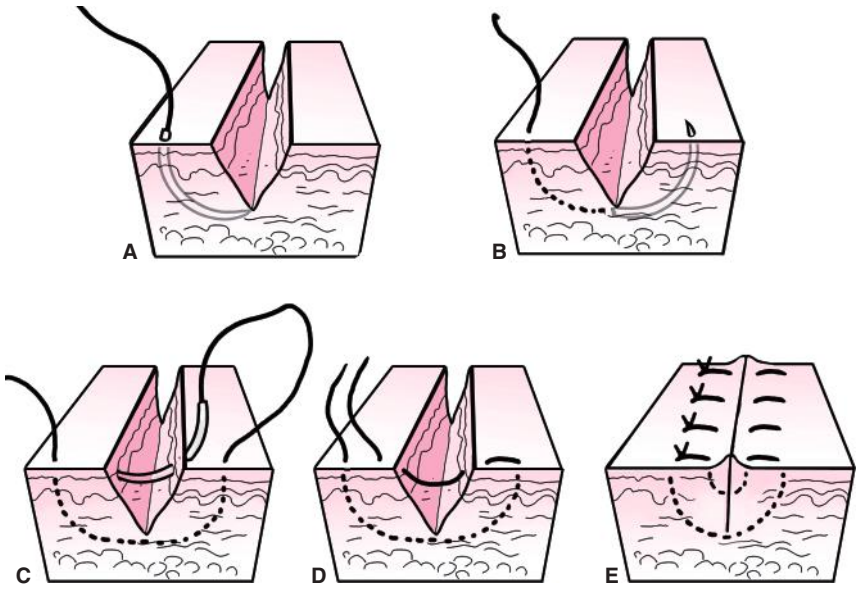

FIGURE 41-7. Vertical mattress suture. **A.** The needle should enter and exit the skin 1.0 to 1.5 cm from the wound edge. **B.** The needle should traverse the base of the wound and grasp a large amount of tissue. **C** and **D.** Reverse the needle. The second throw should enter and exit the skin approximately 2 to 3 mm from the wound edge. The first and second throws must be directly over each other and parallel. **E.** Tie the suture to approximate the wound edges. The first throw will close the wound base and relieve the tension at the skin surface. The second throw approximates and everts the skin edges. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-11. By The McGraw-Hill Companies, Inc.]

skin edges, which reduces blood supply to the skin and may result in necrosis of the wound margins.

A modification of the standard vertical mattress suture is the shorthand version. In this approach, the first throw is close to the wound edges ("near to near"); the suture is then grasped and pulled away from the wound, elevating the wound edges while a second throw is performed farther away from the wound ("far to far") (**Figure 41-8**).[21] This shorthand version can be performed in less time with the same outcome; however, blind placement of the larger bite may injure underlying structures.

HORIZONTAL MATTRESS SUTURES

The horizontal mattress is a good suture technique to close wounds with poor circulation to the wound edges because no percutaneous punctures

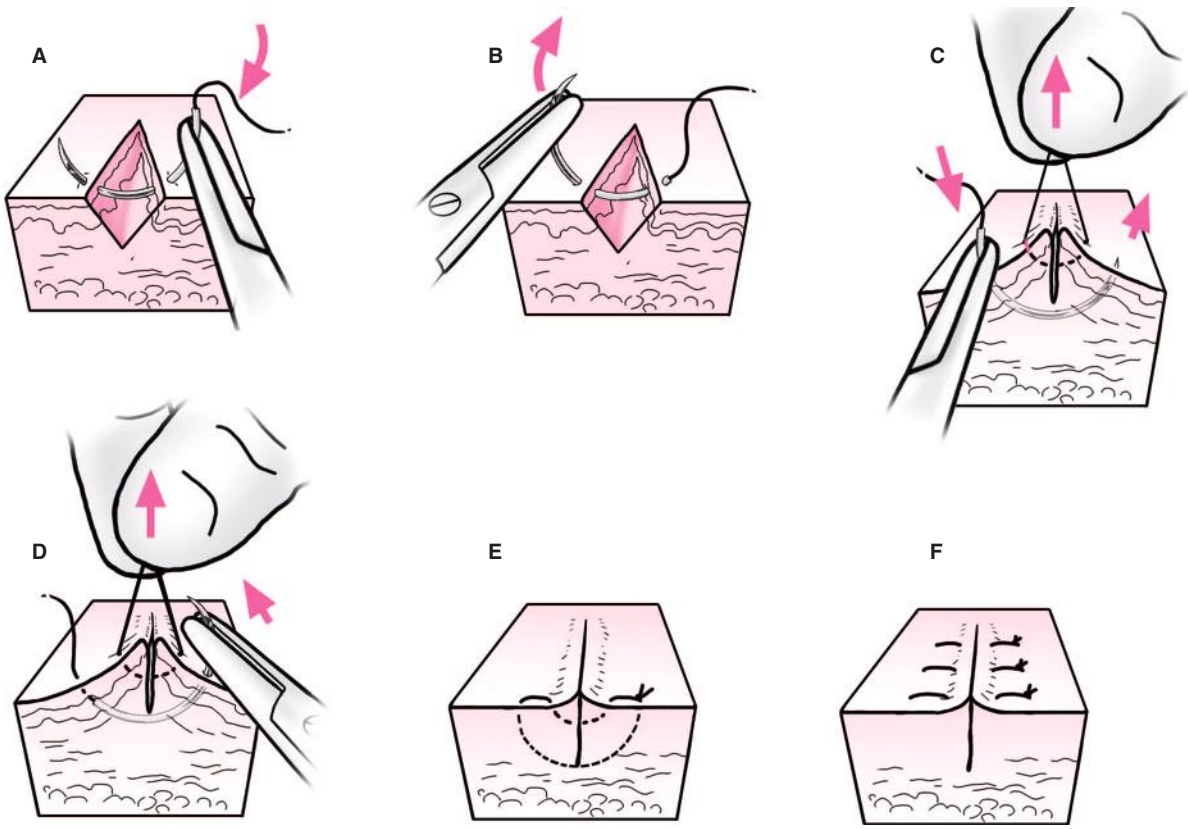

FIGURE 41-8. The "shorthand" vertical mattress suture. **A** and **B.** Place the first throw close to the lacerated wound edge to approximate the skin edges. **C.** Grasp and pull the suture to elevate the wound edges. This allows the needle to more easily take a large bite of tissue on the second throw. **D.** Place the second throw 1.0 to 1.5 cm from the wound edge. Release the suture. **E.** Tie the suture to approximate the wound edges and evert the skin surface. **F.** The final product looks exactly the same as the traditional vertical mattress suture. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. FIGURE 41-9. Horizontal mattress suture. **A.** The needle should enter and exit the skin 0.5 to 1.0 cm from the wound edge. **B.** The needle should traverse the base of the wound. **C.** Reverse the needle and make a second throw 0.5 cm from the first. **D.** The needle must enter and exit the skin and the wound edges so that the first and second throws are parallel to each other. **E.** Pull the free ends of the suture taut to oppose and evert the wound edges. **F.** The final result. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-14. By The McGraw-Hill Companies, Inc.]

that could further disrupt skin perfusion are placed close to the wound edges. This suture also reduces tension at the wound edges and reduces the potential for subsequent local necrosis. Horizontal mattress sutures can close a wound with fewer individual stitches because each stitch encases more tissue than other techniques (**Figure 41-9**). This suture is useful on the volar surfaces of the hands and fingers, because these delicate skin areas may swell but the skin edges are not easily cut due to the placement of the skin punctures far from the wound. The main disadvantage of the horizontal mattress stitch is the skill required to place the suture to achieve wound eversion.

HORIZONTAL HALF-BURIED MATTRESS SUTURES

Horizontal half-buried mattress sutures are particularly well suited for closing the tip of skin flaps and stellate lacerations because they minimize strangulation of the blood supply to the tip. **The key to this stitch is that the needle and suture pass through the dermis of the tip and not the epidermis.** The needle is introduced percutaneously through one side of the wound, then horizontally through the tip at the level of the dermis. The suture is completed by exiting the skin through the other side and tying the knot (**Figure 41-10**).

STAPLES

The major advantages of staples are their speed and relative ease of use.[22-26] They are also cost-effective, especially when devices containing fewer staples are used in the ED, where most lacerations are relatively short. However, of all closure techniques, staples allow the least precision in wound approximation. As a result, **their use should be limited to linear, nonfacial lacerations**. Staples are particularly useful for scalp lacerations because the hair does not require clipping and staples are easier to locate than sutures for removal.[22-25] However, deep sutures may be required to

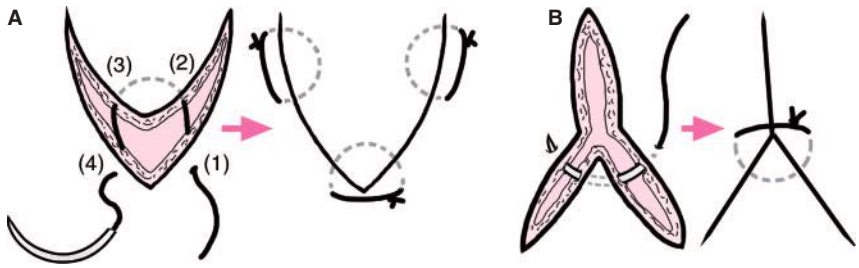

FIGURE 41-10. Half-buried horizontal mattress suture. **A.** To close a flap tip, place the first stitch percutaneously through the skin adjacent to the tip of the flap. Advance the needle through the dermal layer of the flap, the dermal layer of the skin adjacent to the tip of the flap, and out the skin adjacent to the tip of the flap opposite to where the stitch began. The needle must traverse the dermis of the flap and adjacent tissue at the same level of the dermis to properly approximate the wound edges. Gently pull on the free ends of the suture to approximate the flap against the adjacent skin edges. Tie and secure the suture in the usual manner. **B.** To close a stellate laceration, insert the needle through the skin of the largest flap. Advance the needle so that its tip exits the dermis. Continue to advance the needle through the dermis of each flap. The half-buried horizontal mattress stitch should encompass the tips of all the flaps. [Reproduced with permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. All rights reserved. Printed in the United States of America, Figure 78-15. By The McGraw-Hill Companies, Inc.]

close lacerations of the galea aponeurotica, whereas percutaneous sutures are always desirable when hemostasis is difficult. In appropriate patients, staples have infection rates and cosmetic outcomes similar to sutures. Staple removal is more painful than removal of sutures.[27]

Although a variety of stapling devices are commercially available, there are few practical differences between them from the standpoint of the emergency practitioner. The key principle is to approximate the wound edges and align the centerline indicator of the head of the stapler so that the legs of the staple will straddle the wound an equal distance on each side (**Figure 41-11**). Touch the stapler lightly to the skin so that the staple comes out and pinches the wound edges together with eversion. **Pressing firmly downward can cause depression of the wound edges.** After the staple is set, pull the stapler slightly backward to disengage. New stapling devices that allow placement of deep staples are available, but they have not been studied in the ED.

ADHESIVE TAPES

Adhesive tapes are the least reactive and most cost-effective of all wound closure devices.[28] Their application is simple, painless, and rapid, and they also do not require formal removal. However, adhesive tapes tend to slough off when exposed to any tension or moisture. As a result, their use is limited to very low-tension simple wounds or for closure of fragile skin subject to low tension, like superficial skin tears. They are also of little use in noncompliant patients because they are so easy to remove.

In order to increase their adhesiveness, skin tapes should be used in conjunction with an adhesive adjunct, such as tincture of benzoin or Mastisol®, that is gently painted on either side of the wound edges and allowed to dry until tacky. Because these adhesive adjuncts are toxic to wounds, avoid their introduction into the wound itself.

The tapes should be placed perpendicular to the wound edges approximately 2 to 3 mm apart. With long lacerations, the first strip of tape should be placed across the center of the wound followed by additional strips on either side of the wound center (**Figure 41-12**). To reduce the possibility of skin blistering or premature dislodgement, additional strips should be placed over the ends of the other strips, parallel to the laceration.

Simple skin tapes may also be used to reinforce lacerations after suture or staple removal. The cosmetic results and dehiscence rates after closure of small (<4 cm) and superficial facial lacerations with tapes are similar to those with cyanoacrylate tissue adhesives.[29] A version of skin tape comprised of two independent parts, each with an adhesive underside and multiple interlocking filaments attached to pulling ends, is useful for simple wound closure (Steri-Strip™ S Surgical Skin Closure; 3M, St. Paul, MN; **Figure 41-13**).[30,31]

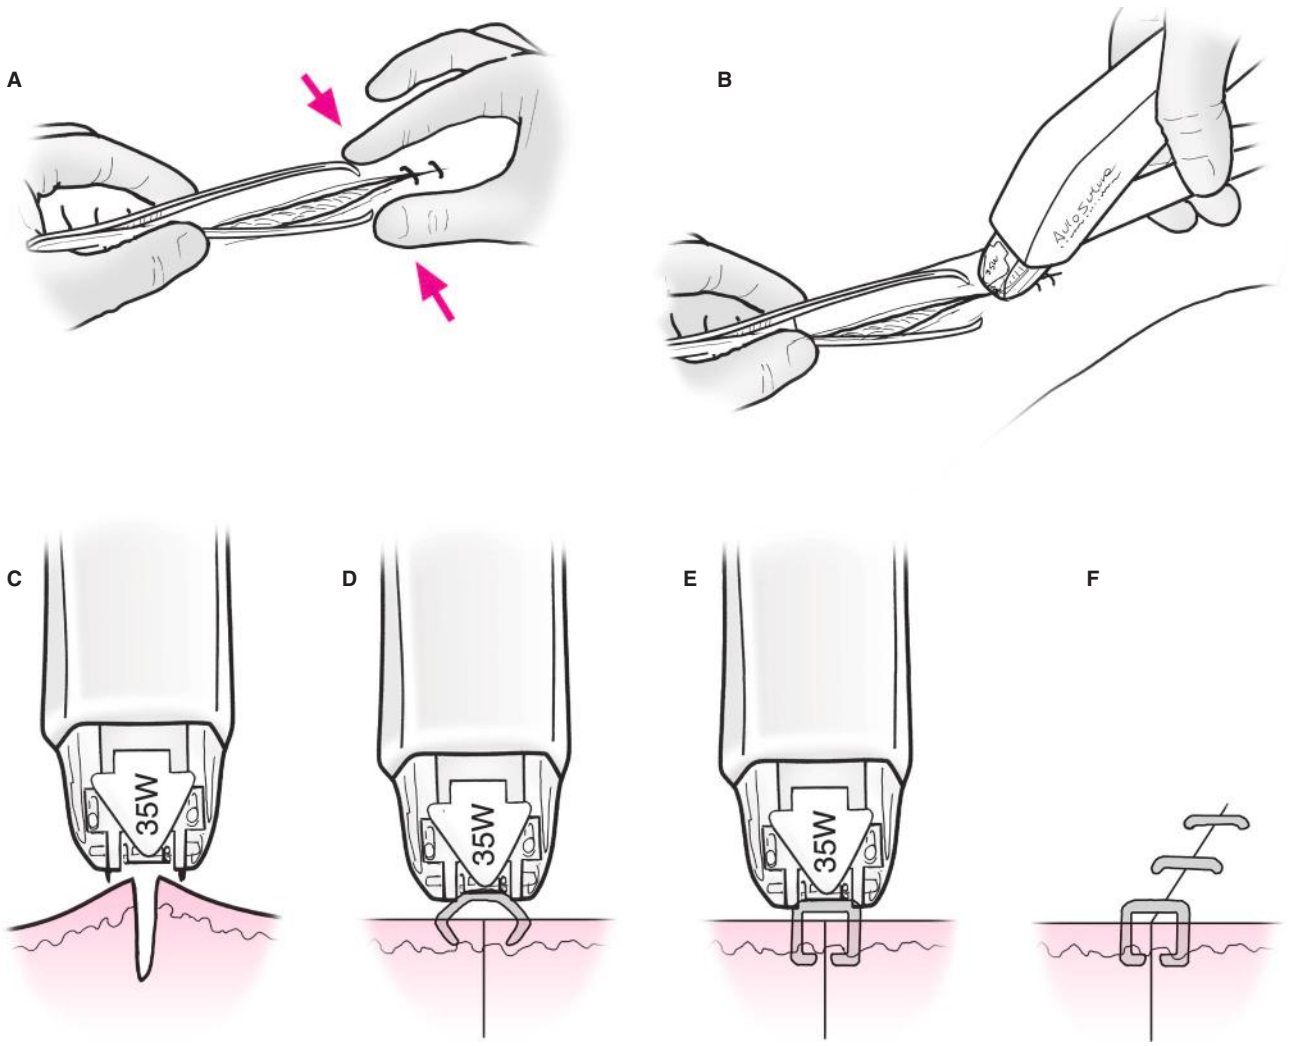

FIGURE 41-11. Laceration repair with staple closure. **A.** The wound edges are opposed and everted. **B.** The stapler is applied over the laceration. **C.** The stapler is applied over the everted wound edges. **D.** The plunger advances the staple into the wound margins. **E.** The anvil bends the staple into shape. **F.** The final result. CYANOACRYLATE TISSUE ADHESIVES

The cyanoacrylate tissue adhesives are liquid monomers that polymerize into a stable bond when they come into contact with moisture.[32] The adhesive is applied topically to the epidermis across the apposed wound edges, forming a strong bridge that holds the wound closed. The adhesive is sloughed off in 5 to 10 days as the skin renews itself.

The tissue adhesives offer many advantages over other wound closure methods. They may be applied rapidly and painlessly to any easily approximated laceration. Because they slough off spontaneously, they do not require removal. The cyanoacrylates form an occlusive dressing that serves as a barrier to microbial penetration. They have antibacterial effects in vitro and reduce infection rates in experimental contaminated wound models in animals.[33]

A B

FIGURE 41-13. Application of Steri-Strip™ S Surgical Skin Closure (3M, St. Paul, MN). **A.** The two adhesive pads are applied to the two sides of the wound approximately 1 to 2 mm from the wound edges. **B.** The skin edges are drawn together by pulling on the clear pulling tabs across the wound at a 45-degree angle in opposite directions approximating and aligning the wound edges.

The cyanoacrylate tissue adhesives are similar in strength to 4-0 poliglecaprone subcuticular sutures, but weaker than staples.[34] Tissue adhesives should not be used alone for high-tension wounds nor should they be used for wounds subjected to varying dynamic tension, like over a moving joint. However, they can be used in conjunction with deep dermal sutures and/or immobilization aimed at reducing wound tension. A variety of octyl- and butyl-based cyanoacrylate adhesives are now commercially available. The tensile strength and surface characteristics of octyl- and butyl-cyanoacrylate differ (**Table 41-6**).[35] Octyl-cyanoacrylate is generally stronger and more flexible than butyl-cyanoacrylate, allowing its use on irregular surfaces and long lacerations. The mechanical characteristics of the adhesive are also determined by a number of additives such as chemical initiators and plasticizers.

Wound closure with the tissue adhesives is faster than with other wound closure methods, is cost-effective compared with sutures, and has comparable rates of infection and ultimate cosmetic appearance.[36-41] Patient-reported pain scores and physician-reported procedure time are lower with tissue adhesives.[42,43] However, there is a small increase, about 4%, in wound dehiscence using tissue adhesives, emphasizing the need to limit the use of adhesives to low-tension wounds.

TABLE 41-6 Comparison of Butyl- and Octyl-Cyanoacrylate

	Octyl-Cyanoacrylate	Butyl-Cyanoacrylate
Number of carbons in side chain	8	4
Bursting strength	High	Moderate
Plasticizers that enhance flexibility	Present	Absent
Water resistance	Moderate	Minimal
Need for refrigeration	No	Yes
Clinical experience	Short and long incisions and lacerations	Limited to incisions and lacerations up to 8 cm
Viscosity	High	Low
Cost	Moderate	Slightly less than octyl-cyanoacrylate
Polymerization time	30–45 s	5–10 s
Working time once applicator opened	2–3 min	Unlimited

Few studies have directly compared the various cyanoacrylate tissue adhesives against each other. For closure of short, simple facial lacerations in children, comparable results are seen with either type of cyanoacrylate.[44] For closure of pediatric operative wounds, octyl-cyanoacrylate had a lower wound dehiscence rate.[45]

To ensure optimal results, tissue adhesives should only be used when laceration edges are easily approximated with the practitioner's hands, forceps, or tape. An assistant can maintain constant and meticulous wound edge apposition while the adhesive is applied. With octyl-cyanoacrylate, the adhesive is carefully expressed through the tip of the applicator and gently brushed over the wound surface parallel to the wound edges in a continuous, steady motion (**Figure 41-14A**). **The adhesive should cover the entire wound and extend 5 to 10 mm on either side of the wound edges.** After allowing the first layer of the adhesive to polymerize for 30 to 45 seconds, apply a second layer of adhesive. With butyl-cyanoacrylate, the adhesive is applied from the tip of the applicator in discrete drops along the wound edges, similar to "spot welds" (**Figure 41-14B**), or as a thin single layer.

With long or complex lacerations, adhesive tape can be used to approximate the wound edges, making closure with an adhesive easier (**Figure 41-15**). Application of a tissue adhesive *on top of adhesive tape* also results in greater wound-bursting strength than either device alone.[46] A combination of a mesh tape and tissue adhesive has recently become available and may be especially useful on very long lacerations.[47] Care in application will reduce some of the common problems associated with tissue adhesives (**Table 41-7**).

HAIR APPOSITION

Simple scalp wounds, without contamination or active bleeding, may be closed via the hair apposition technique.[48,49] This technique is an efficient alternative to more traditional methods of closure, with potentially fewer complications, less pain to the patient, and less overall cost.[50-52] Contraindications to hair apposition closure include large lacerations (e.g., >10 cm), grossly contaminated wounds, uncontrolled bleeding, wounds that gape open and cannot be closed without significant tension, and hair strands adjacent to the wound that are less than 3 cm in length.

After wound irrigation and control of bleeding, select and twist together three to seven stands of hair at least 3 cm in length that lie close to the edge on one side of the wound. Repeat this process directly opposite on the other side of the wound. Then twist these two hair bundles in a full 360-degree revolution and secure the intertwined hair bundles by applying a few drops of tissue adhesive. Repeat this process

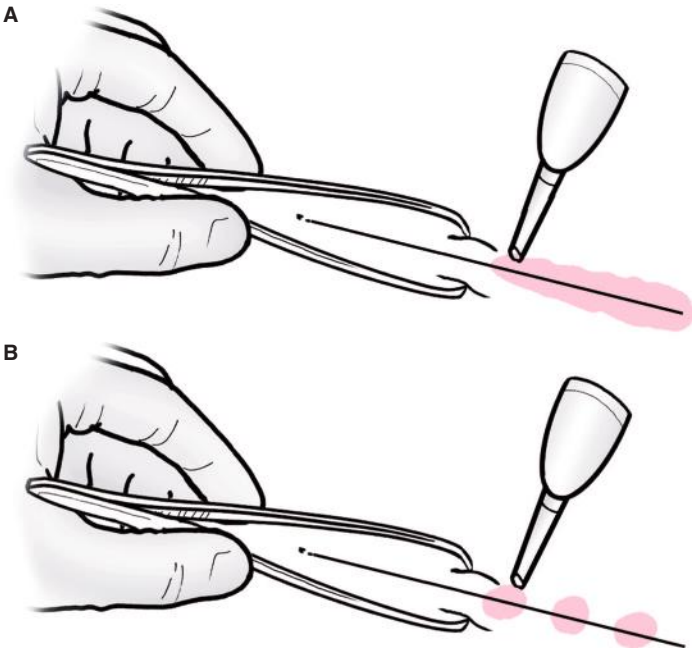

FIGURE 41-14. Laceration repair with tissue adhesives. **A.** Apply the adhesive in two or three layers along the wound edge. **B.** The adhesive may also be applied in spots over the laceration. [Reproduced with modification and permission from Reichman EF, Simon RR (eds): *Emergency Medicine Procedures*. Copyright © 2004 by Eric F. Reichman, PhD, MD, and Robert R. Simon, MD. TABLE 41-7 Avoiding Potential Pitfalls of Tissue Adhesives

Problem	Ways to Avoid the Problem
Runoff	Position patient with wound parallel to floor. Use high-viscosity adhesive. Apply small, controlled amount of adhesive.
Spillage into eyes	Cover eyes with moist gauze barrier. Position patient so adhesive will not run into the eye. For eyebrow and forehead lacerations, place the patient in the Trendelenburg position. For lacerations on the cheek and lower face, place the patient in the reverse Trendelenburg position. Apply petrolatum-based ointment on the eyelashes before applying adhesive.
Wound dehiscence	Avoid adhesive use for high-tension wounds. Reduce exposure to friction or moisture. Use deep sutures or immobilization for high-tension wounds. Do not introduce adhesive into wound.
Wound infection	Use adhesives only for properly selected wounds. Use proper wound preparation, including irrigation, exploration, and, when necessary, debridement. Use proper application technique.
Getting stuck to the wound	Practice expressing small amounts of adhesive and controlling runoff. Alternate the hand used to oppose wound edges prior to complete polymerization of the adhesive.

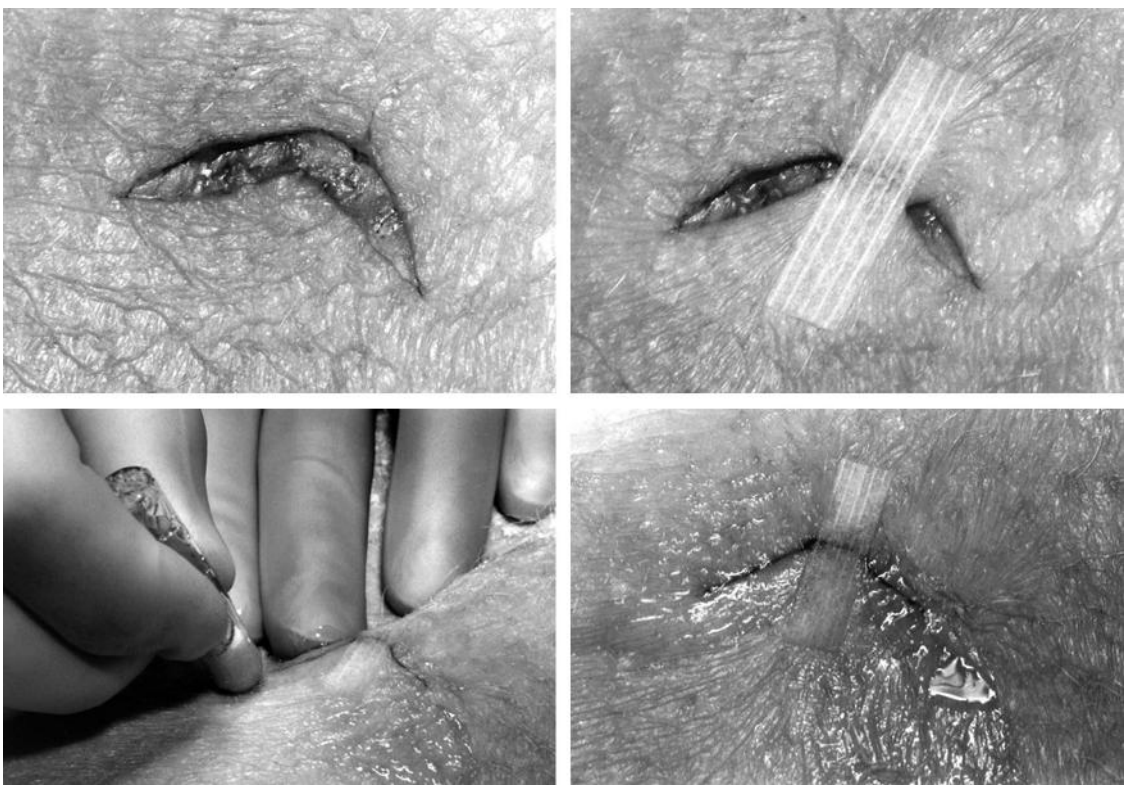

FIGURE 41-15. Closure of a long or complex laceration is achieved by applying adhesive tape to approximate the wound edges followed by application of the tissue adhesive over the approximated wound and tape.

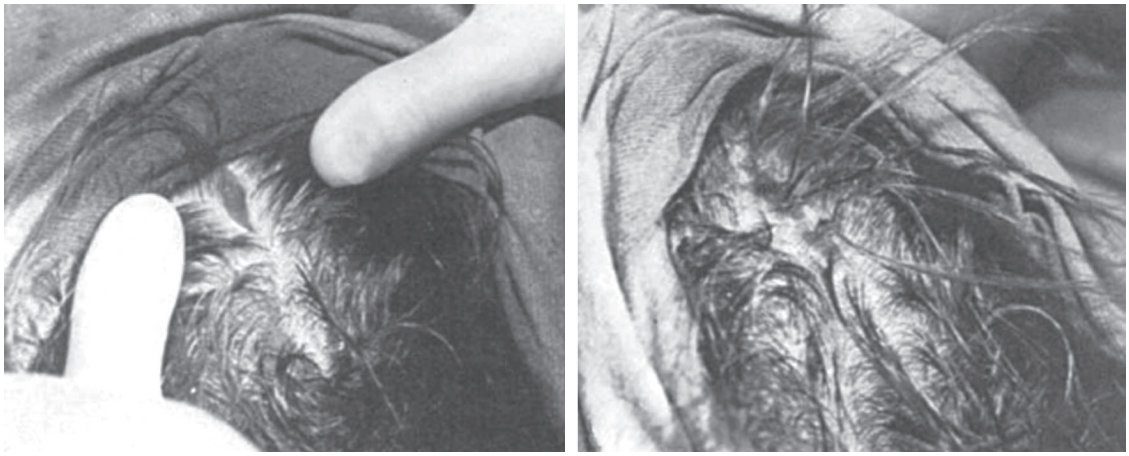

FIGURE 41-16. Hair apposition technique. **A.** Simple linear scalp wound. **B.** Three to seven hair strands on each side of the laceration are separately twisted into bundles. The two bundles on the opposite side of the wound are then twisted in a full 360-degree revolution and secured by applying a few drops of tissue adhesive. The process is repeated as needed to close the full length of the laceration. [Reproduced with permission from Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine*, 4th ed. Copyright © 2004. Saunders, An Imprint of Elsevier.]

as needed to close the full length of the laceration (**Figure 41-16**). The patient will not need routine return because the tissue adhesive will flake off and the hair will unravel in about a week.

CHAPTER 42

Face and Scalp Lacerations

Wendy C. Coates

INTRODUCTION AND EPIDEMIOLOGY

Lacerations of the face and scalp are proximate in location but have important differences regarding repair. Facial wounds are the most cosmetically apparent of all wounds and therefore warrant careful evaluation and meticulous repair technique for the best possible outcome. Scalp wounds are less visible and are typically closed with less attention to detail. Most facial and scalp lacerations can be closed by the emergency physician, but consult with specialists if the technical aspects of closure are complex.

Three common principles guide repair of facial and scalp lacerations.[1] First, cleanse, irrigate, and remove foreign material to minimize infection. Second, limit debridement of skin edges because the excellent blood supply enables tissues to recover that initially appear nonviable. And third, if local anesthetic infiltration distorts anatomy and hinders wound edge alignment, use regional nerve blocks (see chapter 36, "Local and Regional Anesthesia").[2]

Use nonabsorbable monofilament suture for facial skin. Rapidly absorbable suture and tissue adhesives are alternatives in selected locations and for children.[3,4] Use absorbable suture for mucosa and facial layers. To minimize scarring, place percutaneous sutures on the face 1 to 2 mm from the wound edges, 3 to 4 mm apart, with everted edges. Place mucosal sutures 2 to 3 mm from the wound edges, 5 to 7 mm apart, and superficial so as to only include the mucosa and not the underlying muscle or fascia. Use of magnification with surgical loupes may facilitate more accurate suture placement in facial wounds.

Ask about the possibility of domestic violence in patients with facial injuries, and notify appropriate authorities if violence is suspected (**Table 42-1**).[5-7]

PATHOPHYSIOLOGY

Facial and scalp wounds are most often caused by a combination of sharp and blunt mechanisms. Lacerations caused by sharp objects likely have discrete edges but may extend deeply and involve underlying structures, such as the muscles of facial expression, nerves, and arteries. Wounds caused by blunt forces burst the skin open, damage cells, and produce tissue edema, all of which slow the wound-healing process. As a result, it takes an average of 10 times fewer bacteria to cause an infection in a blunt wound compared with a sharp wound. Blunt forces are also more likely to cause diffuse underlying damage, such as fractures of the facial bones or skull.

In most patients with isolated facial trauma resulting in lacerations, the incidence of facial fractures is low, especially in children.[8] However, in multiply injured patients, suspect underlying fracture in facial lacerations involving the infraorbital area, zygoma, nose, lips, and intraoral mucosa, so perform careful physical examination and obtain facial CT scans.[9,10]

Facial and scalp lacerations have a low incidence of postrepair infection, so **primary closure can usually be done in wounds that are not obviously infected, regardless of the duration of time since the injury**[11-13] **or even if injury was from a bite.**[14,15] The presence of foreign bodies, such as soil, glass, or wood fragments, complicates wound healing.[13]

SCALP AND FOREHEAD

ANATOMY

Both the scalp and forehead overlie bone with little cushioning fat and have thick skin (**Figure 42-1**). The one difference is that the scalp has

TABLE 42-1 Maxillofacial Injuries and Domestic Violence in the ED

Most victims of domestic violence have maxillofacial injuries.
Women are more commonly affected than men.
Fist is most common weapon.
Left side of face is most common site of injury (from right-hand-dominant assailants).
Nasal bone is commonly fractured.

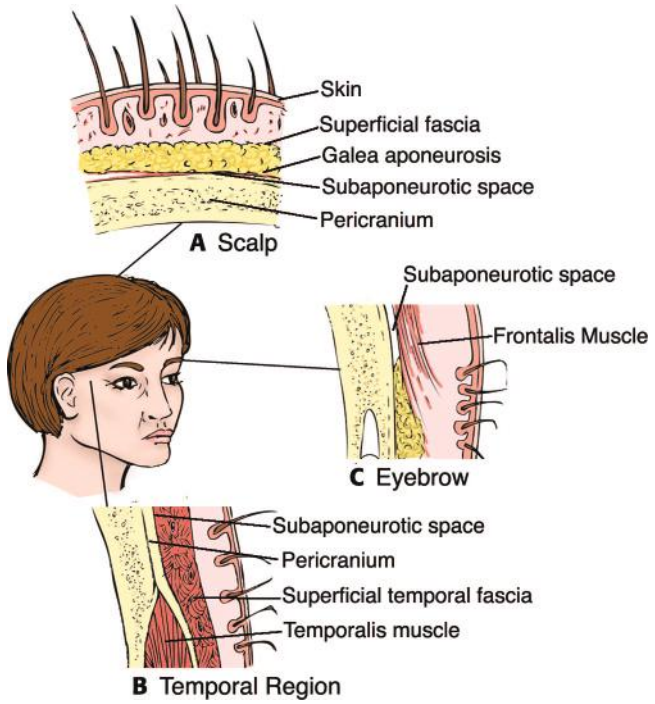

FIGURE 42-1. Layers of the scalp.

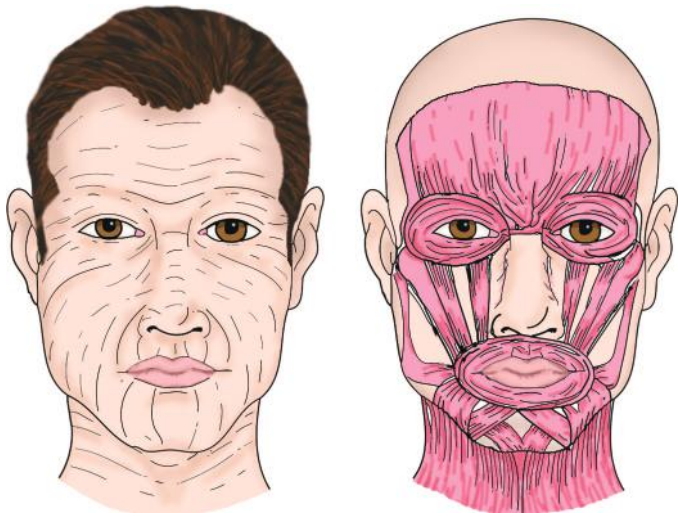

FIGURE 42-2. Skin tension lines. Skin tension lines are perpendicular to underlying muscles.

abundant hair follicles and sebaceous glands. Three branches of the external carotid artery (occipital, superficial temporal, and posterior auricular arteries) and two branches from the internal carotid artery (supraorbital and supratrochlear arteries) provide a rich blood supply to the scalp and forehead. The fibrous dermal tissue limits vessel retraction after injury, so significant hemorrhage can result from an arterial laceration. The potential space between the pericranium (periosteum covering the external surface of the skull bones) and the galea aponeurosis that allows for easy movement of the scalp over the cranium also enables hematoma and infection to collect in this subaponeurotic space and spread to involve the entire forehead and scalp. This high degree of mobility sometimes leads to a scalping injury, in which a large segment of the scalp is torn off in one piece.

CLINICAL FEATURES

For some patients with scalp and forehead lacerations, the wound may be only a minor part of the overall injury. Perform a focused assessment looking for intracranial injury before definitive wound care. Control scalp hemorrhage by applying direct pressure or clamping the involved vessel(s) at the wound edges (e.g., using Raney clips; see chapter 40) until the assessment is completed.[16]

Inspect scalp lacerations, and gently palpate with a gloved finger to determine depth and to identify galeal laceration or depressed skull fracture. Evaluate palpable depressions with a CT scan. Orientation of forehead lacerations has important cosmetic implications. In general, forehead wounds that fall parallel to the lines of skin tension have better cosmetic results than wounds that are perpendicular. The horizontal lines seen on the forehead when the brow is raised are perpendicular to the frontalis muscle underneath (**Figure 42-2**).

TREATMENT

Children may need sedation for wound repair (see chapter 113, "Pain Management and Procedural Sedation in Infants and Children"). Anesthesia can be provided by topical, local, or regional infiltration. Topical agents alone, such as lidocaine-epinephrine-tetracaine, provide adequate anesthesia in about half of patients and reduce the pain of local anesthetic injection.[17-20] Local anesthetics containing epinephrine are often used in highly vascular wounds to help control hemorrhage from small vessels.

Irrigate (see chapter 40, "Wound Preparation") to reduce contamination and lessen the risk of wound infection. Appropriate pressure for irrigation can be accomplished with a 30-mL syringe and 18-gauge IV catheter or commercially available irrigation device. However, in resource-poor situations, because the face and scalp are highly vascular, clean-appearing wounds have been repaired using adhesive strips, without prior cleansing and irrigation.[21]

Repair of Scalp Lacerations Do not shave hair before wound closure, because shaving increases the risk of infection.[22] To visualize the injured area, brush the hair aside or matt it down with an ointment, such as bacitracin zinc or petrolatum.[23] If visualization is still difficult, trim the adjacent scalp hair with scissors.

Suture accessible lacerations of the galea[24] to prevent formation of a subgaleal hematoma (**Table 42-2**).[25]

Close scalp skin with surgical staples or simple interrupted percutaneous sutures using nonabsorbable monofilament or rapidly absorbable material.[26-29] Leave suture tails long, and use sutures of a color different than the hair for easy suture removal.

Hair braiding is a technique combining hair apposition and tissue adhesive.[30-32] In this technique, bring together four to five strands of hair from opposite sides of the wound, twist the strands once, and secure them with a drop of tissue adhesive. This technique requires the wound edges to approximate with little tension, so subcutaneous sutures are sometimes necessary before hair apposition is used to close the skin.

Consider a pressure dressing over a deep scalp laceration for the first 24 hours after repair, to prevent wound hematoma formation.

Repair of Forehead Lacerations Forehead lacerations are categorized as either superficial, meaning the **frontalis muscle** is not injured, or deep, meaning the frontalis muscle is involved. For superficial lacerations, close the skin with 6-0 nonabsorbable interrupted suture, rapidly absorbable suture, or tissue adhesive.[24,33,34] For deep lacerations, close the muscle layer to avoid noticeable defects, especially when the facial muscles of expression are involved. Close the muscle layer with buried 5-0 absorbable suture. Close the epidermal layer with 6-0 nonabsorbable sutures in a simple, interrupted fashion; with skin closure strips; or with tissue adhesive (**Table 42-3**).[35] Strips or adhesives are especially attractive if the patient is at risk for keloids or hypertrophic scars. Use key stitches to align skin tension lines and the hairline (**Figure 42-3**).

Repair of Eyebrow Lacerations Do not clip or shave eyebrows because their delicate contour and form are valuable landmarks for wound edge reapproximation. Debridement of loose or nonviable skin in the eyebrow region should be minimal and, if necessary, done so that the remaining hairs preserve as much as possible of the original length, width, and curve of the eyebrow. Use care to align the hair margins. Use sutures that are a different color from the hair and leave long tails to facilitate removal.

TABLE 42-2 Suturing Guidelines for the Face and Scalp

Area	Suture	Size	Anesthetic	Removal
Scalp				
Galea	Absorbable	4-0	Local	Not removed

Skin	Nonabsorbable monofilament	6-0	Local, infraorbital, or mental nerve block	3–5 d

EYELIDS

ANATOMY

The eyelid is composed of five layers: skin, subcutaneous tissue, orbicularis oculi muscle, tarsal plate, and conjunctiva. The muscular layer controls lid closure and forms both the medial and lateral canthus. Fibers of the orbicularis oculi wrap around the lacrimal system. Nerve supply to the eyelid arises from the temporal and zygomatic branches of the facial nerve. The tarsal plate forms the main body of the lower half of the lid and consists of elastic tissue in a dense matrix of connective tissue. Embedded in the tarsal plate are the meibomian glands, which open onto the white line just in front of the conjunctival edge of the lid margin. In the lid margin, the eyelashes are arranged in three irregular rows with their follicles extending obliquely into the tarsal plate.

The lacrimal system begins at the upper and lower puncta that transition into the canaliculi. The canaliculi travel medially into the lacrimal sac that extends inferiorly to the nasolacrimal duct responsible for tear drainage into the nose (**Figure 42-4**).

TABLE 42-3 Indications for Tissue Adhesives on the Face

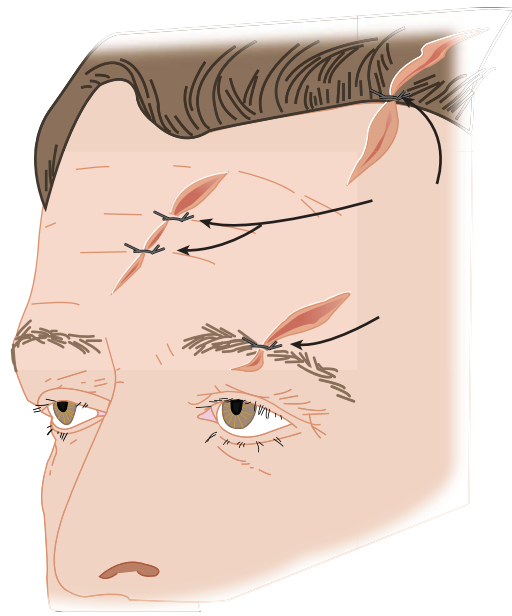

FIGURE 42-3. Key stitches in the forehead to align natural skin tension lines and cosmetically important landmarks.

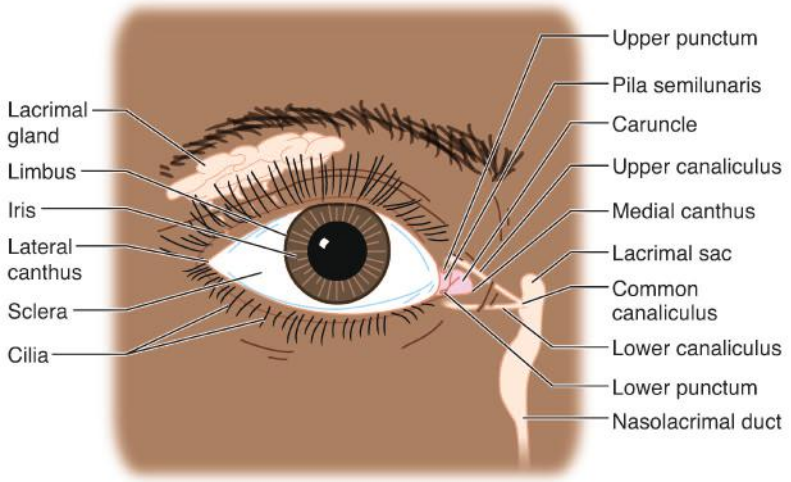

FIGURE 42-4. Periorbital anatomy.

CLINICAL FEATURES

The structures surrounding the eye and eyelids are delicate as well as cosmetically and functionally important. The eyelids are thin and offer limited protection from injuries to the globe, so **examine the eye's structure and function before laceration repair**. Once the integrity and function of the globe and orbital structures are verified, examine the lid for involvement of the canthi, the lacrimal system, or penetration through the tarsal plate or lid margin. **Eyelid injuries within 6 to 8 mm of the medial canthus are at risk for canalicular laceration, especially if associated with medal wall blow-out fractures.**[36] Refer the following injuries to an ophthalmologist or oculoplastic specialist: (1) injuries involving the inner surface of the lid, (2) wounds across lid margins, (3) injuries to the lacrimal duct, (4) wounds associated with ptosis, or (5) injuries extending into the tarsal plate (**Figure 42-5**).

Poor repair of the inside surface of the eyelid can lead to scar formation and persistent corneal irritation. Imprecise approximation of the lid margins leads to notching. Failure to recognize and properly repair the lacrimal system can result in chronic tearing (epiphora). Wounds through the tarsal plate or with ptosis require careful closure of the orbicularis oculi to preserve normal eyelid appearance. In general, wounds that are superficial, and especially those parallel to the lid margins, may be carefully repaired by the emergency physician.

TREATMENT

After topical anesthesia, gently irrigate the wound with normal saline. For closure, use 6-0 or 7-0 nonabsorbable monofilament for simple interrupted percutaneous sutures. Avoid deep penetration of the needle through the lid and into the underlying globe. **Do not use tissue**

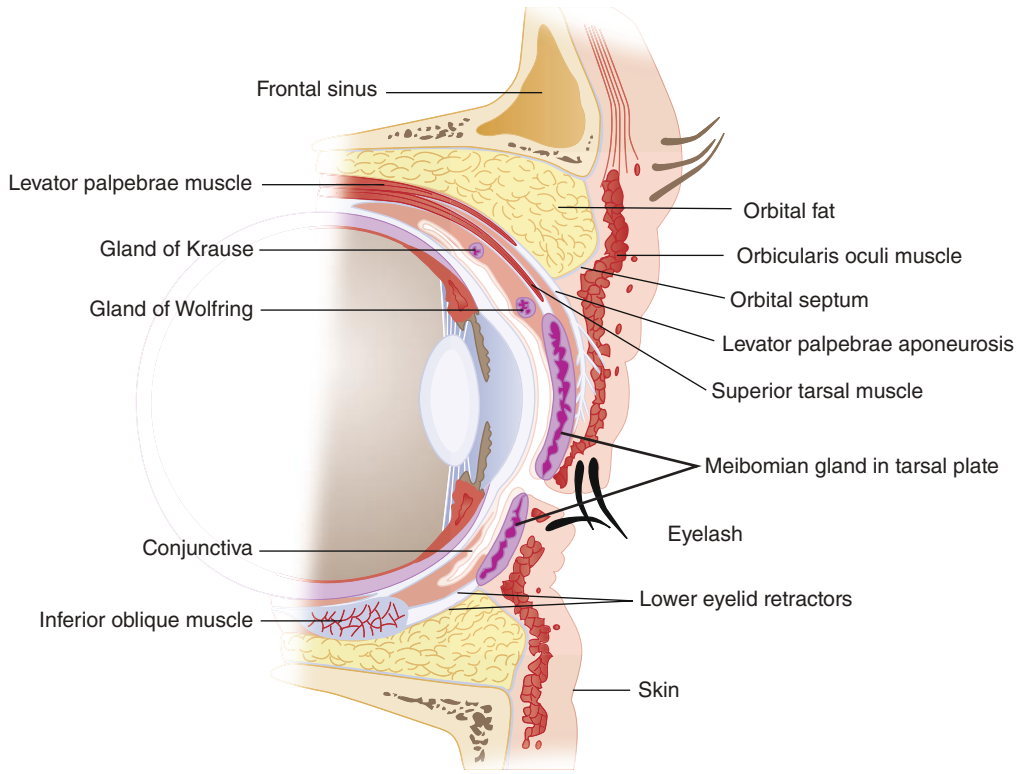

FIGURE 42-5. Cross-section of the eyelid. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology*, 17th ed. New York: Lange Medical Books/Mcgraw-Hill, 2008.]

adhesive near the eye, as adhesives may abrade the cornea or bond the lids together.[37] If tissue adhesive inadvertently finds its way onto the cornea, apply ophthalmic ointment to dissolve the adhesive. If the eyelids are unintentionally bonded, petroleum jelly can dissolve the bond.

Lacerations <1 mm at the lid edge do not need suturing and heal spontaneously. See the chapter 241, "Eye Emergencies" for additional discussion.

NOSE

ANATOMY

The nose is especially vulnerable to blunt trauma, and nasal fracture is the most common fracture in victims of domestic violence and assault.[7] The nose is composed of cartilaginous and osseous structures that support the overlying skin and musculature and the underlying mucosa. It is separated into halves by the septum. Two C-shaped alar cartilages that are covered directly by skin form the tip of the nose. The interior of the nose is covered by specialized skin with mucus-producing cells and thick, long hairs near the end, whereas the proximal portion of the nasal lining is made up of ciliated pseudostratified columnar epithelial cells.

CLINICAL FEATURES

The most important assessment of nasal lacerations is to determine their depth and the involvement of the deeper tissue layers.[38] Exposed cartilage or penetration through all tissue layers increases the risk of infection. Inspect the nasal septum and look for discolored lateral bulging indicating a septal hematoma. This hematoma develops between the cartilage and its protective mucoperichondrial layer and may produce complications such as (1) permanent thickening of the septum, causing partial airway obstruction of the nasal passage; (2) necrosis and subsequent erosion of the septum, resulting in communication between the nasal passageways; or (3) septal erosion leading to a saddle-nose deformity. With direct blunt trauma to the nose, assess for a cribriform plate fracture with cerebrospinal fluid rhinorrhea.

TREATMENT

Epinephrine-containing local anesthetics are acceptable for infiltrative anesthesia on the nose.[39] Topical application of lidocaine into the nasal cavity may provide sufficient anesthesia for local wound repair. Insertion of multiple cotton-tipped swabs or plain nasal packing gauze soaked in 4% lidocaine solution is usually sufficient (**Figure 42-6A**). After several minutes in place and before repair, remove the swabs or gauze.

Close superficial lacerations to the skin layer with 6-0 nonabsorbable monofilament simple interrupted sutures. Close lacerations over exposed cartilage promptly. Preserve any small pieces of loose cartilage under the skin for use in future revision by a plastic surgeon.

If the laceration extends through all tissue layers and involves the nostril, begin closure with a 5-0 nonabsorbable monofilament suture that aligns the skin surrounding the entrance to the nasal canals at the alar margin (**Figure 42-6B**). Initially, leave the ends untied and long to facilitate the closure of the deeper structures. *Gentle* traction on this suture facilitates alignment of the mucosa and cartilage layers during placement of subsequent sutures. Close the mucosal layer with 5-0 rapidly absorbable interrupted sutures, and reirrigate the area gently from the outside. Placement of sutures directly into the cartilage is not recommended; in most cases, closure of the overlying skin is usually sufficient to align the cartilage. If necessary to align cartilage pieces, place a minimal number of 5-0 nonabsorbable sutures through the cartilage. Reevaluate the initial stitch at the alar margin, and then tie it. Finally, suture the remainder of the skin with 6-0 nonabsorbable monofilament material close to the wound edges. With extensive wounds, consider a loose anterior nasal pack with antibiotic-impregnated gauze to prevent scar contracture.

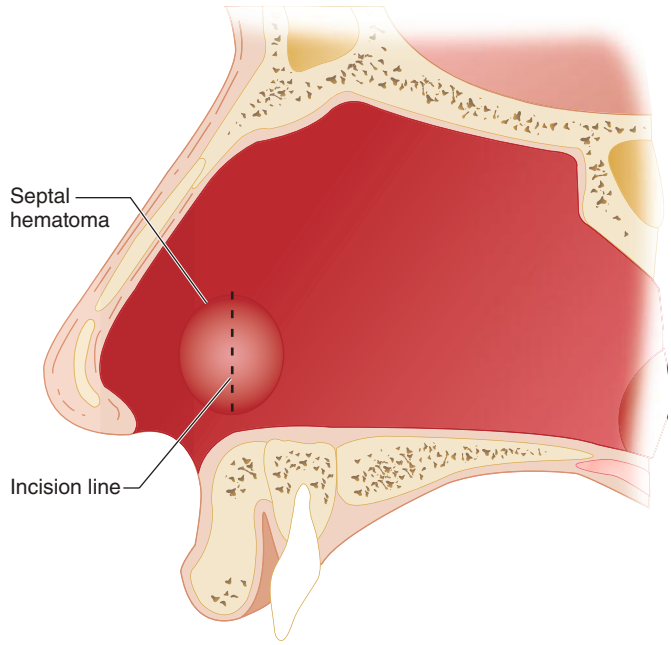

FIGURE 42-7. Incision for drainage of septal hematoma. Septal hematoma with markings for a vertical incision through the mucoperichondrium. [Reproduced with permission from Reichman EF, (ed): Emergency Medicine Procedures, 2ed. Figure 171-5. Copyright © 2013 The McGraw-Hill Companies, Inc. All rights reserved.]

Drain septal hematomas. For a small, unilateral hematoma, the clot can often be aspirated through an 18-gauge needle. Larger hematomas require an incision in the septal mucoperichondrium overlying the hematoma (**Figure 42-7**).[40] After hematoma evacuation, place an anterior nasal pack to discourage reaccumulation of the hematoma. After trauma, it is common practice to prescribe antibiotics to prevent infection of the cartilage and infection after nasal packing.[41] Bilateral hematomas are often drained in the operating room.

EARS

ANATOMY

The external ear begins with the external auditory canal and extends to the fibrocartilaginous framework of the auricle and the soft fatty tissue of the earlobe. The blood supply to the ear arises from the superficial temporal and posterior auricular arteries. The majority of the sensory innervation is from the anterior and posterior branches of the greater auricular nerve. **The auricular branches of the vagus nerve supply the posterior wall of the external auditory canal, so lacerations that involve this area cannot be anesthetized with auricular nerve blocks.**

CLINICAL FEATURES

Lacerations caused by blunt forces to the ear can rupture the tympanic membrane or produce a subchondral hematoma even in the absence of

a laceration. Lacerations caused by blunt or shear forces may also involve the cartilage.[1,42] If a wound extends deep into the canal, verify the integrity of the tympanic membrane. The presence of hemotympanum, mastoid area ecchymoses, or cerebrospinal fluid otorrhea suggests a basilar skull fracture.

TREATMENT

Insert a cotton plug into the ear canal during wound preparation and irrigation. Regional anesthesia by auricular field block is ideal (see chapter 36, "Local and Regional Anesthesia"). Hemostasis before repair of an auricular laceration is important to prevent the formation of a hematoma.

Close superficial lacerations to the skin with 6-0 nonabsorbable monofilament interrupted sutures.[43] Cover any exposed cartilage to prevent subsequent infection. Do not remove crushed or loose pieces of cartilage under the skin, as the pieces may be beneficial if reconstructive surgery is necessary. Do not debride from the edges of an auricular laceration because there is very little excess skin available to cover the existing cartilage.

In most through-and-through lacerations of the auricle, skin approximation will adequately support and align the underlying cartilage (**Figure 42-8A**). Include the thin layer of loose material overlying the cartilage (perichondrium) when placing percutaneous sutures to assist in bringing the cartilage together (**Figure 42-8B**). If the overlying skin is avulsed, refer to a plastic surgeon for repair.[1,42] Complete avulsion of the ear requires immediate plastic surgery consultation.

A perichondral hematoma is a potentially damaging complication after repair of auricular lacerations. The collection of blood and build up of pressure may damage the cartilage and create a deformed external ear. A postrepair **auricular pressure dressing** can prevent hematoma formation. Pressure dressing placement involves several steps (**Figure 42-9**). Start by applying a nonadherent dressing over the repair site—either a piece of gauze with antibiotic ointment or other nonadherent wound dressing. Conform this dressing to the shape of the ear using gentle pressure. Then open and fluff up gauze pads, placing them behind the ear to fill the space between the skull and pinna and in front of the ear to fill the interior contours. Wrap the head and ear with gauze wrap covered with a light (not tight) elastic bandage wrap. **Reevaluate the dressing and the ear in 24 hours. If there is no hematoma, there is no need to reapply the pressure dressing.**

An **auricular hematoma** may develop within the first few days after injury. The patient typically presents with pain and swelling; the ear may look purplish; and the repair site is swollen, warm, and mushy to touch, and blood often oozes when the area is squeezed. Consult with a plastic surgeon or otolaryngologist. Proper treatment requires evacuation of the hematoma and bleeding control. If a specialist is not available, the emergency physician may choose to drain the hematoma. The initial step is to remove all the sutures, drain the blood, and thoroughly irrigate the wound.[40] Then resuture the wound and apply a pressure dressing.

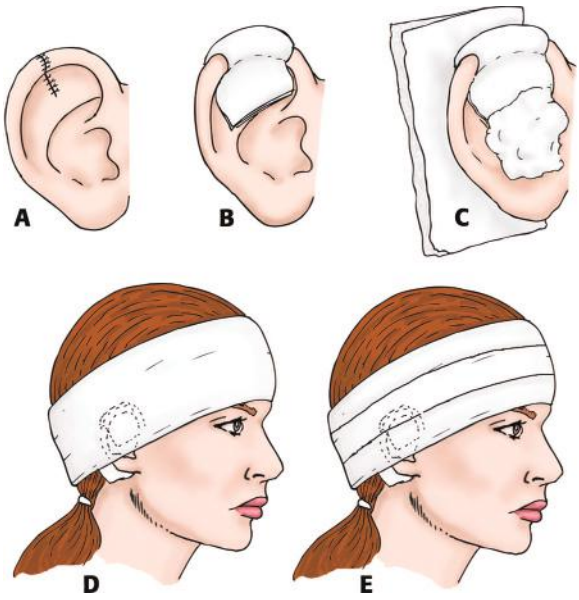

FIGURE 42-9. Auricular pressure dressing. **A.** Apply a nonadherent dressing over the repair site. **B.** Conform this dressing to the shape of the ear using gentle pressure. **C.** Place opened and fluffed gauze pads behind the ear to fill the space between the skull and pinna and in front of the ear to fill the interior contours. **D.** Wrap the head and ear with gauze wrap. **E.** Cover with a light (not tight) elastic bandage wrap. Do not enclose opposite external ear.

LIPS

ANATOMY

The external surfaces of the lips have three distinct regions: the skin, the vermilion, and the oral mucosa. The cosmetically important junction of the skin and the red portion of the lip is the **vermilion border**. The orbicularis oris muscle surrounds the mouth. Its integrity is responsible for retaining the saliva inside the mouth, producing the bilabial sounds of speech, and providing important facial expressions. The infraorbital nerve supplies the upper lip, and the submandibular nerve supplies the lower lip. Both are branches of the trigeminal nerve and can easily be blocked by regional anesthetic techniques. The lips are richly supplied by the labial arteries.

CLINICAL FEATURES

External and intraoral examination is required to appreciate the complete injury. Fully explore lacerations, teeth, and mucosa. Identify missing, impacted, or fractured teeth (see Figure 245-2 in the chapter titled "Oral and Dental Emergencies") or exposed bone of the maxilla or mandible. If portions of the teeth are missing, after adequate anesthesia, explore the wound fully because broken off pieces may become imbedded in the laceration.[44-46] Note if lacerations cross the vermilion-skin and/or the vermilion-mucosal borders.

TREATMENT

Intraoral mucosal lacerations may not need to be sutured if they are isolated and the wound edges spontaneously approximate, especially if <1 cm in length. Larger or gaping wounds should be closed with a rapidly absorbable 5-0 suture. Carefully place the suture to include only mucosa with entrance 2 to 3 mm from the wound edges, and use care to evert the edges. Larger tissue bites can bunch the mucosa and pucker the outside skin.

Through-and-through lacerations that do not include the vermilion border should be closed in layers. Close the mucosal layer with a 5-0 rapidly absorbable suture as described in the previous paragraph, followed by gentle reirrigation from the outside. Next, approximate the

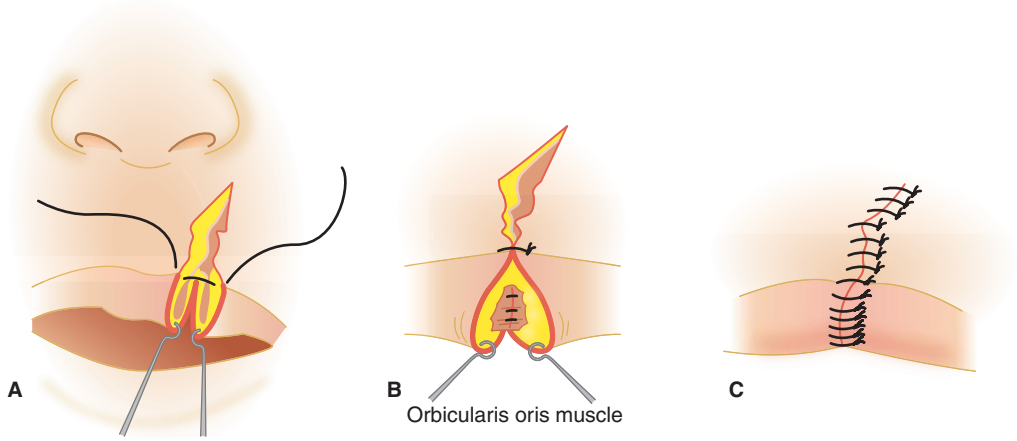

FIGURE 42-10. Lip laceration repair. **A.** The first suture is placed to align the vermilion skin junction. **B.** The orbicularis oris muscle is then repaired with 5-0 absorbable sutures. **C.** The irregular edges of the skin are then approximated with 6-0 nonabsorbable sutures.

orbicularis oris muscle with 4-0 or 5-0 absorbable suture material with a simple interrupted or horizontal mattress technique. Finally, after repeat irrigation, suture the skin with 6-0 nonabsorbable monofilament sutures in a simple interrupted fashion. Alternatively, the skin can be approximated with tissue adhesive.

Wounds that cross the vermilion border should be repaired by placing the first stitch with 6-0 nonabsorbable monofilament suture to precisely align the edges of the vermilion border (**Figure 42-10**). Even 1 mm of step-off will be cosmetically unappealing.[47] After this first stitch, repair the vermilion and skin with the same 6-0 material, and repair the mucosa with 5-0 rapidly absorbable suture. A useful technique in some cases is to leave the initial alignment suture untied and apply gentle traction on the ends to help approximate and align the underlying tissue as the skin and vermilion are closed. Use gentle traction to avoid pulling the suture through the skin in this delicate area. Use clinical judgment for the prescription of antibiotics. Contaminated wounds and through-and-through lacerations likely benefit from antibiotics.

INTRAORAL MUCOSAL LACERATIONS

ANATOMY

Two types of intraoral mucosal lacerations are common: those involving the buccal mucosa and those at the mucosal reflections. Buccal mucosal lacerations near the parotid duct opening, identified as a small papilla adjacent to the upper second molar, may injure that structure. Intraoral mucosal reflections are located at the transition from the cheek to the outside surface of the maxilla or mandible. Because of the loose attachment of the mucosa in this area, lacerations may have great depth and extend deeper than initially suspected.

CLINICAL FEATURES

Visualize and explore intraoral lacerations to determine their depth and extent. **Lacerations of the mucosal reflections are easily missed unless the lips are manipulated to see into all the recesses.** Evaluate the adjacent teeth for fracture or avulsion, because missing tooth fragments may be embedded in the wound, swallowed, or aspirated into the airway.

TREATMENT

Small intraoral lacerations (<1 cm) do not need routine repair and can be allowed to heal naturally. **Suture closure of intraoral lacerations is usually indicated when wounds are large enough to trap food particles or have a tissue flap that interferes with chewing.** Use 4-0 absorbable suture to close the mucosa. To avoid bunching of the mucosa as the suture knot is tied, insert the needle about 2 to 3 mm from the edge of the wound. Include only the mucosa in the suture because an external pucker may be created if the underlying muscle is ensnared in the suture loop. Be sure to evert the edges. Close suture placement is not necessary; typically, sutures placed 5 to 7 mm apart are adequate.

CHEEKS AND FACE

ANATOMY

The cheek area has two structures that influence wound repair: the parotid duct and branches of the facial nerve (**Figure 42-11**).[1] The opening of the parotid duct is adjacent to the upper second molar; wounds in this region can lacerate the parotid duct. As the facial nerve traverses the parotid gland, it divides into five major segments, the precise courses of

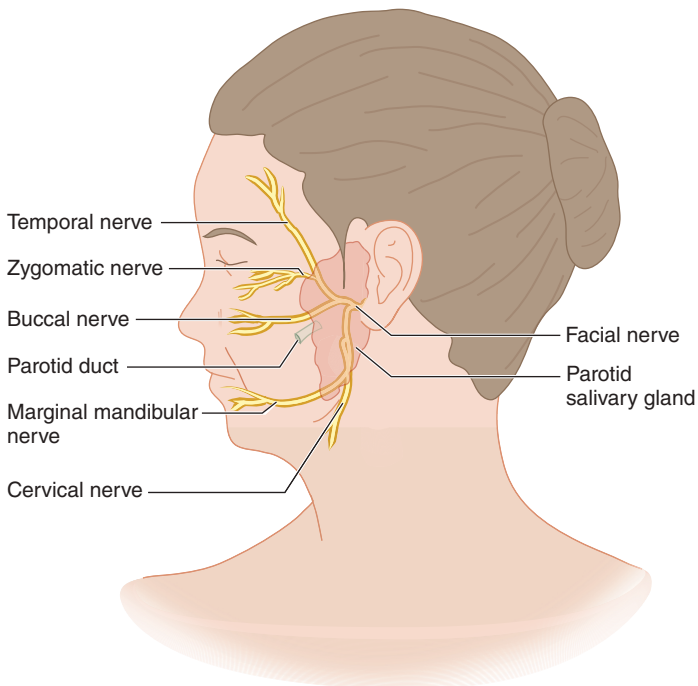

FIGURE 42-11. Cheek anatomy. The course of the parotid duct is within 1.5 cm of the midportion of a line drawn from the lower border of the tragus to the cheilion.[48] The five branches of the facial nerve are the temporal, zygomatic, buccal, marginal mandibular, and cervical.

which are difficult to predict. Therefore, lacerations or deeply placed sutures may ensnare one of these branches.

CLINICAL FEATURES

Evaluate wound depth and assess for damage to the parotid gland, parotid duct, and facial nerve. Assess the teeth for fracture, avulsion, or fragments embedded in the wound. Suspect parotid duct injury when the wound crosses a line from the tragus to the frenulum and is posterior to a vertical line downward from the lateral canthus. The buccal branch of the facial nerve and a branch of the facial artery travel with the parotid duct, so facial paralysis or arterial bleeding from the wound should arouse suspicion that the parotid duct is also injured. Parotid duct laceration can be confirmed by inserting a 19-gauge silastic tube into the intraoral parotid duct papilla and seeing if the catheter is visible in the wound. Alternatively, a small amount of saline can be injected into the tube while observing for flow in the wound. These procedures require patient cooperation and are usually performed by the consulting specialist.

TREATMENT

Repair superficial lacerations that involve the cheek and surface of the face with 6-0 nonabsorbable monofilament, simple, interrupted, percutaneous sutures. Alternatives include rapidly absorbable sutures or tissue adhesives. If there is significant skin tension, place intradermal 4-0 absorbable sutures, and make sure the parotid duct is not caught in the suture (Figure 42-11). If the parotid duct is injured, operative repair is indicated.

A full-thickness cheek laceration traverses the skin and the underlying subcutaneous tissue/muscle and penetrates through the intraoral mucosa. Such wounds are repaired in layers, starting with the intraoral mucosa. Once the mucosa is closed, reirrigate the wound before closure of the skin and subcutaneous layers. The skin and subcutaneous layers can often be brought together with percutaneous sutures using 5-0 or 6-0 material. If this does not allow the subcutaneous tissue to fill in the wound, use a small number of 4-0 absorbable simple sutures to approximate the muscle or subcutaneous tissue.

DISPOSITION AND FOLLOW-UP

Where possible, the wound should be dressed with either an antibiotic ointment or nonadherent dressing material to maintain moisture and encourage wound healing.[49-51]

Patients should be discharged with routine wound-care instructions (see chapter 47, "Postrepair Wound Care") and, if the injury resulted from a major blunt impact, closed head injury precautions. Remove scalp sutures or staples in 10 to 14 days, and remove nonabsorbable percutaneous sutures in the forehead, face, external ear, or lips in 5 to 7 days.

Percutaneous nonabsorbable sutures placed in the eyelid or nose should be removed in 3 to 5 days. A thin layer of ophthalmic antibiotic ointment may be applied in place of a dressing; do not apply antibiotic ointment intended for routine use elsewhere around the eye. Remove intranasal packing in 2 days.

Auricular pressure dressings should be left on for 24 to 48 hours and then removed for inspection of the wound site. If the wound is healing without infection or hematoma, replacement of the pressure dressing is not necessary.

Patients with intraoral lacerations should practice good oral hygiene and rinse their mouth several times a day. Prescription of antibiotics for intraoral lacerations and through-and-through facial wounds is a matter of physician preference.[52]

CHAPTER 43

Arm and Hand Lacerations

Moira Davenport

GENERAL MANAGEMENT PRINCIPLES

Specific issues relative to wounds and lacerations of the arm and hand include potential injury to the arteries, nerves, and tendons that lie close to the skin and the impact of these injuries on the use of the hands in daily and occupational life. Injuries may be classified as either isolated or combinations of closed crush, simple lacerations, open crush, partial amputation, and complete amputation.

HISTORY AND EXAMINATION

Specific considerations in the history include patient age, occupation, mechanism of injury, and hand dominance. Age is important because the potential for bony injury increases with decreasing bone density, and the likelihood for healing and functional recovery decrease because of loss of elasticity. Mechanism of injury identifies wounds that are more prone to infections. Note the time from injury to repair. There is no distinct threshold for infection from time from injury to closure, but wounds sutured >12 hours after injury could be more prone to infection.[1,2]

Examination of arm and hand injuries begins with inspection and continues with evaluation of motor and sensory nerve function, tendon/ligament integrity, and assessment of perfusion. During inspection, observe the position and stance of the arm, hand, and digits. Identify exposed tendon or bone, and note the location of the wound relative to major arteries, nerves, and tendons. Explore the wound carefully for possible foreign body, debris, or other visible contaminants. Note significant soft tissue avulsion or loss of length of the injured part, as these findings may be indications for operative repair.

Active and Passive Movement Examine active motion and resistance to passive movement. Patients with a painful injury may be unwilling to move the affected extremity. After checking sensory function, local anesthesia may be required to obtain an adequate motor exam. The long-held belief that a local anesthetic with epinephrine should not be used for digital nerve blocks has been disproven, and agents containing epinephrine are acceptable for digital nerve blocks.[3-5]

Because there are several muscles with cross innervations, the most distal pure motor function of each major nerve should be tested against resistance (**Table 43-1**).

Individually assess each tendon in, and adjacent to, the injured area. For injuries to the hand and fingers individually examine the extensor digitorum, flexor digitorum profundus, and the flexor digitorum superficialis of each digit. The flexor digitorum superficialis, which splits and inserts at the proximal interphalangeal joint, can be examined by holding all other digits in extension and flexing the proximal interphalangeal joint against resistance. The flexor digitorum profundus, which runs below the flexor digitorum superficialis past the split to attach at the distal interphalangeal joint, can be examined by holding the proximal interphalangeal joint in extension and flexing the distal interphalangeal joint against resistance. The extensor digitorum can be assessed by sequentially flexing the digit at the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints and having the patient

TABLE 43-1 Motor Testing of the Peripheral Nerves of the Upper Extremity

Nerve	Motor Exam
Radial	Dorsiflexion of wrist
Median	Thumb abduction away from the palm Thumb interphalangeal joint flexion
Ulnar	Adduction/abduction of digits

TABLE 43-2 Sensory Testing of Peripheral Nerves in the Upper Extremity

Sensory Nerve	Area of Test
Radial	First dorsal web space
Median	Volar tip of index finger
Ulnar	Volar tip of little finger

extend the digit. Extension should be performed first against gravity and then against resistance applied by the examiner. **Weak, limited, or painful movement suggests partial involvement of a tendon.** Abnormality in motor nerve or tendon function testing warrants a more in-depth examination, including visual inspection and appropriate consultation.

Sensation and Two-Point Discrimination Assess pain and touch in the median, ulnar, and radial nerve distributions (**Table 43-2** and **Figure 43-1**). For injuries distal to the midpalm, assess the digital nerves by static two-point discrimination, testing longitudinally along the ulnar and radial aspect of the volar pad of the potentially involved digits. Static two-point discrimination is evaluated by using electrocardiogram calipers or a paper clip bent into a "V" shape with the two ends separated by approximately 5 to 6 mm. During testing, the two points should not cross the midline, and each stimulus should be timed 3 to 4 seconds apart. **Normal two-point discrimination is defined as <6 mm**; good is 6 to 10 mm, fair is 11 to 15 mm, and poor is >15 mm. Two-point spatial acuity of touch diminishes with age. Young (18 to 33 years) patients have a mean two-point acuity of 2 mm, whereas elderly (>66 years old) patients have a mean acuity of 5 mm.[6] The two most important areas to maintain sensation are the ulnar side of the distal thumb and the radial side of the index volar pad to preserve pinch sensation.

Vascular Assessment Intact radial and ulnar pulses and capillary refill are usually adequate to exclude significant vascular injury. However, an arterial injury proximal to the wrist may not be obvious as a result of collateral circulation. To better assess the integrity of the radial and ulnar arteries, perform **Allen's test**. The test is performed by first instructing the patient to make a fist as tight as possible. Then, apply digital pressure to both the radial and ulnar artery at the volar aspect of the wrist. Next, while maintaining compression of the radial and ulnar artery, have the patient open the hand—a blanched palm indicates that arterial inflow is occluded. Now release the radial artery, and note the time for the hand to return to normal color. Repeat the entire process, this time releasing and assessing flow from the ulnar artery. If the patient cannot make a fist, occlusion of both arteries will still blanch the hand, but the color change will not be as evident or pronounced. **Refill times >3 seconds raise suspicion for a significant vascular injury.**

A Doppler probe is useful to detect a diminished pulse, detect flow in digital arteries, and to calculate an arterial pressure index. The **arterial pressure index** is the ratio of the systolic blood pressure between the injured and the uninjured side. It is useful to assess the vascular integrity of an injured arm or leg. To obtain the index, place a blood pressure cuff proximal to the ankle or wrist of the injured limb and distal to the wound. Then use a Doppler probe to determine the systolic pressure at the dorsalis pedis or posterior tibial artery, or the radial or ulnar artery. In the absence of a diminished pulse or an arterial pressure index ratio <1.0, the likelihood of a clinically significant occult arterial injury is exceedingly small (sensitivity 95%, specificity 97%).[7,8] Lack of obvious arterial bleeding does not rule out arterial injury because cleanly transected arteries may contract and prevent obvious bleeding. Any abnormal findings warrant consultation with a vascular surgeon as well as with a hand surgeon.

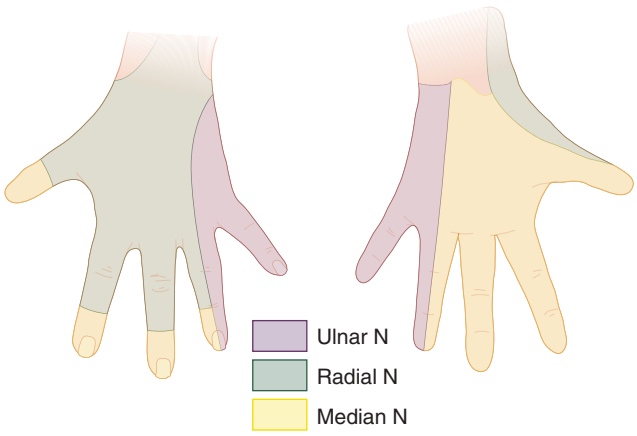

FIGURE 43-1. Sensory innervation to the hand.

IMAGING

Obtain radiographs with anteroposterior, oblique, and lateral views if bony injuries, foreign bodies, or joint penetration are suspected. Additional oblique views of the hand and digits are useful to visualize small areas with overlapping bones. For isolated finger injuries, dedicated anteroposterior and lateral radiographs of the involved digit(s) are preferred, as the detail on hand films alone is often not adequate for complete visualization of small, subtle fractures. **Plain radiography visualizes radiopaque objects as small as 1 mm.** When there is suspicion for a radiolucent-retained foreign body, especially wood, other imaging modalities (US, CT, or MRI) may be necessary (see chapter 45, Soft Tissue Foreign Bodies).

WOUND VISUALIZATION AND TOURNIQUET APPLICATION

Because wounds and the affected structures are often small, patient positioning, bright lighting, and a bloodless field are necessary for wound evaluation. For some injuries, a bloodless field may require a proximal tourniquet to temporarily halt arterial inflow and allow adequate visualization of the injury. Penrose (rubber) drains are typically used to tourniquet an injured finger, and pneumatic tourniquets placed around the arm are used with forearm and wrist injuries. To tourniquet a digital injury, place a 1-in. Penrose drain around the base of the finger, stretch the drain away from the hand, and secure the drain with a clamp or hemostat. If time allows, the digit can be exsanguinated before tourniquet placement by wrapping the digit with the Penrose drain from distal to proximal, then carefully removing the drain from distal to proximal before securing it around the base of the digit. **Excessively high pressures and tourniquet times >15 to 20 minutes can cause neurovascular damage and may be avoided by limiting the stretch of the drain to no more than 50% of the original length.**[9]

For more proximal injuries, especially those with brisk arterial bleeding, an inflated manual blood pressure cuff is used. **Esmarch's technique** is as follows: Elevate the injured extremity and apply an elastic bandage starting distally and proceeding proximally to the area where the cuff will be applied. This will help to exsanguinate the limb and prevent backflow bleeding. The cuff is applied around the upper arm and inflated to pressures above the systolic blood pressure of the patient, but not to exceed 250 mm Hg. The cuff tubing is clamped with a hemostat instead of closing the air release valve to prevent slow air leakage. The maximum cuff inflation time is limited to 30 minutes to limit ischemic damage to the distal muscles and nerves.

Once adequate visualization is obtained, examine the area for foreign bodies and tendon and joint capsule injuries. **Examine the arm and hand in a variety of positions, including the position of injury and a full, passive range of motion, to avoid missing injuries that may move out of the field of view when the extremity is examined in a neutral position.** Examine lacerations near a joint carefully to identify violation of the joint capsule. If the location and depth of the injury raise the question of extension into the joint capsule, joint injection for a **saline load test** should be done. After standard sterile preparation of the area, inject the joint with normal saline at an area away from the laceration. Inject 5 mL in the wrist and 1 to 2 mL in finger joints.[10] Inject sufficient amounts of saline to adequately stress the capsule. False-negative results may be obtained if too little fluid is injected.[11,12] Fluid dripping from the joint indicates an open joint capsule and requires specialty consultation. For small joints or questionable exams, a few drops of sterile fluorescein for

IV use (Ak-Flor®) may be added to the injected saline and the joint examined with a Wood's lamp for evidence of fluorescent effluent. **Do not use methylene blue because it stains the intra-articular surfaces** and may affect operative management of intra-articular injuries.

WOUND DRESSING AND POSTREPAIR CARE

After the injury is repaired, apply antibiotic ointment to the repaired incision/sutures and cover the wound with a nonadherent dressing. Wrap the area loosely with a soft dressing to allow for adequate circulation. A small portion of the fingernail or volar pad should remain visible to allow serial assessment of capillary refill in patients with digital injuries. Certain injuries, especially large lacerations in close proximity to a joint and those with tendon involvement, may be splinted for protection and limitation of pain. A padded aluminum splint is satisfactory for isolated digital lacerations. Provide adequate analgesia and remind the patient to keep the injured extremity elevated above the level of the heart to reduce edema. A follow-up wound check is recommended within 48 to 72 hours. Sutures are usually removed 8 to 10 days after the injury.

Prophylactic antibiotics are not needed for uncomplicated hand lacerations.[2] The definition of an uncomplicated hand laceration is as follows: (1) not caused by a human or animal bite; (2) not associated with a burn; (3) not complicated by a fracture through bone or a joint; (4) not involving tendons, bones, large vessels or nerves; (5) no severe soft tissue damage or maceration.[2] Antibiotics are generally given for complicated hand lacerations, mammalian bite wounds, injuries >12 hours old, contaminated wounds, injuries with exposed bone, or injuries occurring in patients with concurrent medical problems that may affect wound healing (i.e., diabetes, renal or peripheral vascular disease, immunocompromise).[13-15] Antibiotics should be chosen to cover suspected contaminants and pathogens and should be given early in the ED by a route that quickly achieves high blood and tissue concentrations.

Provide tetanus immunization or booster as needed.

Indications for admission to the hospital include injuries that require repair in the operating room, those that require a course of IV antibiotics, or the presence of social issues such as abuse cases, homelessness, or other factors affecting the patient's ability to follow basic aftercare instructions.

INJURIES IN CHILDREN

Because of the presence of an open epiphysis in children, a fracture can be difficult to identify using plain radiographs. It is often necessary to obtain radiographs of the unaffected side for comparison. If a complicated repair is indicated and the child is unable to tolerate the procedure after local anesthesia alone, procedural sedation may be required. The continuous high activity level of children makes keeping dressings intact a problem, rendering routine hand dressings and protective finger splints ineffective. If the dressing and immobilization is essential to wound healing, the child should be placed in a bi-valved long arm cast.

DORSAL FOREARM, WRIST, AND HAND LACERATIONS

The forearm has six extensor compartments located dorsally, all of which are innervated by the radial nerve (**Table 43-3**). Tendons and nerves distal to the wound should be individually examined.

The skin on the dorsum of the forearm and hand is thin and lacks underlying tissue, which allows skin avulsion to occur easily and makes wound edge approximation sometimes difficult.[16] For most lacerations, simple 5-0 nonabsorbable percutaneous sutures should be adequate for closure. To provide better cosmesis for injuries to the dorsum of the hand, we recommend subcuticular stitches with 5-0 absorbable material. A pull-through subcuticular closure with nonabsorbable suture is preferred for linear lacerations (**Figure 43-2**).[16] For deep wounds that penetrate through the muscle fascia and lacerate the muscle belly, closure of the fascial defect with 4-0 absorbable suture is generally recommended. However, deep sutures increase the potential for infection in a contaminated wound.

CLENCHED FIST INJURIES

Patients with lacerations to the dorsum of the hand should be questioned about the possibility of a **clenched fist injury or "fight bite,"** wounds created by the patient throwing a punch and impacting the front teeth of the intended target and producing a small laceration (3 to 5 mm) over the dorsal metacarpophalangeal joint.[17] Extension of the hand after the fight deeply inoculates oral bacteria into the wound. *Staphylococcus aureus* is the most common bacterial species isolated from human bite wounds, followed by *Streptococcus* spp., *Corynebacterium* spp., and *Eikenella corrodens*. In clenched fist injury infections, polymicrobial involvement is the rule. Human bites can also transmit herpes, actinomycosis, syphilis, tetanus, and hepatitis B and C.[17] Bites are not the only way to inoculate the hand with human oral flora; significant hand and finger infections have been reported after toothpick injuries. Patients sustaining such puncture wounds should receive antibiotics to protect against the above-mentioned bacteria.[18]

Obtain radiographs on clenched fist injuries to evaluate for embedded teeth, air in the joint/soft tissues, and fractures. Patients who delay evaluation and develop obvious infection require exploration, open irrigation, and debridement in the operating room followed by admission for IV antibiotics and elevation. If the patient presents soon after the injury and without evident infection, then evaluation, exploration, irrigation, and debridement can be done in the ED with appropriate equipment and physician expertise. It is important to visualize the full extent of the wound, evaluate the hand through full range of motion, and exclude injury to the extensor tendon and joint capsule. If no injury to these structures is seen, the wound should be copiously irrigated and covered with a nonadherent dressing. **Lacerations resulting from clenched fist injuries should not be sutured, but rather allowed to heal by secondary intention.**

Splint the hand in a position of function (**Figure 43-3**). A 3- to 5-day course of prophylactic antibiotics should be prescribed, usually amoxicillin-clavulanic acid. Give the first antibiotic dose in the ED. Instruct the

TABLE 43-3 Extensor Compartments in the Forearm

Compartment	Muscle	Function
First compartment	Abductor pollicis longus	Abducts and extends thumb
	Extensor pollicis brevis	Extends thumb at MCP joint
Second compartment	Extensor carpi radialis longus	Extends and radially deviates wrist
	Extensor carpi radialis brevis	Extends and radially deviates wrist
Third compartment	Extensor pollicis longus	Extends thumb at interphalangeal joint
Fourth compartment	Extensor digitorum communis	Splits into four tendons at level of the wrist; extends index, long, ring, and little digits
	Extensor indicis proprius	Extends index finger
Fifth compartment	Extensor digiti minimi	Extends little finger at MCP joint
Sixth compartment	Extensor carpi ulnaris	Extends and radially deviates wrist

Abbreviation: MCP = metacarpophalangeal.

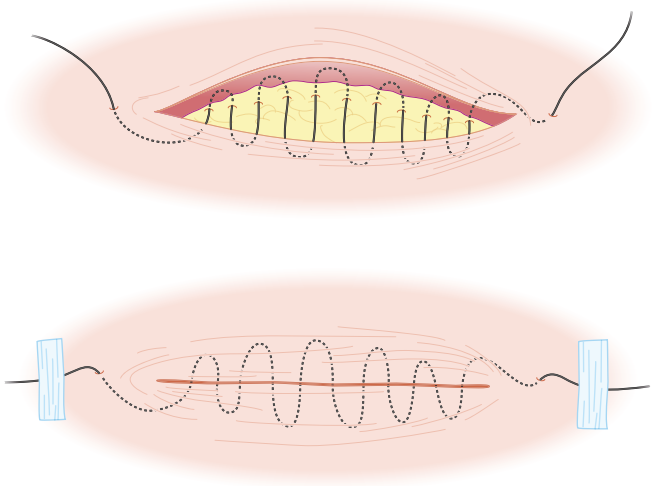

FIGURE 43-2. Pull-through subcuticular suture.

patient to elevate the extremity and return for reevaluation in 24 to 48 hours. If there is already evidence of infection or joint/tendon involvement, consult a hand surgeon and consider admission for observation and IV antibiotics, typically ampicillin-sulbactam or cefoxitin.

EXTENSOR TENDON LACERATIONS

The dorsal skin of the hand is thin and freely mobile, allowing for extensive range of motion for all joints. Because of this mobility and the superficial nature of the extensor tendons, a careful examination through a full range of motion at the site of injury in a neutral position and in the position of injury is necessary to avoid missing a tendon injury. Refer extensor tendon injuries of the thumb or those with severe contamination to a hand surgeon. An experienced emergency physician can repair extensor tendon injuries between the distal wrist and metacarpophalangeal joints. In this case, it is recommended to consult the hand surgeon for treatment preferences and ensure continuity of care. Small partial extensor tendon injuries (<50% transected) should be repaired with absorbable synthetic material.[19] Larger partial tendon injuries (>50% transected) and complete extensor tendon lacerations should be sutured with 4-0 (5-0 for smaller tendons) colorless nonabsorbable material, such as polypropylene or nylon, and the skin closed with 5-0 nonabsorbable suture material.[19] A figure-of-eight stitch with the knot placed at the edge of the tendon is recommended to repair lacerated extensors (**Figure 43-4**).

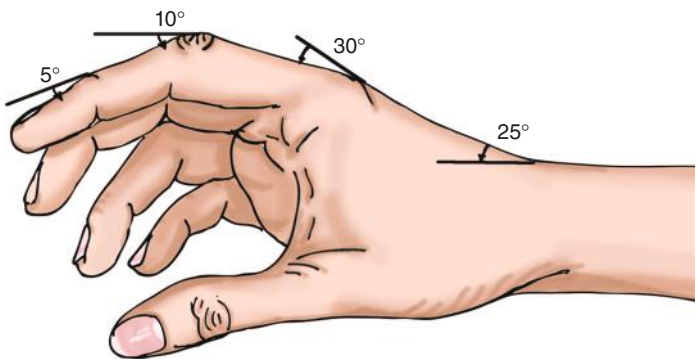

FIGURE 43-3. Wrist and hand position when splinted in "position of function." The wrist is extended 25 degrees so that the thumb metacarpal is in alignment with the forearm. The thumb is abducted away from the palm. Metacarpophalangeal joints are flexed to 30 degrees. Proximal interphalangeal joints are flexed to 10 degrees. Distal interphalangeal joints are flexed to 5 degrees.

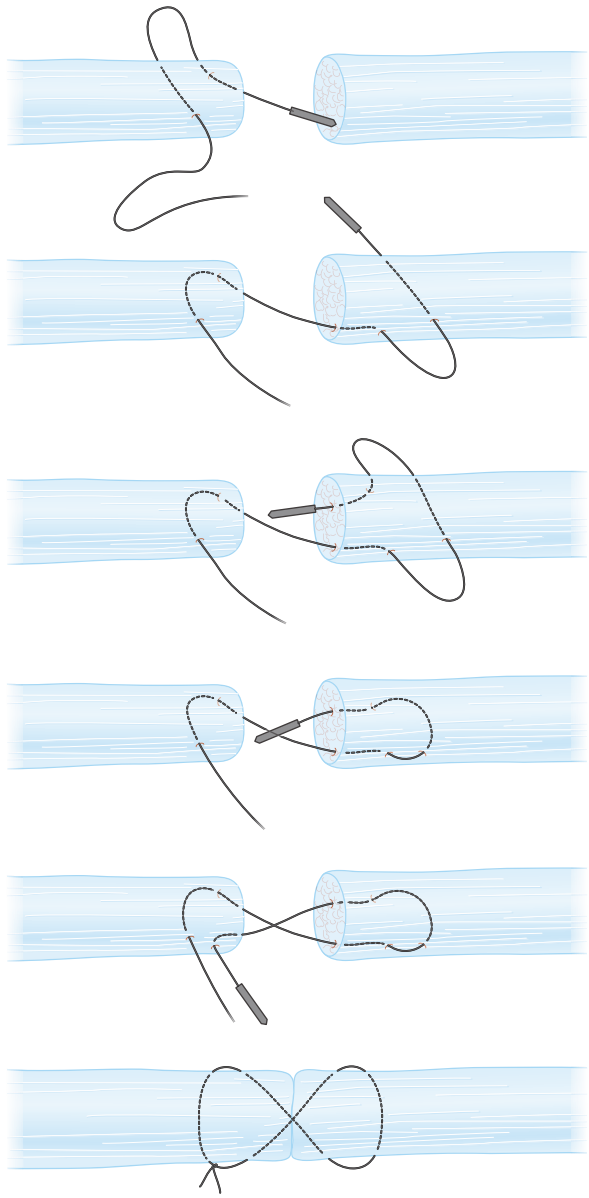

FIGURE 43-4. Extensor tendon laceration repair with a figure-of-eight stitch.

After repair of the tendon and overlying skin, **splint the hand or digit in a position of function** with instructions to maintain elevation of the extremity (**Figure 43-3**). Follow-up with a hand surgeon is recommended within 7 days.

Complications can be seen with disrupted extensor mechanisms. The **mallet finger deformity** (inability to extend the distal interphalangeal joint, resulting in the joint being held in flexion) and **swan neck deformity** (hyperextension of the proximal interphalangeal joint resulting from unrepaired mallet finger deformity) are caused by the complete disruption of the terminal extensor mechanism and subsequent proximal and dorsal displacement of the lateral bands (**Figures 5A** and **5B**). A **boutonniere deformity** (hyperflexion of the proximal interphalangeal joint with hyperextension of the distal interphalangeal joint) is usually a delayed complication after injury to the proximal interphalangeal joint. The central slip of the extensor tendon is disrupted, allowing the lateral bands to move volarly and operate as flexors at the proximal interphalangeal joint while still producing extension at the distal interphalangeal joint (**Figure 43-5C**). If these injuries are open, operative repair is required. Closed injuries may be treated by splinting the digit in extension (distal interphalangeal joint for mallet finger and both proximal interphalangeal and distal interphalangeal joints for Boutonniere's deformity)

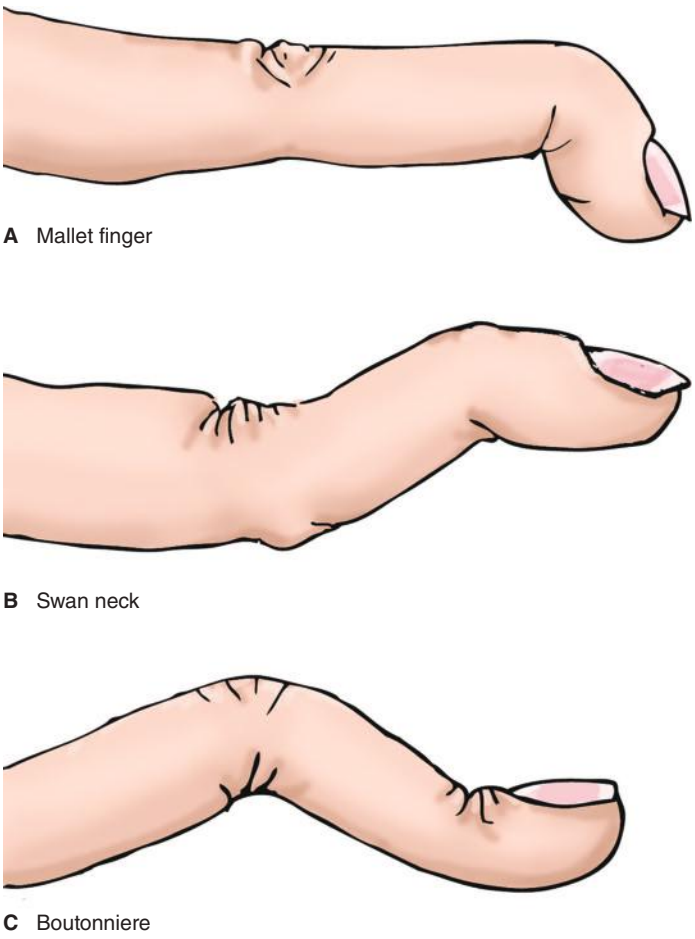

FIGURE 43-5. **A.** Mallet finger. **B.** Swan neck finger. **C.** Boutonniere's deformity.

for up to 6 weeks or until operative repair. All cases should be referred to a hand surgeon for follow-up.[20,21]

VOLAR FOREARM, WRIST, AND HAND LACERATIONS

Patients with volar wrist lacerations should be questioned about suicidal attempts, and potentially suicidal patients require psychiatric evaluation after wound repair.[22] There are 12 flexor tendons innervated by the median and ulnar nerves located on the volar surface of the forearm that cross the wrist (**Table 43-4**). Tendons and nerves distal to the wound should be individually examined.

Injuries in the elbow region may affect the radial and ulnar nerves, which run in close proximity to the lateral and medial epicondyles, respectively. The radial nerve emanates from the spiral groove in the humerus approximately 10 cm proximal to the lateral epicondyle. The ulnar nerve travels behind the medial epicondyle as it runs between the two heads of the flexor carpi ulnaris into the forearm. The median nerve in the elbow region is more protected, as it runs in close proximity to the brachial artery and crosses anteriorly to the ulnar artery at the origin of the anterior interosseous nerve in the forearm. Although injuries to these nerves are more common with fractures and dislocations, simple soft tissue injuries at the elbow may result in nerve damage due to the superficial location and lack of overlying protective soft tissue in this area.

TABLE 43-4 Flexor Tendons in the Forearm

Flexor Tendon	Function
Flexor carpi radialis	Flexes and radially deviates wrist
Flexor carpi ulnaris	Flexes and ulnarly deviates wrist
Palmaris longus	Flexes wrist
Flexor pollicis longus	Flexes thumb at MCP and interphalangeal joints
Flexor digitorum superficialis	Flexes index, long, ring, and little digits at MCP and PIP joints
Flexor digitorum profundus	Flexes index, long, ring, and little digits at MCP, PIP, and DIP joints

Abbreviations: DIP = distal interphalangeal; MCP = metacarpophalangeal; PIP = proximal interphalangeal.

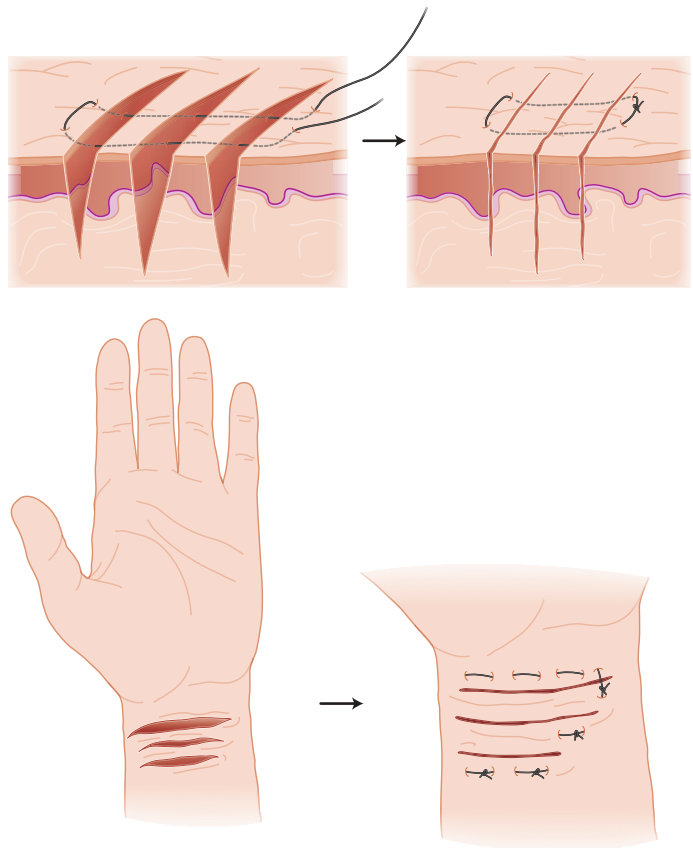

FIGURE 43-6. Horizontal mattress sutures for multiple parallel lacerations.

For most simple lacerations to the volar surface of the forearm and wrist, 4-0 or 5-0 nonabsorbable monofilament percutaneous sutures, such as nylon or polypropylene, should be used. For gaping injuries or injuries under high stress, a layer of deep sutures using 4-0 absorbable material may be required. Alternatively, mattress sutures can be used as well. For deep wounds that penetrate through the muscle fascia and lacerate the muscle belly, closure of the fascial defect with 4-0 absorbable suture is generally recommended.

Injuries that involve more than one parallel laceration, classic for suicide attempts, may require horizontal mattress sutures to cross all lacerations for closure to prevent compromising the vascular supply of the island of skin located between incisions (**Figure 43-6**). Alternatively, adhesive tapes or tissue adhesives alone or in conjunction with sutures may be used.[16]

PALM LACERATIONS

The palmar skin surface is well adapted for contact with objects in the environment. Palmar skin is thicker than dorsal skin and has an underlying connective tissue fascial layer, making it much more adherent to bone. The thenar, palmar, and digital creases are connections between the skin and underlying fascia, and these areas have no intervening adipose tissue. Because tendons, nerves, and arteries course through this area, palm lacerations have great potential to damage these deep structures through small and innocuous-appearing lacerations.[23,24] **Carefully assess digital flexor tendon function and two-point discrimination.**

Carefully approximate creases during skin closure. The thickness of palmar skin makes eversion of the edges especially difficult. For this reason, interrupted horizontal mattress sutures with 5-0 nonabsorbable monofilament are recommended to ensure that sutures do not pull through the skin.[16]

FLEXOR TENDON LACERATIONS

Flexor tendon injuries are usually repaired in the operating room by a hand surgeon because of the complexity of the anatomy and the reparative procedures required. Early consultation is important, as many surgeons prefer to repair complete flexor tendon lacerations within 24 hours after injury. If operative repair of the flexor tendon is going to be delayed, the wound should be appropriately cleaned, the skin closed, and the affected extremity splinted. **Splint with the wrist and metacarpophalangeal joint flexed and the proximal interphalangeal and distal interphalangeal joints in extension to prevent contraction of the surrounding muscles.**[25] The hand surgeon can follow up the patient in 2 to 3 days to schedule the flexor tendon repair within 7 days of the injury. **Timely repair is important, as postinjury scarring and tendon retraction make flexor tendon repairs more difficult after 10 to 14 days.** Rapid repair is also recommended to restore vascular and synovial flow to the area and maximize biologic properties of healing.[25] Patients with suspected partial flexor tendon lacerations should also have follow-up with a hand surgeon because unrepaired partial flexor digitorum superficialis disruption can produce a trigger finger.[26]

FINGER LACERATIONS

In general, isolated finger lacerations are straightforward injuries to examine and repair. Vascular status is checked by capillary refill, and sensory nerve status is checked by static two-point discrimination. Assess motor function of the extensor and flexor mechanisms. Careful examination and wound exploration of hand and digit lacerations is important, regardless of size. A prospective study of patients with metacarpal or digit lacerations <2 cm in size found that more than half had an associated deep structure injury, most commonly a tendon, with extensor tendon defects more common than flexor tendon injuries.[24]

Simple interrupted sutures with 5-0 nonabsorbable suture provide adequate closure for most digital lacerations.[16] Alternatively, small, <2 cm, clean, and uncomplicated hand and digit lacerations can be treated conservatively without wound closure.[27] Although there appears to be no difference in cosmetic appearance or time to return to normal function without wound closure compared with wound closure, this practice has not been widely adopted.

DIGIT AMPUTATIONS

Deep finger lacerations may include partial or complete amputations of the digit. Amputations should involve the consultation of a hand surgeon to discuss the possibility of replantation. Relative indications for replantation are injuries in children, injuries to the thumb, multiple digit amputation, and single digit amputation proximal to the insertion of the flexor digitorum superficialis.[28,29] Goals of replantation are to "preserve 2 sensate digits able to oppose each other"[30] with "motion preferred over strength."[31]

The strongest contraindications to replantation are crush and avulsion injuries because neurovascular damage to the amputated digit is significant and functional outcome is poor. Other relative contraindications include multiple levels of injury to the amputated part, prolonged ischemia time (>24 hours) of the amputated part, patients in poor health, or significant comorbid factors, such as diabetes or severe pulmonary or cardiac disease that may lead to significant perioperative mortality.[28] Another relative contraindication is a smoking history, as replants in smokers are prone to profound vasospasm, leading to loss of the replanted digit. The final relative contraindication for replantation is injuries between the metacarpophalangeal joint and the midlevel of the middle phalanx. Fingers replanted at this level are often stiff due to recurrent tendon adhesions between the flexor digitorum superficialis and flexor digitorum profundus tendons, limiting the function of the adjacent uninjured fingers as well as the reattached finger.

DIGITAL NERVE INJURIES

Suspect digital nerve injuries when static two-point discrimination is distinctly greater on one side of the volar pad than the other, or when it is >10 mm. Digital nerve injuries can be repaired using microsurgical techniques either acutely or days to weeks after the injury. Concomitant injuries and wound contamination are the most common indications for delayed repair. Prognosis depends on the specific injury and the age of the patient. Nerve contusions have variable healing, with a range of 12 days to 6 months. Nerve transection injuries do slightly better than crush injuries, but even with microsurgical repair, recovery is often incomplete.

FINGERTIP INJURIES

Fingertip injuries occur distal to the insertion of the deep flexor and extensor tendons at about the level of the lunula. This location is among the most frequently injured parts of the hand. Such injuries may involve the skin, pulp tissue, distal phalanx, and the perionychium (the nail, nail bed, and surrounding structures) (**Figure 43-7**).[32] The goals of healing are to maintain length and cosmetic appearance and have the fingertip approach normal sensation and function.

DIGITAL TIP INJURIES WITH SKIN AND PULP TISSUE LOSS ONLY

Distal fingertip amputations that are 1 cm² or less in size without exposed bone or nail bed involvement can usually be treated conservatively with serial dressing changes alone (Figure 43-8, line A).[32] The key to this technique is the use of nonadherent dressing on the wound itself; this initial dressing is then covered with standard gauze for additional wound protection. Ideally, apply the nonadherent dressing only to the wound itself so that the surrounding intact skin does not become macerated. Provide a follow-up wound check in 2 days. Wound care is vital for proper healing. Instruct the patient to soak the injured fingertip for 10 minutes a day in warm water to which an antibacterial soap has been added, followed by tap-water irrigation and application of a new sterile nonadherent dressing. Change dressings daily for the first 10 to15 days and every other day thereafter. Complete healing may take 4 to 8 weeks. Conservative management of fingertip injuries without bone exposure appears to be superior in terms of cosmetic appearance, improved function, and sensibility of the involved digit.[32] Conservative management is advocated in children <12 years of age, as there is greater regenerative potential in this age group than in adults.

An alternative, but less favored technique, is to use a viable amputated portion as a full-thickness skin graft. The amputated tissue is cleaned and debrided of nonviable tissue, the undersurface of the skin is then defatted with sharp scissors, and the graft is sutured to the defect using

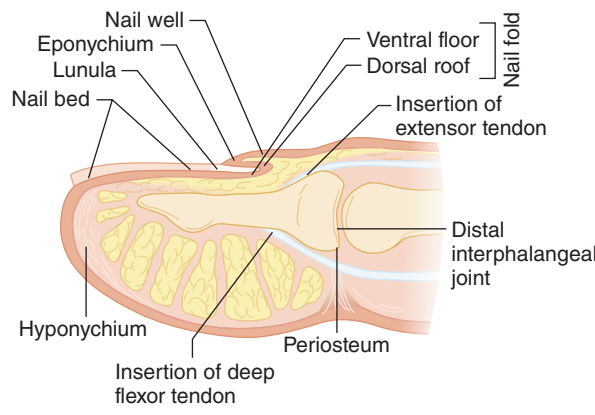

FIGURE 43-7. Anatomy of the perionychium.

percutaneous nylon sutures. Suture ends are left long and tied over a 2×2-cm gauze stent dressing to compress the graft firmly against the fingertip. Unless obvious infection develops, the stented dressing is left undisturbed for 7 to 12 days until follow-up with a hand surgeon. A split- or full-thickness skin graft harvested from a distant site is another means of wound closure in situations in which the severed skin tip is either not available or nonviable, significant pulp tissue loss is >1 cm^2, or the patient's desire to have full use of the hand precludes waiting the 4 to 8 weeks necessary for healing by secondary intention. In these cases, consultation with a hand specialist is appropriate.

DIGITAL TIP INJURIES WITH EXPOSED BONE

Skin grafting will be unsuccessful if a significant loss of tissue at the fingertip exposes the distal phalanx tuft, as bone does not provide adequate vascularity to support donor tissue.[29] Several treatment options exist, and the method used should be based on the best way to preserve the digit length and maintain the sensitivity and functionality of the fingertip. The size and geometry of the injury, the angle of the amputation, and the availability of the amputated tip will determine the options available for repair.[33]

If the bony protuberance is <0.5 cm in length and the soft tissue defect is <1 cm^2, the bone may be trimmed back using a rongeur and the wound left to heal by secondary intention with wound care, as described in Digital Tip Injuries With Skin and Pulp Tissue Loss Only. A dorsal, obliquely angulated wound may be treated in the ED with bone shortening followed by primary closure of the wound using the adjacent volar tissue (**Figure 43-8**, line D). Fat from the local tissue may need to be trimmed to allow wound closure without tension. The nail should be removed, and the nail bed and surrounding structures should be repaired. Although results are comparable to those following conservative management, shortcomings include loss of length as well as tenderness of the fingertip and some degree of functional disability.

Amputations that are angled either in a transverse or volar direction have less favorable outcomes, as there is not always adequate soft tissue and skin coverage to allow for primary closure and preservation of length (**Figure 43-8**, lines B, C, and D). Consultation with a hand surgeon is necessary, as these injuries often require techniques beyond the scope of practice of most emergency physicians.

Incomplete digital tip amputations, defined by the retention of the neurovascular bundle as well as portions of the underlying bone, are among the most difficult injuries to reconstruct and require consultation with a specialist. If adequate circulation is retained in the tip, the injury is treated with fracture reduction, internal pin fixation, and repair of the soft tissue injury. This procedure is optimally performed in the operating room.

Consult a hand surgeon for a complete digital tip amputation occurring proximal to the lunula, to evaluate the potential for replantation in the operating room.[28] Replantation of a complete amputation distal to the lunula is not usually advocated for adults because the procedure is technically demanding and has a generally poor prognosis.

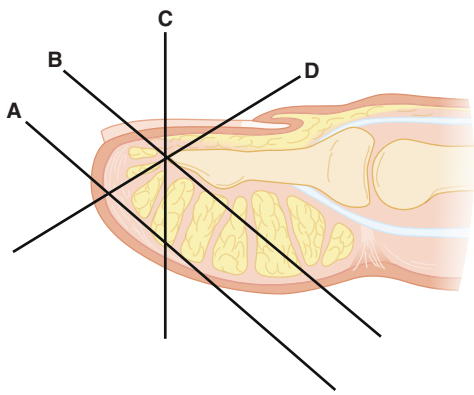

FIGURE 43-8. Fingertip amputations. (**A**) Volar angulation without bone exposure. (**B**) Volar angulation with bone exposure. (**C**) Transverse or perpendicular angulation with bone exposure. (**D**) Dorsal angulation with bone exposure.

However, specialist consultation is indicated in patients with specific occupational concerns and when the affected digit is the thumb or index finger.

Although fingertip injuries are quite common in children, most require only conservative management owing to the rapid healing ability of the young. Repairs in young children should be done using absorbable sutures to eliminate the need for suture removal, as suture removal often requires repeat procedural sedation. Surgical procedures such as grafts and advancement flaps should be avoided. A completely amputated composite tip may be reattached to serve solely as a biologic dressing, and parents should be informed that the tip might necrose, dry up, and turn black as the underlying wound continues to heal. In children <6 years of age, the hand specialist may opt for replantation and revascularization of the composite tip.

INJURIES INVOLVING THE NAIL AND NAIL BED

The nail, nail bed, and surrounding soft tissue make up the perionychium (**Figure 43-7**). The nail bed is made up of the germinal and sterile matrices. The germinal matrix begins at the proximal base of the nail (typically 3 to 5 mm proximal to the eponychium) and extends to the lunula. From there, the sterile matrix extends distally to the hyponychium. Nail injuries can be described as simple nail bed laceration, stellate laceration, severe crush, and complete avulsion. Injury to the perionychium is most commonly due to closure of the fingertip in a door and is usually located at the distal portion of the nail bed. The mechanism of injury is a force directed to the dorsum of the nail, causing it to bend or break, and crushing the nail bed against the unyielding distal phalanx. Distal tuft or phalanx fractures are associated with approximately 50% of nail bed injuries, so imaging of the involved digit(s) is needed, as discussed in the Imaging Studies section. Nail plate deformity permanently affecting nail growth is the most common complication resulting from inadequate treatment.

SUBUNGUAL HEMATOMA

Disruption of the blood vessels of the nail bed without fracture of the nail results in accumulation of blood under the nail. A subungual hematoma that covers >50% is treated with trephination of the nail plate to allow decompression and drainage of the hematoma. Various tools for this purpose include a heated paper clip, electric nail drill, electrocautery, 18-gauge needle, or scalpel. The disadvantages of the heated paper clip include coagulation of the hematoma and introduction of carbon particles into the nail bed, which may delay healing and cause tattooing. Use of a needle, scalpel, or nail drill can be painful and may necessitate a digital nerve block. A hand-held electrocautery device provides rapid and painless trephination. Do not apply alcohol or other flammables to the fingertip before electrocautery, because flames result when electrocautery is then applied. **Simple trephination produces a good to excellent outcome in most patients regardless of subungual hematoma size, injury mechanism, or the presence of fracture.**[34,35] After drainage, instruct patients to soak the affected finger in warm water containing antibacterial soap two to three times a day for 7 days and to follow basic wound-care principles.

NAIL BED INJURIES

Nail removal is recommended only if there is associated partial nail avulsion or surrounding nail fold disruption. Nail removal can be accomplished with adequate anesthesia, elevation of the nail off the nail bed using iris scissors, elevation of the eponychium off the nail, and then removal by gentle longitudinal traction with a hemostat. Tourniquet application to the digit with or without exsanguination may be required to adequately visualize the extent of nail bed laceration. Lacerations of the nail bed should be carefully repaired using 6-0 absorbable sutures to provide a smooth surface so the nail can grow without cosmetic deformity. Tissue adhesives can also be used to repair small nail bed lacerations. The use of tissue adhesives facilitates nail replacement by providing an additional structural anchor and minimizes venous bleeding associated with suturing the delicate nail bed tissue. Crush injuries often result in stellate lacerations, which may require extensive, meticulous

repair using magnifying loupes for visualization. Nail bed injuries in children can also be repaired with a good outcome.[36]

Gently cleanse the removed nail with saline, taking care to avoid damage to the germinal matrix. Once the nail is clean, trephinate the nail to prevent the development of a postrepair subungual hematoma, and secure the nail in its anatomic position. To secure the nail, place a 5-0 nonabsorbable suture through the proximal end of the nail plate, and then pass the suture underneath and through the center of the eponychial fold. Once the nail plate is secured in its anatomic position, tie the suture down over the nail. The replaced nail acts as a natural splint to the terminal phalanx, prevents formation of synechiae, and protects the sensitive nail bed. If the nail is not available, nonbiologic stents or a sterile piece of aluminum foil (such as that used to wrap suture materials) may be fashioned to resemble the avulsed nail, inserted under the eponychium, and sutured in place similar to a replaced nail.

Then dress the fingertip with nonadherent gauze, and apply a volar splint to limit distal interphalangeal joint movement. Provide postoperative wound-care instructions (e.g., regarding hand elevation as well as neurovascular checks) and adequate pain relief. Unless obvious purulence is noted, leave the dressing undisturbed for 5 to 7 days. At that time, examine the site for new hematoma formation. The suture attached to the nail can be removed after 3 weeks. The existing nail will be dislodged by the new (growing) nail after an additional 1 to 3 months of growth.

If an associated distal phalanx or tuft fracture coexists with a nail bed laceration, it usually manifests as an avulsion of the nail out of the proximal eponychial fold. In this case, remove the nail, stabilize the fracture by manual reduction, and repair the nail bed as described previously. Once replaced in its anatomic position, the nail serves as a biologic splint to maintain fracture reduction owing to its proximity to the underlying bone. Unstable reductions require consultation with a hand surgeon for internal fixation using Kirschner wires to prevent deformity of the nail bed.

NAIL BED AVULSION INJURIES

Avulsion injuries to the nail bed have the poorest prognosis of any fingertip injury. An avulsion or crush injury may tear the nail completely away from the digit, with fragments of germinal matrix tissue left on the underside of the avulsed nail. These matrix fragments should be preserved for use as free grafts and, when possible, reattached to the nail bed using 6-0 or 7-0 absorbable sutures. When the nail or avulsed nail bed fragments are not available, or if the nail bed defect is large, a full-thickness nail bed graft can be harvested from the patient's toe and sutured into the nail bed of the affected finger. Consultation with a hand surgeon is needed, as these injuries are complex, and repair is technically challenging.

Avulsion injuries may also incompletely tear the proximal portion of the nail out from under the eponychium. Management entails replacement of the nail root into its anatomic position using a series of three horizontal mattress sutures (**Figure 43-9**). One suture is placed through the center and one in each corner of the eponychial fold. The sutures are then passed through the proximal portion of the corresponding segment of avulsed germinal matrix and then back out through the nail fold, pulling the matrix back to its anatomic position.

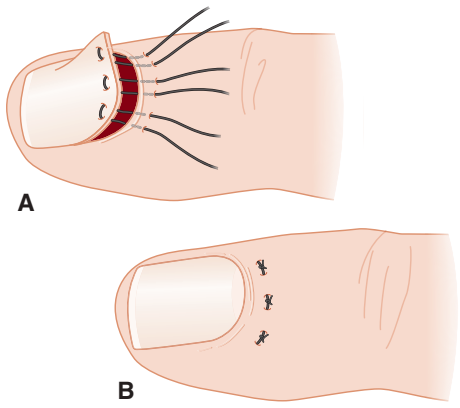

FIGURE 43-9. A and B. Technique for repair of an avulsion of the germinal matrix using three horizontal mattress sutures.

FIGURE 43-10. Tight ring with swollen finger tightly flexed at proximal interphalangeal joint. (Image used with permission of J. Stephan Stapczynski, MD.)

RING TOURNIQUET SYNDROME

A tight ring encircling the proximal phalanx may become entrapped as a result of distal swelling (**Figure 43-10**). As the digit expands, venous outflow is restricted by the tight ring, producing more swelling. This vicious cycle may lead to nerve damage, ischemia, and digital gangrene. The presence of impaired sensation (diminished static two-point discrimination) or diminished perfusion (delayed capillary refill) indicates significant constriction. Rapid ring removal is then warranted, typically cutting the ring. If sensation and perfusion are intact, removal can be attempted with slower techniques that preserve the ring. However, if there is an underlying phalangeal fracture, it is prudent to cut the ring.

In all ring-preservation methods (string technique, rubber band technique), the hand should be elevated to encourage venous and lymphatic drainage and thus reduce swelling. Additionally, the finger can be circumferentially wrapped with a $^1/_2$- to 1-in. elastic band (e.g., Penrose drain), starting from the distal tip and winding the band tightly around the finger, progressing toward the proximal phalanx to reduce swelling. Leave the wrap in place for several minutes before it is unwrapped and the ring is removed. A digital nerve block or other method of regional anesthesia is often required prior to ring removal. A metacarpal or tendon sheath block produces less swelling of the finger but may not provide as much anesthesia as a digital block.[37] After ring removal, reassess sensation and perfusion.

CHAPTER 44

Leg and Foot Lacerations

Annabella Salvador-Kelly
Nancy Kwon

INTRODUCTION

Lower extremity injuries most frequently involve the lower leg and ankle, followed by the foot and toes, hip, and then knee.[1] Lacerations and wounds occur from sports and recreational activity,[2-8] tools and equipment,[9-11] occupational activity,[12] and explosions.[13]

ANATOMY

In the foot, the plantar epidermis and dermis are thick, except in the arch area. This thick skin is able to withstand the force produced by a moving body but is also quite sensitive to two-point discrimination and pressure. The heel has an 18-mm-thick modified pad of fat separated into chambers by fibrous septae. There is an additional broad internal fibrous arch, called the *inner cup ligament*, which helps maintain the shape of the heel. The skin of the sole readily hypertrophies and can become quite thickened, especially in people who walk barefoot. The dense fibrous fatty tissue of the ball of the foot and heel makes wound exploration and visualization difficult in the ED.

In contrast to the protective plantar surface, skin on the dorsal aspect of the foot and the entire ankle provides little protection for underlying tendons, nerves, and blood vessels. The dorsum of the foot, the ankle, and the pretibial surface are particularly vulnerable to blunt-force injuries. Most lacerations on the dorsal foot and in the ankle area are easily explored, except for posterior ankle lacerations, a limitation when partial laceration of the Achilles tendon is considered. Lacerations involving the shin, calf, and thigh usually present few problems regarding wound exploration and visualization.

Several important tendons in the leg are at risk for injury. The fibularis longus and fibularis brevis (also known as the peroneus longus and peroneus brevis) tendons, which contribute to foot plantar flexion and eversion, run behind the lateral malleolus and can be lacerated at this location (**Figure 44-1**). The extensor hallucis longus tendon, which extends the first toe, runs along the top of the first metatarsal and may be injured when heavy objects are dropped on the foot. The Achilles tendon, the primary contributor to foot plantar flexion, may be severed by penetrating injuries to the posterior ankle. Lacerations of the shin rarely involve vital nerves or tendons. Infrapatellar lacerations can transect the patellar tendon, resulting in inability to extend the leg. Suprapatellar lacerations may involve the quadriceps tendon, also resulting in impaired knee extension.

Sensory nerves predominate in the foot, with most motor control of the foot being performed by nerves and muscles in the lower leg (**Figures 44-2 and 44-3**). **The exceptions to this generalization are that the posterior tibial nerve innervates the intrinsic foot musculature, and the deep peroneal nerve innervates the extensor digitorum brevis and extensor hallucis brevis muscles; injuries to these nerves may result in toe clawing.**[14] The common peroneal nerve can be injured in complex fractures, sharp injuries, or lacerations of the lower extremity resulting in foot drop (**Figure 44-4**).[15]

Arterial injury resulting from penetrating and blast wounds most commonly affects the superficial femoral, popliteal, crural, common femoral, and deep femoral arteries (**Figure 44-5**).[16] Arterial injuries are at high risk for limb loss.[17]

ASSESSMENT

HISTORY

Obtain a description of the mechanism of injury, assessing the potential for damage to underlying tissue, the risk of a retained foreign body, and degree of potential contamination. Determine the time interval from injury to evaluation, because delayed presentations can increase the incidence of infection. Inquire about foreign body sensation, paresthesias, anesthesia, weakness, or loss of function suggesting a nerve, vascular, or tendon injury.

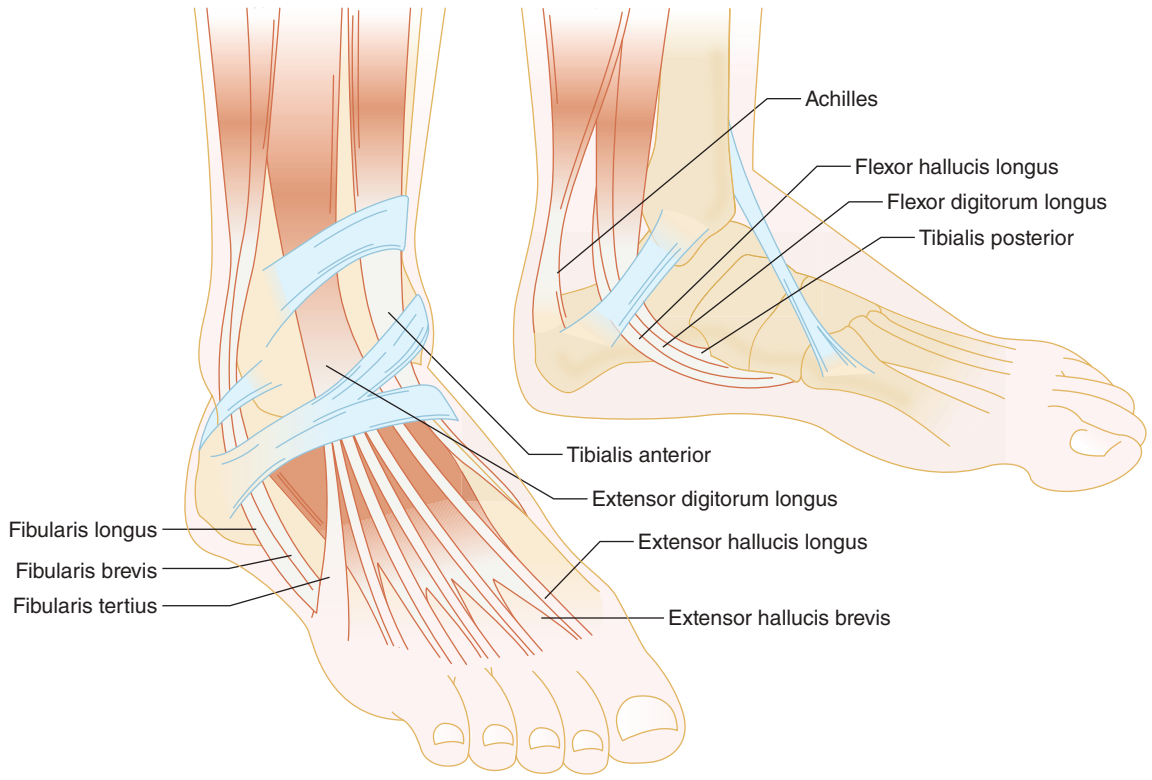

FIGURE 44-1. Tendons of the foot.

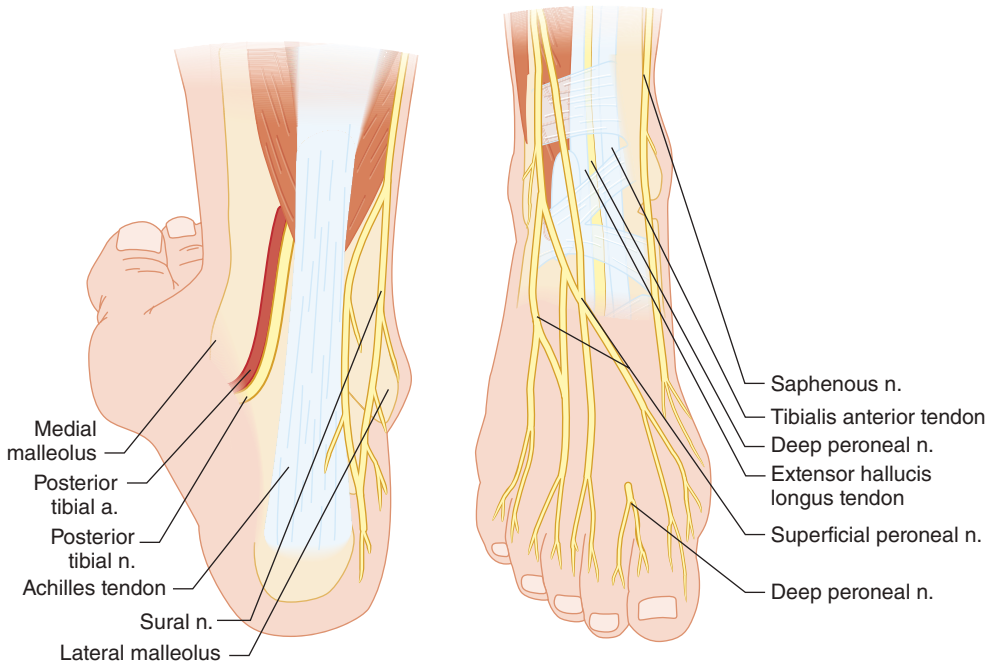

FIGURE 44-2. Nerves of the foot. a. = artery; n. = nerve.

The patient's age influences wound healing and functional status following the injury. Ask about tetanus immunization status and conditions that increase the risk for infection or delayed wound healing such as diabetes, immunosuppression, or vascular disease. Note the social history, because patients who smoke, consume alcohol, or use illicit substances may be at additional risk of poor healing secondary to vascular disease.

PHYSICAL EXAMINATION

Inspect the wound, noting its location and proximity to underlying nerves or arteries. General appearance, obvious injuries, or visible foreign bodies should be noted; more detailed wound exploration typically waits until after anesthesia and radiographs, if needed. If a nerve laceration is suspected, light touch and/or static two-point

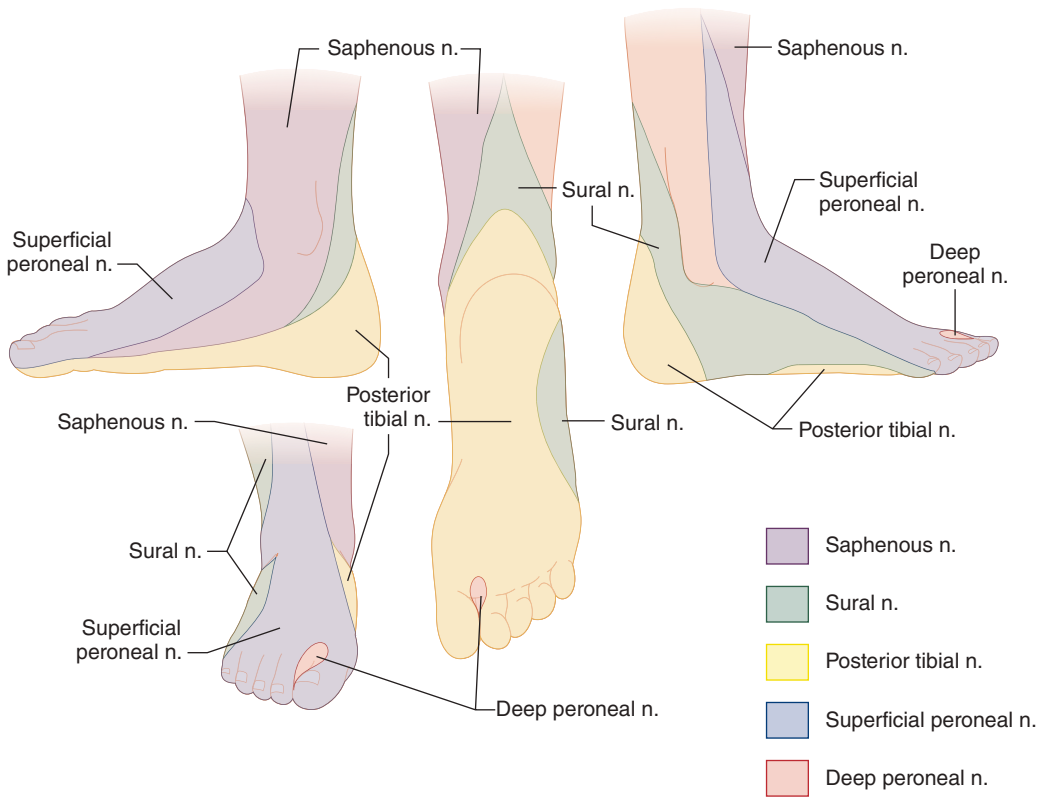

FIGURE 44-3. Sensory innervation of the foot. n. = nerve.

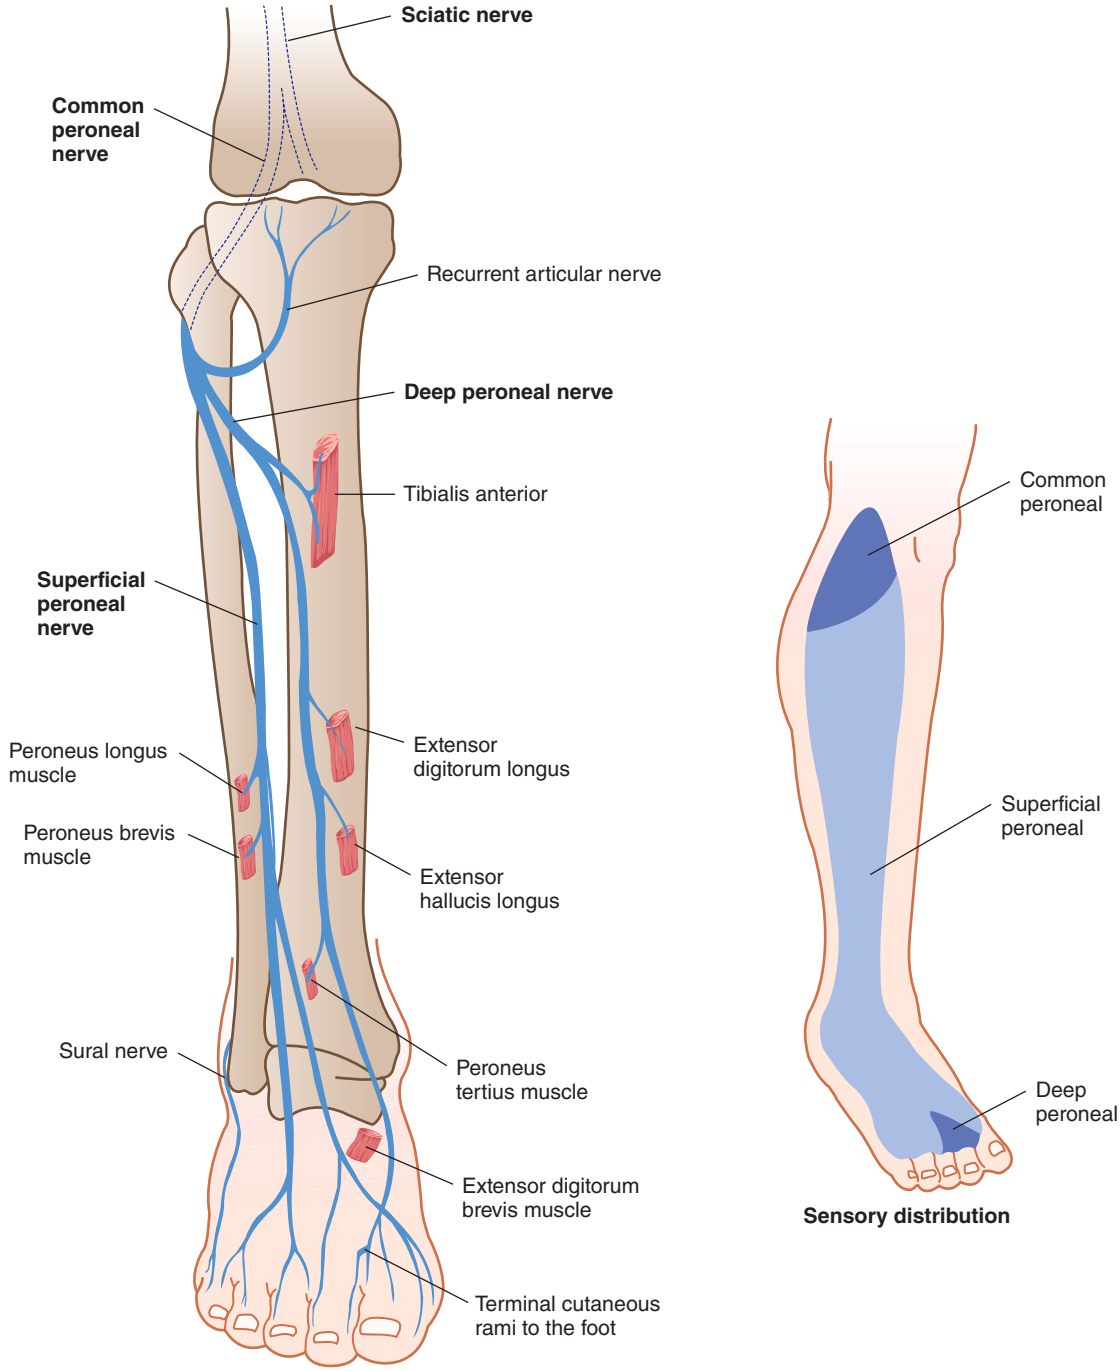

FIGURE 44-4. Common peroneal nerve. [Reproduced with permission from: Waxman SG: Appendix C. Spinal nerves and plexuses. In: Waxman SG (ed): *Clinical Neuroanatomy,* 27th ed. New York, NY: McGraw-Hill; 2013. Figure C-16.]

discrimination should be tested in the foot and toes and compared with the uninjured side. Two-point discrimination varies in the foot, with normal values of 1.5 cm in the hind, mid, and forefoot, and <1 cm in the big toe, but these measures are not reliable in patients with diabetes or peripheral vascular disease.[18] Sensory deficits to the foot can result in significant long-term morbidity. Motor function may be easier to assess after anesthesia or reduction of an associated fracture or dislocation. Obtain prompt surgical consultation if motor nerve or major sensory nerve injury is identified because primary repair may be indicated.[14] Nerve injuries caused by open blunt injuries are not typically repaired at the time of injury, in part because of the risk of infection and in part because of the possibility that a contused nerve will regain function without surgical intervention.

Evaluate for tendon injuries by assessing motor function, palpating the tendon, and observing the tendon through its entire range of motion. A partially injured tendon may be noted to "catch" on the synovial sheath during range of motion. Lacerations of the Achilles tendon may be easily visualized with simple exploration through the open wound, by palpating a defect in the tendon, or by US. Sometimes, the tendon laceration may not be visible or palpable, and presence of active plantar flexion of the foot cannot be used to exclude the injury. The Achilles tendon is not the only structure responsible for plantar flexion of the foot—the tibialis posterior muscle flexes the foot at the ankle. The Thompson test can assist in detecting an Achilles tendon rupture. The patient lies prone on the examination cart with the feet hanging over the edge of the bed, and the examiner places one hand on

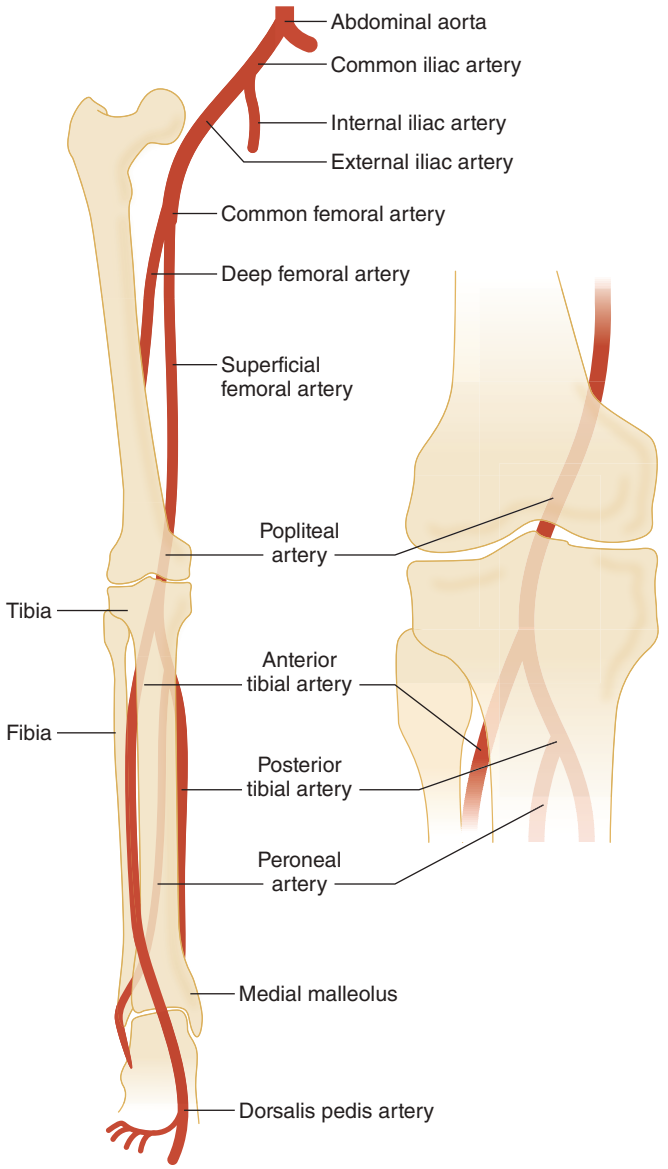

FIGURE 44-5. Major arteries of the leg.

each mid-calf (**Figure 44-6**). If the Achilles tendon is intact, the foot plantar flexes when the calf is squeezed, and comparison with the unaffected side is helpful to detect subtle movement. A positive Thompson test is when the affected foot does not flex, indicative of an Achilles tendon rupture.[19]

Document the location, length, estimated depth, and general shape of the wound. Provide anesthesia, cleanse the wound, and carefully inspect the full extent of the wound for foreign bodies. The loose, thin skin over the dorsum of the foot allows for adequate visual, digital, and instrument exploration for tendon lacerations, as well as for foreign body discovery. The dense tissue of the plantar surface of the foot limits wound visualization, and the risk of creating further injury limits exploration. An exception to this general rule of limited exploration on the weight-bearing plantar surface is in an infected wound with suspected foreign body. With significant injury to the leg, like a crush injury, consider compartment syndrome and evaluate accordingly.

ANCILLARY STUDIES

Obtain radiographs when a fracture, radiopaque foreign body, or joint penetration is suspected.[20,21] Foregoing radiographs and using wound exploration alone to exclude a foreign body is a reasonable approach, but carries a

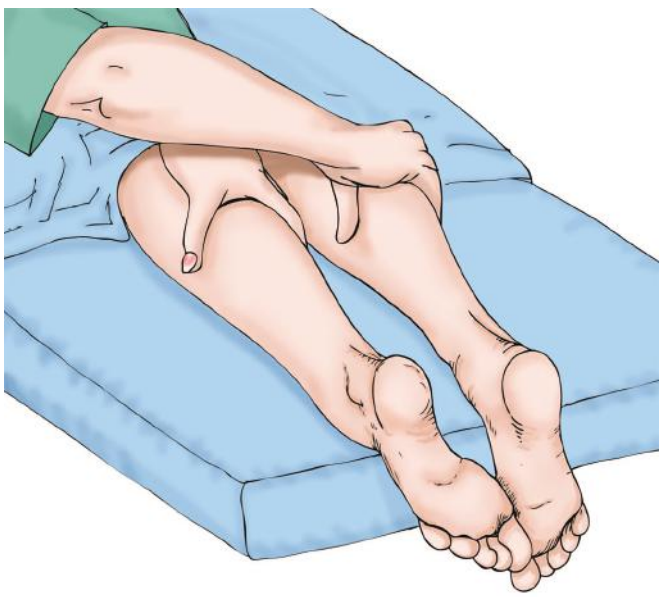

FIGURE 44-6. Thompson test.

small risk of missing a retained object.[22-24] CT or MRI can detect retained organic material. Bedside US may identify retained foreign bodies and detect tendon lacerations and fractures (see chapter 45, "Soft Tissue Foreign Bodies"). Fluoroscopy is a useful dynamic imaging modality that may assist in identifying and removing foreign bodies. No single imaging modality or wound exploration will identify every foreign body; emphasize close follow-up if the mechanism of injury suggests a potential for a foreign body but none was identified on imaging or wound exploration.

Lacerations in proximity to joint spaces may penetrate the articular space. Detecting joint penetration by physical examination alone is often difficult. Intra-articular gas on plain radiograph is a sign of joint penetration. **If the radiograph does not display intra-articular gas, use the saline load test to determine joint integrity, especially in the knee and ankle**.[25,26] Inject sufficient amounts of saline to adequately stress the capsule, because false-negative results may be obtained if too little fluid is injected.[27,28] Volumes injected into the knee may vary based on the location of the approach; mean volumes of injected fluid needed for a positive result are approximately 65 mL and 95 mL, respectively, at the inferomedial and superomedial locations.[26-28] Fluid leaking from the wound indicates joint penetration. **Do not add methylene blue** to the injected saline to aid in visualization of fluid existing in the wound because it does not increase diagnostic accuracy compared to saline alone and the resultant staining of the articular surfaces may affect operative management of intra-articular injuries.[29]

TREATMENT

ANESTHESIA

Anesthesia can be administered by topical, local, or regional routes. The toes can be anesthetized using standard digital blocks. Epinephrine-containing local anesthetics can be safely used for digital blocks in toes (see chapter 36, "Local and Regional Anesthesia").

Lacerations to the dorsum of the foot can be sufficiently anesthetized by infiltration of local anesthetic. The plantar surface of the foot is sensitive to the infiltration of a local anesthetic, so regional nerve blocks may be helpful. The sural nerve block and the posterior tibial nerve block (see chapter 36) are the two most commonly used nerve blocks for the foot. Topical local anesthetic preparations can achieve adequate anesthesia on the dorsum of the foot and leg, but may be ineffective on the dense epidermis of the plantar surface of the foot. In children, distraction techniques, use of child-life specialists, anxiolytics, and conscious sedation may help alleviate anxiety and pain response (see chapter 113, "Pain Management and Procedural Sedation in Infants and Children").

WOUND PREPARATION

Wound irrigation with copious amounts of saline is recommended due to the increased risk of infection with lower extremity lacerations (see chapter 40, "Wound Preparation").[30-32] Debridement to remove devitalized tissue is an important aspect of wound care to reduce the risk of wound complications, but debridement should be limited on the plantar surface of the foot or on the shin because skin in those areas is not pliable enough to be stretched and cover a defect. Any opening resulting from debridement would then require repair under tension across the laceration.

A "golden period" of 6 hours for laceration repair with the lowest risk of infection is not substantiated by published evidence.[32-34] Repair of clean-appearing wounds without visible contamination presenting after 6 hours is acceptable if primary closure is felt beneficial. Otherwise, consider delayed primary closure in cases of delayed presentation or heavy contamination (see chapter 41 "Wound Closure").

WOUND CLOSURE

Wound location, size, and shape guide the decision to close with adhesive strips, sutures, or staples. Staples are acceptable for linear lacerations through the dermis as long as the wound is sharp with straight and accurately aligned wound edges, minimizing the potential for scar formation. Most foot and leg lacerations do not have these characteristics, so using staples will often result in less aesthetic wound healing.[31] Staples should not be used on the foot because they are uncomfortable when attempting to walk during recovery. Lacerations of the lower extremity can be under increased wound tension compared with other anatomic sites, so these lacerations are frequently repaired using techniques such as multiple-layered closure or horizontal mattress closure.

FOOT AND ANKLE LACERATIONS

DIGITAL LACERATIONS

Digital lacerations frequently require special attention. Nail bed injuries often accompany digital fractures. Clinical signs such as bleeding from the eponychium and a laceration proximal to the nail bed suggest a possible open fracture.[35] Nail bed lacerations place the underlying bone at risk for bacterial contamination because the skin is directly attached to the periosteum with no intervening layer of subcutaneous tissue. Missed open fractures have resulted in osteomyelitis and growth delay of the digit in children. Consider removal of the nail to evaluate for nail bed laceration if a subungual hematoma occupies a large portion of the nail plate or if there is disruption of the nail or nail folds.[36] Repair the nail bed with either absorbable sutures or tissue adhesives.[37] Nail bed lacerations are considered to be open fractures of the distal phalanx, so prophylactic antibiotics are recommended.[35] Conversely, simple nail trephination is adequate for drainage of subungual hematomas without nail or nail fold deformities.

Tendon injuries of the digits may require consultation, especially when the extensor hallucis longus is involved, because injury to this tendon impairs functionality during the swing phase of the gait cycle. Surgery is often recommended for patients with extensor hallucis longus tendon lacerations, and grafting may be needed.[38,39]

INTERDIGITAL LACERATIONS

Lacerations between the toes are difficult to repair because the confined interdigital space is difficult to access for suturing. An assistant gently separating the toes enhances the exploration and repair of interdigital lacerations. Simple interrupted sutures often lead to skin inversion and risk of failure of the initial wound repair with interdigital lacerations. The more effective closure technique, albeit somewhat more difficult to perform, is to place horizontal or vertical mattress sutures. Use 5-0 monofilament nonabsorbable sutures on a small cutting needle. Use monofilament absorbable sutures in young children, thus avoiding suture removal. When a web space laceration involves the neurovascular bundle, the skin is usually closed without attempting to repair the neurovascular injury, followed by subsequent referral to a specialist.

HAIR-THREAD TOURNIQUET SYNDROME

Hair-thread tourniquet syndrome, also referred to as *acquired constriction ring syndrome*, is an unusual type of toe injury usually seen during infancy[40] and rarely seen in older children.[41] A long strand of hair or thread becomes wrapped around a toe, often producing strangulation and digital ischemia. This can be an occult source of irritability for infants.[40] Complete removal is required to restore perfusion and allow skin healing. Two standard approaches to salvage the compromised digit are to either unwind the hair or thread if possible or, otherwise, make a midline longitudinal incision along the extensor surface of the toe to cut the hair or thread.[42] To cut the hair, it will often be necessary to split the fibers of the extensor ligament, but avoid transecting the fibers. The multiple strands of hair or thread are then removed using fine forceps without teeth. The toe often retains the initial appearance, making the physician uncertain whether all of the strands have been removed or cut. A novel but unvalidated method is to apply hair-dissolving compounds.[43] Hair-thread tourniquet syndrome can cause deep cutaneous lacerations that result in tendon lacerations requiring operative repair.[44] Hair-thread tourniquet syndrome is not the result of intentional injury and does not warrant reporting as suspected child abuse.[45]

PLANTAR FOOT LACERATIONS

Repairing a laceration on the plantar surface is best done with the patient placed in a prone position, with the foot overhanging the cart or elevated by placing a pillow beneath the ankle. A large suture needle with thick thread is required to penetrate the hypertrophied epidermis and dermis of the sole of the foot. If there is tissue loss or the site is under tension, vertical mattress sutures may be required. In the arch area, achieving tissue eversion can be difficult. Do not use adhesive tapes, tissue adhesives, and staples on the plantar surface. Small or superficial wounds to the plantar surface typically heal rapidly without sutures. Repair small plantar lacerations if the wound gapes open or there is a risk for infection.

DORSAL FOOT AND ANKLE LACERATIONS

Dorsal surface lacerations are repaired almost exclusively with nonabsorbable, monofilament suture material, most commonly 4-0 or 5-0 for small lacerations. Use careful technique suturing the skin to avoid vessels, nerves, and tendons that lie just under the surface. Deep sutures are not recommended for the same reason. Running sutures are acceptable on the dorsal surface, and smaller lacerations may be closed with adhesive tapes or tissue adhesives. For lacerations under tension, consider applying a splint to restrict movement, allowing for healing during the first 5 to 7 days.

The decision to repair tendon lacerations in the foot depends on the functional impairment caused by the injury compared with the benefits of repair. Many extensor tendon lacerations involving the mid-foot and forefoot can go unrepaired without compromising foot function. The skin is closed and the foot splinted, leaving the injured tendon alone. Lacerations of the extensor hallucis longus or tibialis anterior require consultation with an orthopedist or podiatrist because dorsiflexion of the great toe and foot are important in walking and running.[39,46] Closure without tendon suturing and with immediate mobilization is acceptable in patients with partial lacerations of the extensor hallucis longus tendon.[39]

Flexor tendon lacerations across the toes (excluding the great toe) can usually be left unrepaired without significant functional sequelae, but occasionally a hammer toe or claw toe deformity develops. Lacerations of the flexor hallucis longus are frequently repaired, although long-term benefit is unproven, even in athletes.[46]

LEG LACERATIONS

PRETIBIAL LACERATIONS

Managing pretibial skin lacerations, especially in the elderly patient with comorbidities, is challenging. These wounds often occur on the distal third of the pretibial region, which is poorly vascularized and slow to heal. Pretibial wounds are approached according to the type and severity (**Table 44-1**).[47,48]

Wounds where the edges can be approximated without tension can be closed with adhesive tapes or simple sutures. Wounds with tension can be closed using horizontal mattress sutures with 4-0 nonabsorbable sutures. Occasionally, the 4-0 suture is too fine and cuts through the skin, so use 3-0 sutures. The natural contraction of the thin skin makes closure more difficult because sutures often cut through the fragile skin when attempting to approximate the wound edges. A technique to overcome this problem is to re-enforce the wound edges with adhesive tape applied along the edges before closure with placement of percutaneous sutures penetrating through the adhesive tape.[49-51] Additionally, to minimize tension across the wound, tincture of benzoin can be applied over the sutures, and then broad adhesive tape strips (1/2 in.) can be placed over the sutures to minimize tension across the wound. Alternatively, the wound edges can be held in place by adhesive strips perpendicular to the wound, with sutures placed through the strips, thereby removing the shear force of the strip on the skin.

Flap lacerations with significant skin loss are best repaired with primary excision and skin grafting.[48,52] Apply a foam adhesive dressing (such as 3M™ Tegaderm™; 3M, St. Paul, MN) to absorb exudate and reduce healing time.[53] Patients should remain ambulatory during the healing of pretibial injuries, even after skin grafting.[54] Protecting the repair from the tension created by foot plantarflexion is useful; consider using a lightweight plastic ankle-foot orthosis.[55]

TABLE 44-1 Pretibial Lacerations

Classification	Description	Management
Ia	Simple linear laceration not under tension	Primary closure with adhesive strips or sutures
Ib	Simple linear laceration under tension	Primary closure using methods to reduce skin tension
IIa	Flap laceration with no skin loss and/or wound hematoma	Close with adhesive strips
IIb	Flap laceration with some necrosis and/or hematoma	Excise small nonviable areas; close with adhesive strips
III	Flap laceration with significant skin loss or necrosis	Primary excision and skin grafting under local anesthesia
IV	Degloving injury	Plastic surgery consult

KNEE LACERATIONS

Close simple lacerations in the knee area with 4-0 nonabsorbable sutures, using interrupted or horizontal mattress sutures because of the marked active skin tension in this area. **As already noted, assess for joint capsule penetration and laceration of the patellar and quadriceps tendons.** The common peroneal nerve is prone to injury as it runs over the head of the fibula laterally, so distal limb motor function should be assessed (foot eversion and dorsiflexion). Deep popliteal wounds can injure the popliteal artery and tibial nerve. Popliteal artery injuries typically require emergent repair because, in most individuals, there is minimal collateral circulation at the level of the knee (Figure 44-5).

The knee should be splinted or placed in a knee immobilizer to decrease active tension and promote better wound healing. Knee area lacerations in children can be closed with tissue adhesives and splints to restrict movement.

PROXIMAL LOWER EXTREMITY LACERATIONS

Proximal lower extremity lacerations are usually straightforward, and thickness of the soft tissue layers helps to prevent injury to vital structures. Lacerations to the proximal lower extremity also have less tension on them, allowing for easier exploration, debridement, and repair. Assess lacerations to the proximal femoral area for injuries to the femoral artery, vein, and nerve. Although acute traumatic femoral artery injuries are uncommon, they are associated with a high incidence of limb loss and morbidity.[17]

DISPOSITION AND FOLLOW-UP

Most patients with lower extremity lacerations will be able to go home after ED evaluation and treatment. Patients at high risk for compartment syndrome, those with limited mobility and inadequate home assistance, and patients requiring operative repair should be admitted. Patients may require ancillary devices such as crutches, walkers, and wheelchairs. Elevation of the extremity decreases swelling and infection risk. Sutures are typically removed in 10 to 14 days.

Significant tendon lacerations of the lower extremity are usually repaired a few days to weeks after the initial injury. Treatment in the ED consists of skin closure; splinting of the foot, ankle, and leg; initiation of prophylactic antibiotics; instruction for non–weight-bearing crutch use; and arrangement for the patient to follow up with an orthopedist or podiatrist.

SPECIAL CONSIDERATIONS

AGE CONSIDERATIONS

The preverbal child may have particular difficulty limiting movement of the injured extremity and is more likely to contaminate the wound.

Generous dressings aid in protecting any lower extremity laceration; the general rule is **"the smaller the child, the larger the dressing."**

Elderly patients tend to have thin skin and decreased subcutaneous fat, especially over the pretibial surface, making wound edges more difficult to appose, resulting in closure under tension. Additionally, fragile skin in elderly patients predisposes sutures to tear through the skin. Adhesive tapes may be needed to reinforce the closure. Elderly patients are more likely to have medical conditions that can delay wound healing and are less likely to be adequately immunized against tetanus. Assess for fall risk and the ability to perform daily tasks after repair and immobilization of the injured leg.

AMPUTATION

Reimplantation of a severed toe is not typically performed. Reattachment of an amputated great toe, forefoot, or entire foot is occasionally done, although it is extremely complex. Immediate consultation with a reimplantation surgeon is essential in such circumstances. Any severed part should be gently washed (not scrubbed) with sterile saline to remove gross debris, wrapped in saline-soaked gauze, and placed in a plastic bag that is then closed and placed in an ice water bath.

RETAINED FOREIGN BODIES

Retained (nonreactive) foreign bodies, such as glass, can pose a problem. Chronic pain, especially during walking, can occur if the material is not removed. In the absence of chronic discomfort, inert foreign bodies can remain in the foot, where they typically become encapsulated without causing injury or infection. Conversely, reactive organic material does not become encapsulated and does promote infection. Therefore, reactive organic material should be aggressively identified and removed. Fluoroscopy may be useful to help locate and remove radiopaque foreign bodies. Deep foreign bodies in the foot can be extremely difficult to remove in the ED, and such cases are best referred to the surgeon for location and removal in the operating room.

PROPHYLACTIC ANTIBIOTICS

Although infection occurs in 3% to 8% of lower extremity lacerations, and up to 34% of plantar lacerations, there is no evidence to support routine antibiotic prophylaxis in uncomplicated lacerations (see chapter 47, "Postrepair Wound Care"). However, use prophylactic antibiotics for complicated lacerations in the setting of bites, open fractures, tendon or joint involvement, presence of foreign debris, and obvious infections.[56] Diabetes and other predisposing medical conditions, wound contamination, and laceration length greater than 5 cm are factors that predispose to wound infection.[32]

Similar to wound infections in other parts of the body, most lower extremity wound infections are due to either *Staphylococcus* and/or *Streptococcus* species. Animal bites to the leg and foot require coverage against *Staphylococcus, Streptococcus,* and *Pasteurella.* Asplenic or immunocompromised patients who sustain a dog bite should receive coverage against *Capnocytophaga canimorsus.* Amoxicillin-clavulanate will cover all four organisms

The most common organisms causing soft tissue infections in plantar puncture wounds are *Staphylococcus* and *Streptococcus*. *Pseudomonas aeruginosa* is a frequent cause of osteomyelitis and osteochondritis when the puncture occurs through the sole of a shoe.[57] **Open fractures should receive antibiotic prophylaxis. Consensus practice guidelines typically recommend coverage for gram-positive organisms for grade I and II open fractures, with added coverage for grade III injuries.**[58]

CHAPTER 45

Soft Tissue Foreign Bodies

Richard L. Lammers

INTRODUCTION

Soft tissue foreign bodies may be encountered when managing new wounds or evaluating complications of old wounds. This chapter discusses methods of detecting and removing them.

Methodically search fresh wounds for contamination by foreign material. If a foreign body is discovered within a wound cavity or deeply embedded in tissue, decide if removal of the material is urgent, can be delayed, or is even necessary. The decision to remove foreign bodies located below the dermal layer of skin depends on the size, location, composition, accessibility, and anticipated mechanical and inflammatory effects of the object. Many foreign bodies should be removed in the ED. For example, all foreign material within the cavities of fresh lacerations should be irrigated away, debrided, or extracted with instruments. Occasionally, patients with subcutaneous foreign bodies should be referred to appropriate specialists for delayed removal.

Most foreign bodies are detectable during clinical examination.[1,2] Imaging studies are used to evaluate wounds when a concealed object is possibly present.[3]

PATHOPHYSIOLOGY

Transient inflammation is an integral part of normal wound healing. A small amount of foreign debris in a wound provokes an inflammatory response in an effort to eliminate or contain the invader. Large quantities of devitalized tissue, foreign debris, bacteria, or other irritants present within a wound intensify this protective response. Excessive or prolonged inflammation delays wound healing and destroys surrounding soft tissue and bone, producing periosteal reactions, osteolytic lesions, synovitis, and arthritis. If the body fails to dissolve or extrude foreign material, it may become encapsulated within a fibrous capsule. Once a retained foreign body is encapsulated, inflammation subsides.

The type, timing, and intensity of an inflammatory reaction are determined primarily by the chemical composition and physical form of the foreign object. Material that is inert—such as glass, metal, or plastic—may not elicit any abnormal tissue response. Objects with smooth, nonporous surfaces produce less inflammation and fibrosis than those with rough surfaces. Most metals are inert, but those that oxidize will cause mild to moderate inflammation. Earrings with studs dipped in gold paint cause earlobe swelling and inflammation when the paint flakes off. Vegetative foreign bodies, such as wood, thorns, and spines, trigger the most severe inflammatory reactions. Sea urchin spines, other marine foreign bodies, and hair may cause chronic inflammation with granuloma formation.

In some cases, inflammation is caused by a local toxic reaction. For example, blackthorns contain an alkaloid that produces intense inflammation. The oils and resins in redwood and cedar splinters also cause considerable inflammation. Sea urchin spines and catfish spines contain venom that causes severe burning pain at the puncture site and a variety of systemic symptoms (see chapter 213, "Marine Trauma and Envenomation"). A sudden, local inflammatory reaction from a rose thorn or cactus spine may be an allergic response to fungi on the plant. Some cacti cause a delayed hypersensitivity reaction. Systemic toxic and allergic reactions are unusual but serious complications of foreign bodies. Although toxicity is unlikely, foreign bodies containing lead, such as bullets, have the potential to produce systemic lead poisoning, particularly if they are in contact with pleural, peritoneal, cerebrospinal, or joint fluid.[4,5]

Infections are the most common complication of retained foreign bodies, producing local wound infection, cellulitis, abscess formation, lymphangitis, tenosynovitis, bursitis, septic arthritis, and osteomyelitis.[6,7] Infections associated with retained soft tissue foreign bodies are characteristically resistant to therapy; antibiotics, anti-inflammatory drugs, and steroids may produce a partial regression but seldom eradicate the infection.[8]

Some infections will resolve spontaneously once the foreign bodies are removed. Bacteria are infrequently detected after plant thorn injuries, possibly due to the empiric use of antibiotics, but when bacteria are found, *Pantoea agglomerans* is the most commonly reported isolate.[9,10] Vegetative foreign bodies may also cause fungal infections, particularly in immunosuppressed patients.

Foreign objects can also cause mechanical damage by compressing or lacerating anatomic structures or occluding vessels. Repeated movement of tissue containing a foreign object increases the fibrous reaction.

CLINICAL FEATURES

HISTORY

Every wound has the potential for concealing a foreign body, but only a small percentage of lacerations and puncture wounds actually contain them.[1,2,11] Historical factors associated with a higher risk for a retained foreign body include the mechanism of injury, composition and shape of the wounding object, and the shape and location of the resulting wound. Blows to the mouth may fracture teeth, embedding fragments in the lip, tongue, or buccal mucosa of the patient or in the hand of the assailant.[12-14] Objects that shatter, splinter, or break in the process of causing a wound often leave remnants behind. Thorns, spines, and sharp wooden branches are usually brittle and tend to penetrate deeply into puncture wounds before breaking. Wood splinters are notorious for fragmenting, especially when they are pulled out of a puncture wound.

Patients impaled by long, thin metallic objects, such as hypodermic or sewing needles, may remove them without realizing that a portion of the object broke off beneath the skin surface. Both remnants of a needle and impurities in street drugs can cause persistent pain or abscess formation at the site of IV drug use. Nails that penetrate socks and shoes may drive leather, rubber, or cloth into the plantar surface of a patient's foot. Blunt objects with a diameter >4.5 mm may push a plug of skin deep into a wound, resulting in an epidermal inclusion cyst. If any object pulled from a wound does not appear intact, the wound should be explored for further contaminants.

The patient's description of a foreign body sensation in a fresh wound is a useful sign in adults—the perception of a foreign body more than doubles the likelihood of one being present.[11] However, foreign body sensation is less useful in verbal-age children.[15] If a patient reports a sudden, sharp pain on the bottom of the foot while walking barefoot, consider the possibility of impalement with a needle, toothpick, splinter, or shard of glass.

Patients with retained foreign bodies may present to the ED after a wound heals complaining of sharp pain with movement or with pressure over the site. Failure of a wound to heal also may be evidence of a retained irritant. Chronic, delayed, and recurrent infections are associated with retained foreign bodies (**Figure 45-1**). New puncture wounds that become infected and infections that are resistant to antibiotic therapy suggest a retained foreign body. Arthritis in a joint near an old puncture wound may be plant thorn–induced synovitis.[7,8] Unsuspected foreign bodies may present as soft tissue masses.[16]

A

C

B

FIGURE 45-1. **A.** A diabetic patient presented with redness, swelling, and mild pain of her left foot. Although she admitted to walking barefoot on occasion, she had no recollection of stepping on a sharp object. **B.** A small, healing puncture wound was visible on the plantar surface of her foot. **C.** Lateral radiographic view.

FIGURE 45-2. This patient's leg was punctured by a wooden stake 2 days before presentation. **A.** Surrounding cellulitis and point tenderness lateral to the wound indicated the probability of a retained foreign body. **B.** The entrance to the wound was extended. **C.** A 3.7-cm piece of wood was removed.

PHYSICAL EXAMINATION

Physicians are occasionally surprised by foreign bodies that are embedded in small or seemingly superficial wounds. Physical findings that are associated with the presence of a foreign body include a discoloration or visible mass under the epidermis, palpation of a mass, sharp well-localized pain with palpation over or adjacent to a wound, and limitation of passive range of movement of a joint near a wound.

Old wounds with retained foreign bodies may have a persistent purulent drainage, a chronic draining sinus, or a chronic granulomatous reaction. A sterile abscess that complicates wound healing may be the result of a foreign body.

Some foreign bodies are discovered in wounds unexpectedly, but most are found during a deliberate and careful exploration of wounds considered to be at risk.[1,2,11] Adequate lighting, good hemostasis, appropriate anesthesia, and patient cooperation are essential. Magnifying loupes can enhance visualization of small debris fragments or foreign bodies. Make effort to visually inspect all recesses of a wound. **Wounds deeper than 5 mm and wounds whose depth cannot be visualized have a higher association with foreign bodies.** If punctures and other narrow wounds make direct visualization difficult and there is concern about a foreign body below the surface, the wound margins should be extended with a scalpel (**Figure 45-2**).

Wounds that penetrate deeply into adipose tissue are difficult to explore and easily hide foreign material. Blind and gentle probing with a hemostat is a less effective but sometimes acceptable alternative to wound exploration when the wound is narrow and deep and extending the wound is not desirable. This method is used frequently to evaluate plantar puncture wounds caused by nails and to search for clear glass, which is difficult to see in a wound. A closed hemostat should be introduced into the wound and either used as a probe or spread open and then withdrawn. If an instrument strikes a metallic or glass foreign body, it will produce a grating sensation. The instrument should not be used to grasp blindly in hopes of clamping an unseen object. Blind probing is especially dangerous in hands, feet, or face, where direct visualization is the preferred method of exploration.

DIAGNOSIS

Imaging studies should be ordered in most cases in which a retained foreign body is suspected but not found during wound exploration or when exploration of the entire wound is technically impossible.[3,17] Imaging is also useful after initial removal of multiple foreign bodies to determine if all the pieces were found.

Four imaging modalities are available: plain radiography, US, CT, and MRI.[18] The sensitivity and specificity of each imaging modality depend on the object's size, shape, density, and orientation relative to the imaging beam (**Table 45-1**).[3,18] Materials that are the same density as surrounding soft tissue are difficult to see with any type of radiographic or sonographic technique.

LOCALIZATION METHODS

Accurate localization of a foreign body before removal is important because blind searching is time consuming and can cause further injury. However, it is usually easier to detect the presence of a foreign body than to locate its exact position. If a foreign body is radiopaque, one can estimate its location and depth by taping radiopaque skin markers, such as lead circles, paper clips, or a grid, on the skin at the wound entrance or directly over the object.[19] With multiple projections, the object can be seen in relation to the markers. Hypodermic needles can be used as skin markers. Two or three needles are inserted into the skin near the object at approximately 90 degrees to each other to provide a frame of reference around the object. Plain films taken in multiple projections allow the physician to gauge the distance of the object from the closest needle or its distance between two needles (**Figures 45-3** and **45-4**).

The limitations of this technique are that it does not provide a true three-dimensional view and that images on radiographs are distorted by divergence and parallax. Tendons and other structures may block the most direct path to the foreign body.

TABLE 45-1 Imaging Modalities for Detection of Soft Tissue Foreign Bodies[20–23]

Material	Plain Radiographs	High-Resolution US	CT	MRI
Wood	Poor	Good	Moderate to good	Moderate
Metal	Excellent	Good	Excellent	Poor
Glass	Excellent	Good	Excellent	Good
Organic (most plant thorns and cactus spines)	Poor	Good	Good	Good
Plastic	Moderate	Moderate to good	Good	Good
Palm thorn	Poor	Moderate	Good	Good

FIGURE 45-3. Hypodermic needles used as skin markers.

IMAGE STUDY SELECTION

Unless a foreign body is embedded at a relatively superficial level or lies within the cavity of a fresh wound, it will not be easily detected or located by physical examination. If a foreign body is suspected based on the mechanism of injury but not found during exploration of a wound, a radiograph should be ordered first, because plain radiography will detect as many as 80% to 90% of all foreign bodies. It is also prudent to order films if a patient believes there is a retained object.[11,15,17] If the wound was caused by metal, glass, or gravel and no foreign body was found on plain films or wound exploration, the physician can end the search. For objects not routinely visible (or not found) on plain radiography, like wood, sonography is the modality of choice, with CT or MRI as alternatives.[18] **The bottom line is that no single imaging modality is ideal for all types of foreign bodies.**

PLAIN RADIOGRAPHY

Most foreign bodies that can be missed during the initial clinical evaluation can be seen on plain radiographs, but the images must be inspected carefully to detect small and faint objects.[3] **Metal, mammalian bone, some types of fish bones (cod, haddock, grey mullet, red snapper, and sole), teeth, pencil graphite, certain plastics, glass, gravel, sand, and aluminum are visible on plain radiographs.** Almost all glass is visible on radiographs if it is 2 mm or larger, and glass does not have to contain lead to be visible on plain films (**Figure 45-5**).[24] A radiopaque fragment is more easily seen if its long axis is positioned parallel to the central ray of the x-ray beam, increasing its apparent density; thus a foreign body may be evident on one radiographic view but not another.

Obtain plain film radiographs using an underpenetrated soft tissue technique, producing a lighter image that increases the contrast between the foreign body and surrounding tissue. **If the radiograph is displayed on a digital imaging system, the contrast and brightness of the image can be adjusted to achieve the same effect as an underpenetrated film.** Digital edge enhancement adjustments may make the foreign object stand out from the background. Radiographs should be taken in multiple projections to separate the shadow of the foreign body from underlying bone and to help gauge the depth of the object in the tissue (**Figure 45-6**). Chronic inflammatory changes may create secondary bony changes, such as osteolytic and osteoblastic lesions, pseudotumor formation, and periosteal reaction, revealing the object's location.

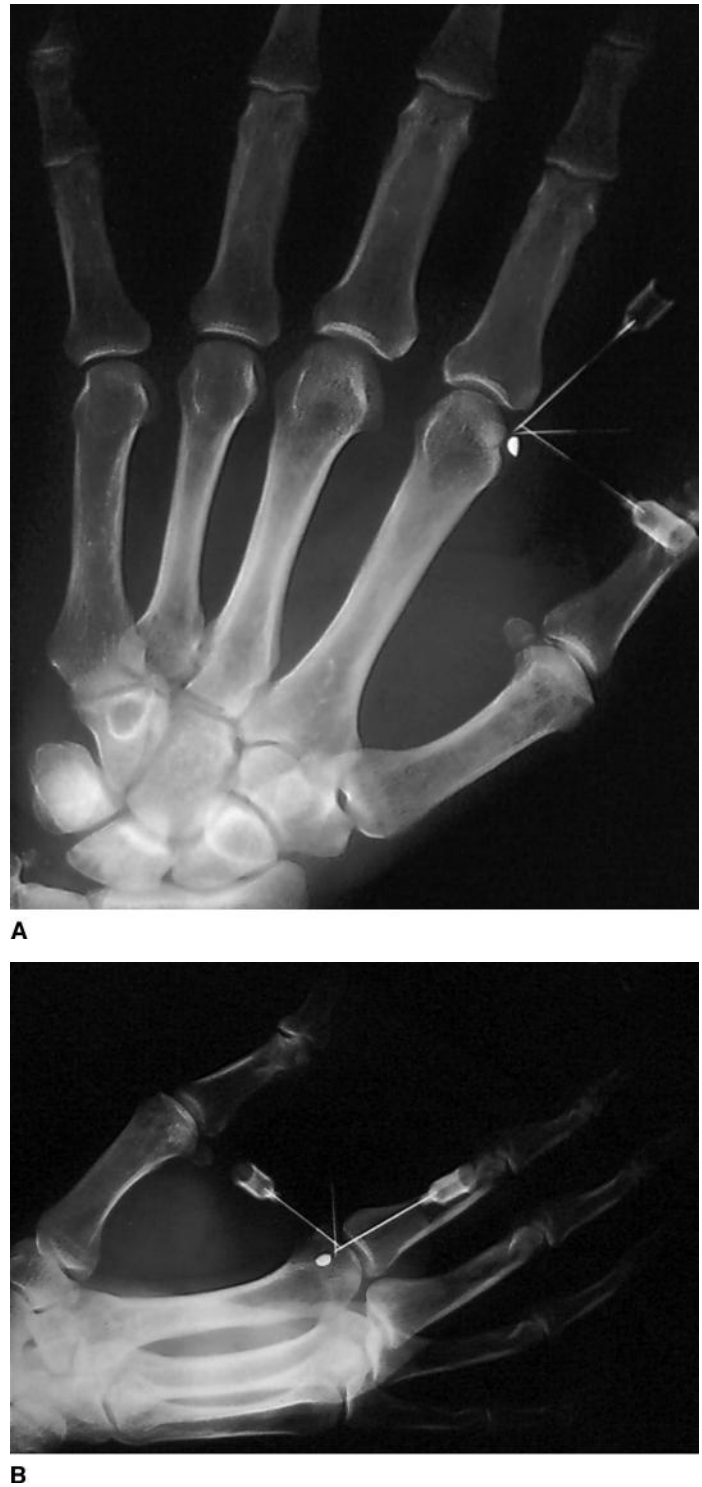

FIGURE 45-4. Needle markers are used to triangulate the location of a radiopaque foreign body. **A.** Plain radiograph, anteroposterior view. **B.** Oblique view.

Many common or highly reactive materials, such as wood, thorns, cactus spines, some fish bones, other organic matter, and most plastics, are not visible on plain radiographs.[3,18,25] Sometimes, there is indirect evidence of their presence. A radiolucent filling defect may occur when the object is less dense than surrounding tissue. However, even

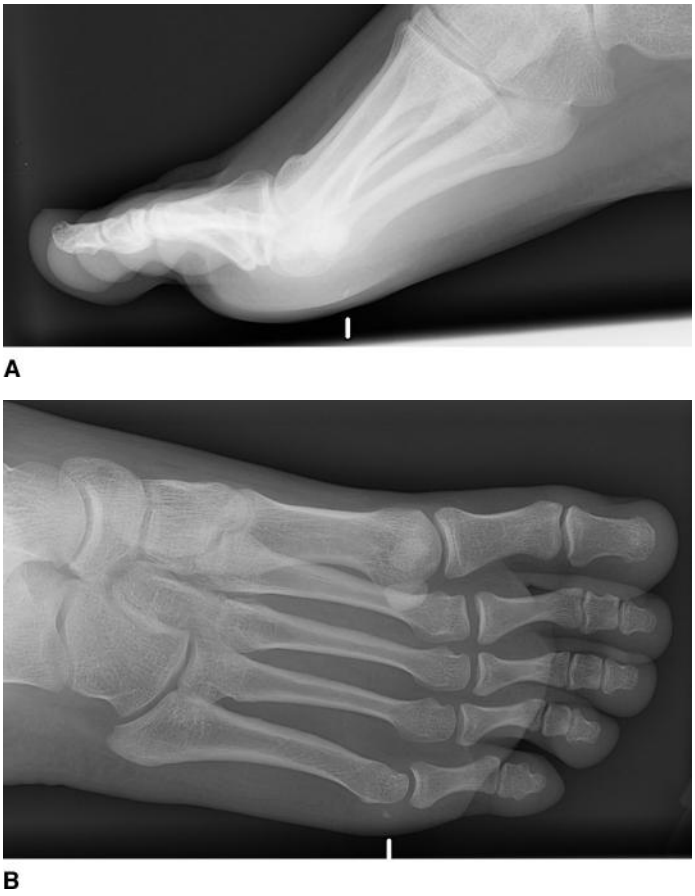

FIGURE 45-5. **A.** The marker points to a glass fragment in the plantar surface of this patient's foot on the lateral view of this radiograph. **B.** Oblique view.

radiopaque foreign bodies may be invisible on plain films if they are obscured by, or impacted in, bone.

CT

CT is capable of detecting more types of foreign materials than plain film radiography because it is 100 times more sensitive in differentiating densities (**Figure 45-7**).[18] Subtle density differences can be distinguished with a narrow radiographic density window adjustment, particularly if a computer workstation is used to vary the gain and contrast settings. **Thorns, spines, wood splinters and toothpicks, fish bones, and plastic foreign bodies can be identified with CT.**[3] In dry wood, the interstices between the fibers are filled with air, imparting reduced radiodensity and making dry wood less visible on CT.[18] Water-rich wood, either fresh from a tree or as occurs when dry wood has been imbedded in tissue long enough to absorb serohematic fluid, is more visible as a slightly hyperdense object on CT.[26]

CT will often detect the inflammatory response to an object that has been in place long enough to elicit the reaction. CT may detect objects embedded in bone, and isodense objects may be outlined by surrounding air within the wound. Digital edge enhancement can further improve the visibility of these objects. CT images can be created in multiple planes and can demonstrate the relationship of a foreign object to important anatomic structures. The principal disadvantages of CT are its cost, higher radiation dose, and the fact that wood and other organic material have radiographic density close to water, making them difficult to distinguish from surrounding tissue. **Another pitfall of CT is that wood foreign bodies may initially mimic air bubbles on CT images.**[27]

US

US is useful for directing exploration and foreign body removal.[28-30] **US can identify a wide variety of soft tissue foreign bodies such as wood, fish bones, sea urchin spines, other organic material, fiber, and plastic, with >90% sensitivity for foreign bodies >4 to 5 mm (Figure 45-8).**[31-36] Detection rates may be less due to the size and sonographic nature of the foreign body, the number of foreign bodies, the presence of confounding factors (e.g., bone, blood, purulence, scars, old sutures) associated with the foreign body, and operator skill and experience. Foreign bodies appear as hyperechoic foci, usually with acoustic shadowing extending distally.[37] A hyperechoic rim, or **halo sign**, indicates an abscess or granuloma around the object. Sonography can estimate the depth of a foreign body below the skin surface.[34]

FIGURE 45-6. **A.** The identity of this metallic foreign body is not apparent on the anteroposterior view of this radiograph. **B.** The shape and depth of the blade are best seen on the lateral view. **C.** Oblique view.

FIGURE 45-7. This patient sustained forehead lacerations when he struck his head on a car windshield. Glass foreign bodies were not identified before wound closure and were not visible on plain films, but were evident on CT.

With experience, sonography can be applied to body areas previously difficult to image for soft tissue foreign bodies, such as the hands and feet.[38-41] Soft tissue gas does not appear to reduce the ability to detect a foreign body but does decrease the ability to discriminate between metal and wood.[42]

An important technical aspect of US for soft tissue foreign body detection is the transducer frequency.[43] **Higher frequencies have a reduced effective depth of penetration for the US wave. A 3.5-MHz transducer will locate foreign bodies that are as deep as 10 cm, a 5-MHz transducer at depths of approximately 7 cm, a 7.5-MHz transducer at depths of 5 cm, and a 12.5-MHz transducer at depths of 2.0 to 0.2 cm.** Conversely, the resolution of the image—ability to distinguish two adjacent objects and detect small objects—is greatest with higher frequencies. Thus, low frequencies can detect larger objects at greater depth but may miss smaller objects and may not be able to discriminate multiple objects. Higher frequencies will detect smaller and multiple objects, but only at shallower depths, and may miss deeper objects. **Use both low and high transducer frequencies for best advantage.**

US has a unique set of limitations. Areas with many echogenic structures, such as calcifications, sesamoid bones, and tendons, may hide foreign bodies within their acoustic shadows, so these areas must be scanned slowly to detect foreign bodies that are small or oriented perpendicular to the skin surface. Some areas of the body that are prone to foreign body penetration, such as the web spaces of the hands or toes, may not accommodate a US probe using standard gel. In this circumstance, a water-bath interface between the probe and body part is useful.[38-40,43,44] False-positive findings result in an unnecessary surgical dissection. False-positive rates for sonography vary from 3% to 15% in clinical case series, depending on the material being studied.[34,36,45,46]

Once a foreign body is confirmed by plain films or CT studies, US can be used in place of fluoroscopy to guide an instrument to the object during retrieval.[28-30,38,39] The scanning beam should be oriented parallel to the long axis of a hemostat, which can be directed toward the long axis of the foreign body (**Figure 45-9**). Transverse and longitudinal scans provide views in multiple planes. A 7.5-MHz linear-array transducer can be used to find objects that are small and superficial (up to 5 cm deep), and a 5.0-MHz transducer can be used for larger and deeper objects. The linear scan is preferred for localization, and the sector scan for retrieval.[28] The primary advantage of sonography is the avoidance of radiation exposure.

MRI

MRI can detect nonmetallic radiolucent foreign bodies and, in comparison studies, is more accurate (less sensitive than US but fewer false-positive interpretations) than any other modality in identifying wood, plastic, spines, and thorns.[3,18,47] **MRI should not be used with gravel or metal-containing foreign bodies because ferromagnetic streaks obscure visualization.** MRI may provide more information than CT about the position of a foreign body relative to (and its effects on) nearby structures, such as tendons, neurovascular bundles, joints, and muscles.

FLUOROSCOPY

Bedside fluoroscopy accurately detects radiopaque (metal, gravel, glass, and pencil graphite) foreign bodies as small as 3 mm.[48,49] Using fluoroscopy to accurately detect glass foreign bodies can be accomplished in a brief training session.[50,51] Advantages are convenience, reduced cost, shortened ED time, and, if done with brief intermittent imaging and appropriate shielding, less radiation exposure than CT. An important limitation is that the body part must be able to fit within the fluoroscopic beam path and be thin enough that a viewable image can be obtained. For most adult patients, this limits fluoroscopy to the limbs. Fluoroscopy can be used to assist foreign body removal by helping guide the instrument, as the body part (usually extremity) can be rotated during fluoroscopic imaging to provide a real-time, three-dimensional view of the object relative to the physician's instruments, skin surface, or skin markers.[48,49] An incision is made between needles or markers, or dissection is carried along the path of the closest needle.

GENERAL TREATMENT PRINCIPLES

Once a soft tissue foreign body is discovered, weigh the risk of leaving the foreign body in place against the potential harm of attempting to remove it. Not all foreign bodies must be removed, and not all that require removal must be extracted in the ED. General indications for foreign body removal include potential for later infection, toxicity, injury, and functional problems (**Table 45-2**). Usually, objects that are small, inert, deeply embedded, and causing no symptoms can be left in place. Bullets that come to rest deep within a muscle belly are usually not removed because the procedure can cause more damage than leaving the foreign object in place. However, projectiles may drag bits of clothing or skin into the wound, so the entrance wound deserves cleaning and debridement. Bullet migration and embolization are rare but possible complications. Bullets near vessels can enter the systemic circulation. Bullets that cause distal ischemia, thrombus formation, or wall erosion or that lie within the lumen of a blood vessel require immediate removal in the operating room.

Thorns, spines, wood splinters, and other vegetative materials should be promptly removed because they cause intense and excessive inflammation. Foreign objects that are heavily contaminated, such as fractured teeth and soil-covered objects, should be removed as soon as possible. Antibiotic treatment cannot replace foreign body removal. Glass, metal, and plastic are relatively inert, and removal can be postponed, if necessary. Glass foreign bodies in hands or feet can cause persistent pain with gripping or walking, and they can sever nerves or tendons years after the initial injury. Patients with deep, sharp foreign bodies in these locations should be referred to appropriate specialists for eventual removal.

Sometimes, harmless foreign bodies are psychologically distressing to patients, particularly when they are visible under the skin surface or produce a lump. Patient concern may be a justification for elective removal.[52]

The techniques for soft tissue foreign body removal are based on clinical experience; there are no controlled or randomized studies comparing different approaches or techniques.[53,54] Successful removal of foreign bodies requires adequate local or regional anesthesia and good lighting. Depending on location and depth, tourniquet control of bleeding and assistance may be needed. Depth and accessibility of the object and physician time are the limiting factors for removal of foreign bodies by the emergency physician. Foreign bodies buried deeply in adipose tissue or muscles are difficult to locate. Although most foreign bodies in hands should be removed because the hand is mobile and sensitive, deep exploration of the hand by the emergency physician is not recommended because knowledge and experience are needed to avoid injury

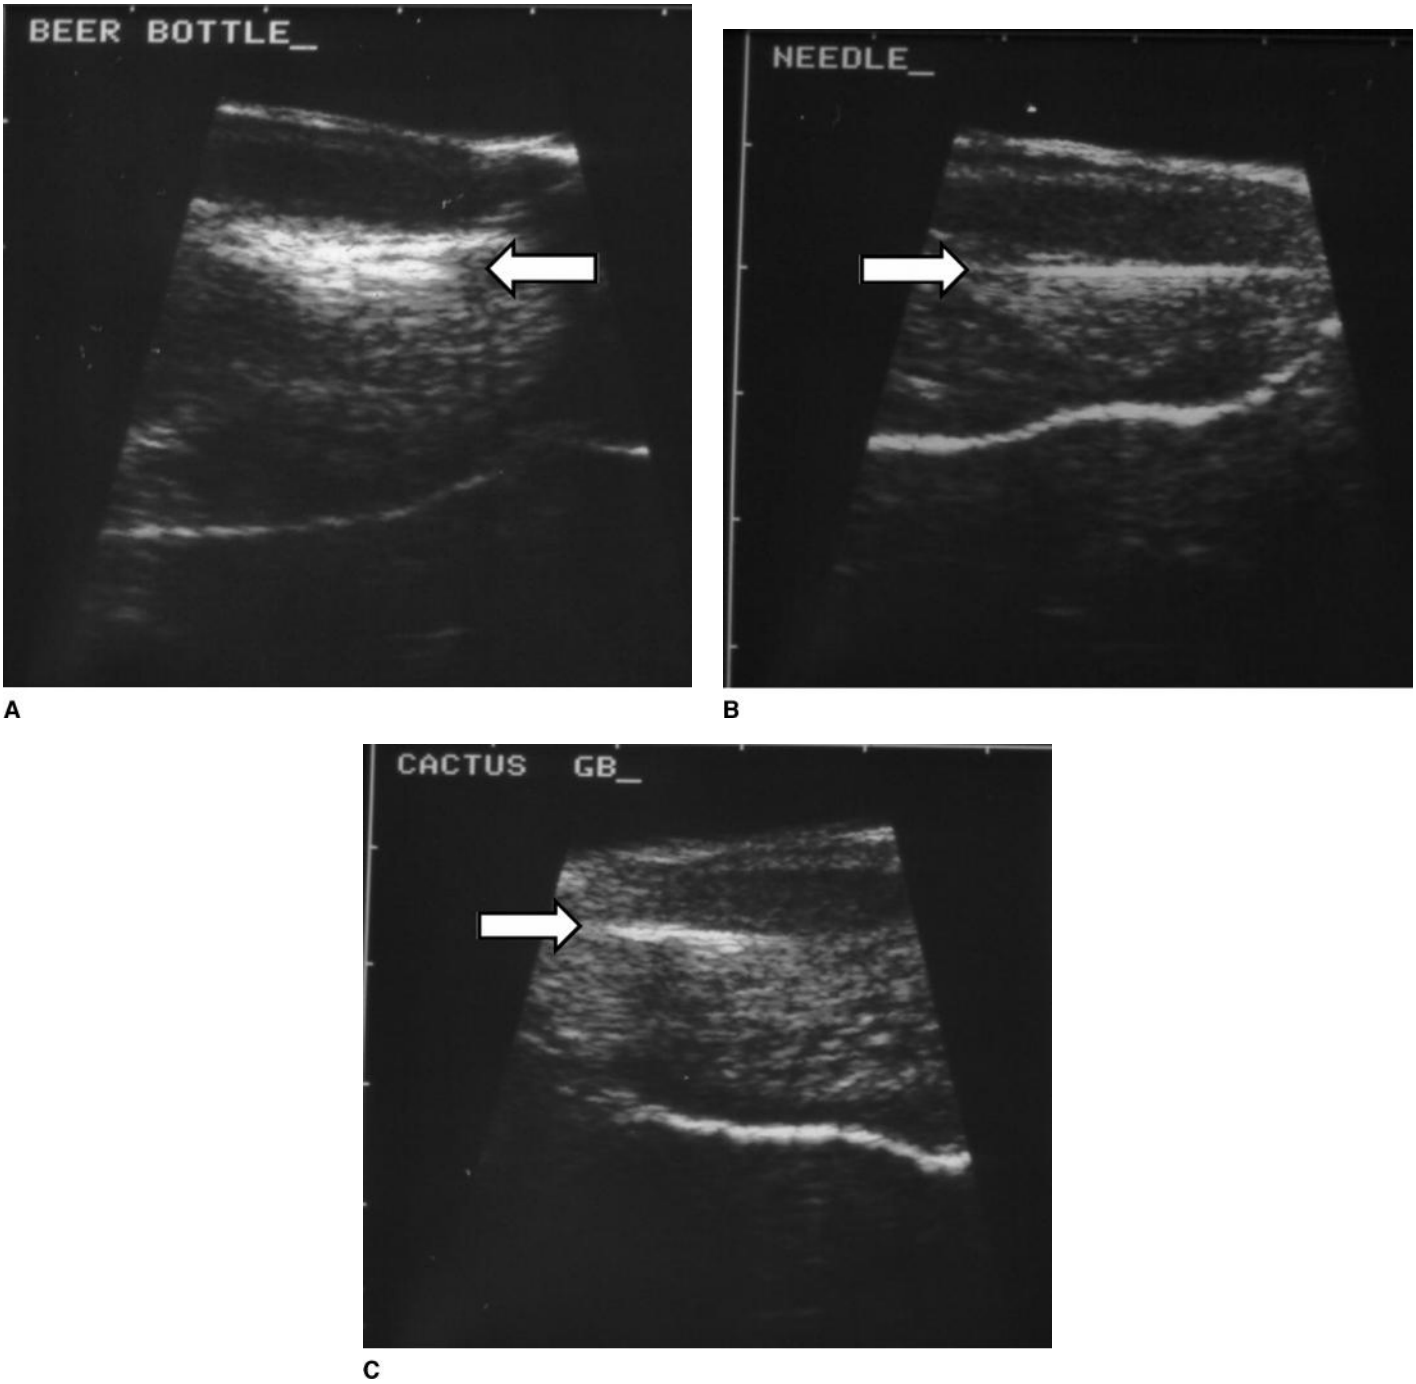

FIGURE 45-8. Sonographic images of (**A**) beer bottle glass (*arrow*), (**B**) sewing needle with long axis parallel to the scan plane (*arrow*), and (**C**) cactus spine (*arrow*), in a tissue model. All objects appear as bright, hyperechoic foci.

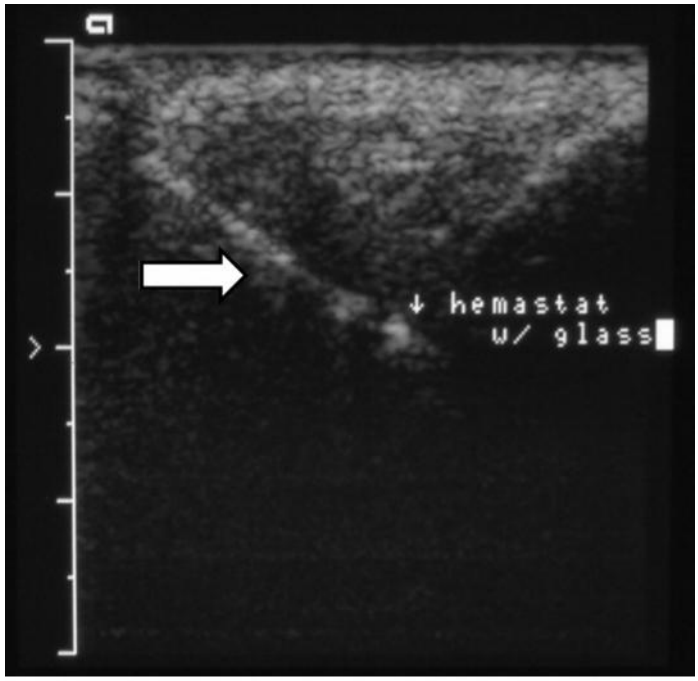
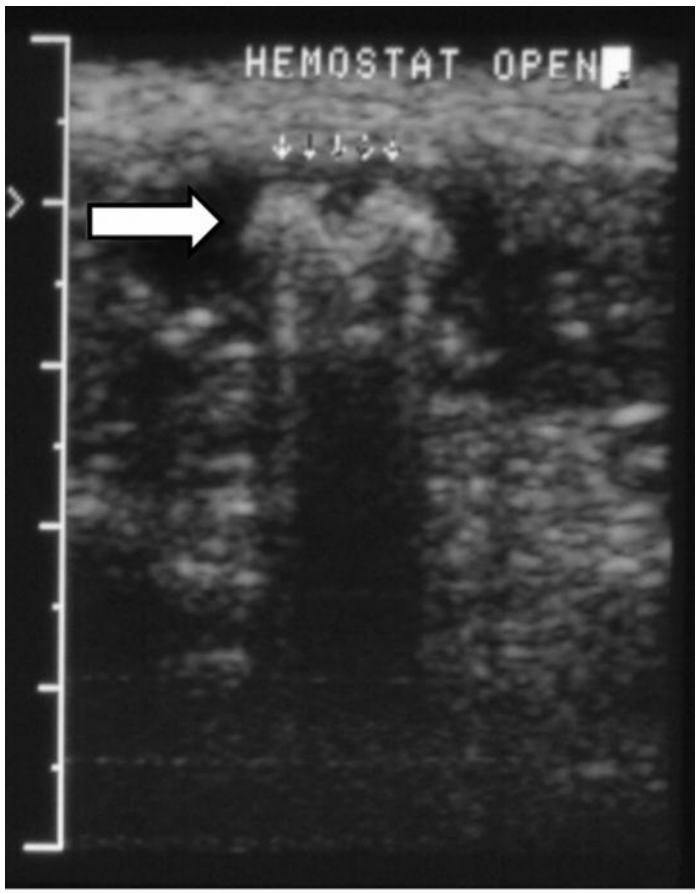


to numerous closely spaced vital structures. The "No Man's Land" of the hand (see Figure 268-10 in chapter titled "Injuries to the Hand and Digits") should not be explored either.

In a busy ED, it may only be possible to devote 15 to 30 minutes to a removal procedure, particularly when other patients demand attention. This amount of time is sufficient for locating most foreign bodies. Inform the patient before the procedure that the duration of the exploration will be limited and a best effort will be made to locate and remove the foreign body. If unsuccessful, referral to an appropriate specialist will be made.



POSTREMOVAL TREATMENT

After removal of a foreign body, irrigate the wound thoroughly with standard wound irrigation techniques (see chapter 40, "Wound Preparation"). A puncture wound is difficult to clean adequately because either the small wound diameter prevents the irrigation fluid from reaching the wounded tissue or the fluid enters the wound but does not completely drain (see chapter 46, "Puncture Wounds and Bites"). In general, if the puncture site is contaminated, the entrance wound can be enlarged to allow more effective cleaning, and if foreign debris is impregnated in tissue, the contaminated area can be debrided or excised. **If multiple radiopaque objects were removed, obtain a postprocedure plain radiograph.**

The decision to close lacerations, incisions, and block excisions depends on the potential for infection. **Wounds in which all foreign contaminants can be removed and those in locations with good blood supply can be closed primarily. Otherwise, delayed primary closure is preferred.** Provide necessary tetanus immunization. There is no proven

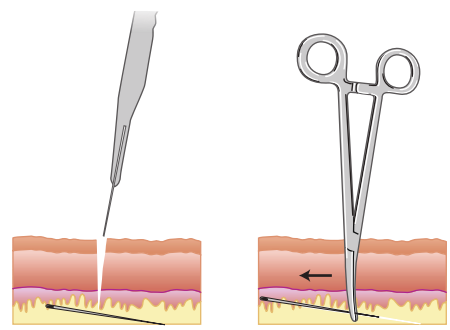
TABLE 45-2 Indications for Foreign Body Removal

Potential for inflammation or infection
Vegetative or chemically reactive material
Heavy bacterial contamination (e.g., teeth, soil)
Proximity to fractured bone
Established infection
Allergic reaction
Potential for toxicity, as with heavy metals
Spines with venom
Impingement on nerves, vessels, or tendons
Intra-articular or intravascular location

benefit for prophylactic antibiotics for uninfected wounds containing foreign bodies.[55] Antibiotics are justified for infected wounds, particularly when removal must be postponed.

If a foreign body is deliberately left in place, inform the patient of the proposed plan and necessary follow-up. If foreign material was removed, warn the patient that there is always a possibility that not all pieces were found despite careful exploration and imaging studies.

DELAYED REMOVAL



Refer patients to surgeons or interventional radiologists for delayed removal of foreign bodies.[56-58] Inform the patient that the object is present but unlikely to cause harm before it is removed. **If a foreign body is near a joint or highly mobile region, the affected area should be splinted before removal to prevent further injury or migration of the object.**

SPECIFIC FOREIGN BODIES AND REMOVAL PROCEDURES

METALLIC NEEDLES

Long, thin foreign bodies, such as sewing and hypodermic needles, may be difficult to locate in soft tissue. Two techniques are available for removing needles that are parallel to the surface of the skin. If the needle is superficial enough to be palpable, make an incision at one end to expose and grasp it with a hemostat. If the needle is deep, make an incision perpendicular to the needle at its midpoint, where it can be clamped with a hemostat and pushed out of the entrance of the original wound (**Figure 45-10**). Sometimes application of a magnet may attract the foreign body to the magnet for removal. Do not apply magnets in patients with pacemakers or implanted defibrillators.

Long, thin foreign bodies that are oriented perpendicular to the skin surface can be elusive. If a needle or nail can be reached with an alligator

A B

FIGURE 45-10. **A.** An incision is made perpendicular to the needle at its midpoint. **B.** The needle is grasped through the incision with a hemostat and backed out of the puncture wound.

forceps or hemostat, it can be pulled straight out (**Figure 45-11**). If a needle lies beyond the reach of an instrument, the entrance wound can be enlarged with a skin incision (**Figure 45-12**). However, the incision may easily pass to the side of the object, so undermine the skin edges and apply pressure on the skin edges that will displace the foreign body into the center of the wound, where it can be seen and grasped. Once removed, the needle and the wound should be inspected to ensure that the object was removed in its entirety.

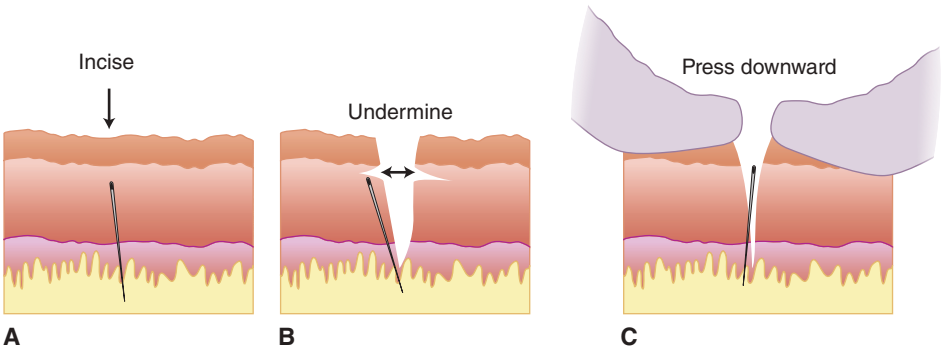

FIGURE 45-12. **A.** The entrance site is enlarged with a skin incision. **B.** If the incision passes to the side of the object, the skin is undermined. **C.** Pressure on the skin edges displaces the foreign body into the center of the wound.

WOOD SPLINTERS AND ORGANIC SPINES

Solid foreign bodies can be pulled out of puncture wounds with forceps, but wood splinters and organic spines (e.g., cactus, sea urchin, and fish) may disintegrate with this technique. Only superficial splinters that are a few millimeters long can be grasped and removed with a fine-point splinter forceps. A splinter parallel to the skin surface should be lifted out of the wound after incising the skin along the long axis of the object (**Figure 45-13**). If the splinter is lodged in the subcutaneous tissue, the entrance wound should be enlarged with a skin incision so the foreign body can be grasped under direct visualization. Wood fragments may be impossible to locate precisely. One solution is to create an elliptical incision around the puncture wound and extract the fragment in a block of tissue (**Figure 45-14**). Avoid incorporating nerves, vessels, or tendons within the excised block. Either technique creates a larger wound but allows a better inspection and more thorough cleaning after removal.

Subungual splinters should be removed because of the risk of subsequent infection with the possibility for distal phalanx osteomyelitis. If the splinter is underneath the distal end of the nail, it can be grasped by a splinter forceps or hooked by a hypodermic needle bent at its tip. More proximal splinters can be reached by anesthetizing the finger and removing a wedge of the nail overlying part of the foreign body (**Figure 45-15**). If there are multiple splinters, the entire nail can be removed in one piece, the foreign bodies extracted, and the nail placed back under the cuticle and tacked down on to the nail bed (see chapter 43, "Arm and Hand Lacerations").

Numerous, tiny cactus spines in the dermis can be plucked out individually with forceps or extracted together with depilatory wax, professional-quality facial gel, rubber cement, or household glue. Larger spines and thorns should be removed with incision or excision techniques.

FISHHOOKS

Fishhooks have a variety of sizes and shapes based on a common pattern (**Figure 45-16**). The barb, which is a projection extending backward from the point of the hook, keeps the point embedded in the fish's mouth and makes removal from skin a challenging task. Most fishhook injuries involve the hands, head, or face (**Figure 45-17**).

There are several methods for removing fishhooks imbedded in skin. The best strategy depends primarily on the depth of the hook. If the hook has multiple barbs, take precautions to avoid impaling the treating physician, bystanders, or the patient (a second time) during removal by taping or cutting off the exposed barbs. With any technique, the skin should be cleaned and anesthetized at the entry site. If the hook is superficial, use the **retrograde technique** by applying gentle downward pressure on the shank while the hook is simply pulled back out along the path of entry (**Figure 45-18**).

The **string-pull method** is a variation on the retrograde technique. Wrap string around the bend of the hook where it enters the skin. Depress the end of the shank with one hand to disengage the barb from deeper tissue. With the other hand, give a quick pull on the string, extracting the hook (**Figure 45-19**). The disadvantages of this technique

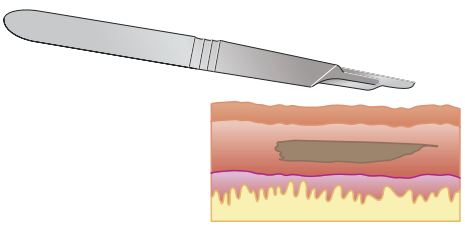

FIGURE 45-13. To remove a friable foreign body such as a wood splinter that is parallel to the skin surface, an incision is made along its long axis. The object can be lifted out and the entire length of the wound inspected for remnants.

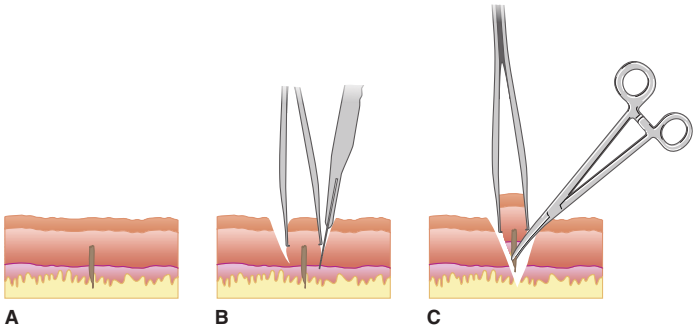

FIGURE 45-14. Block excision is effective for foreign bodies that are friable, difficult to find, buried in fatty tissue, or stain surrounding tissue. **A.** A small, elliptical incision is made around the original wound. **B.** The incision is undercut until contact is made with the foreign body. **C.** The block of tissue is grasped with a forceps, the foreign body is clamped with a hemostat, and both are removed.

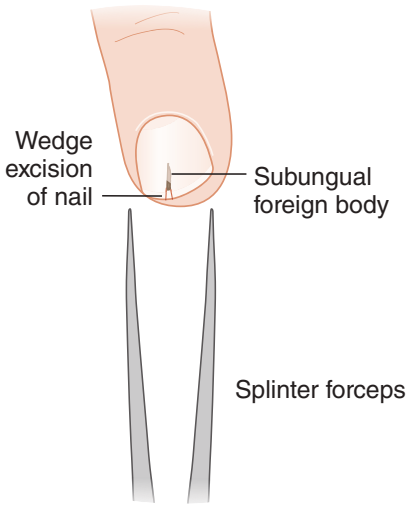

FIGURE 45-15. Subungual foreign bodies that are beyond the reach of a splinter forceps can be exposed by excising a wedge of the overlying nail.

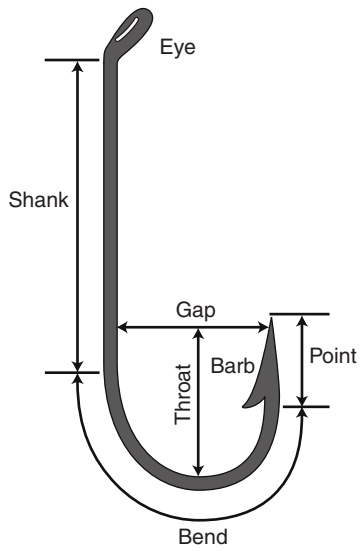

FIGURE 45-16. Anatomy of a fishhook.

FIGURE 45-17. Fishhook in ear.

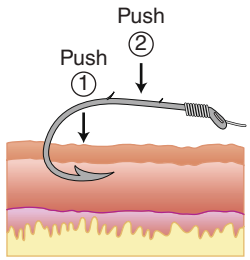

FIGURE 45-18. Simple retrograde technique for fishhook removal. While pressing the skin over the tip of the hook to disengage the barb and applying gentle downward pressure on the shank, back the hook out of the skin. If the barb catches on skin fibers, other techniques must be used.

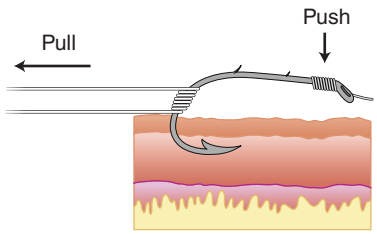

FIGURE 45-19. String-pull technique for fishhook removal. String or suture material is tied to the curve of the hook. The hook is positioned as described in the simple retrograde technique (Figure 45-18), and a quick pull on the string will dislodge the hook.

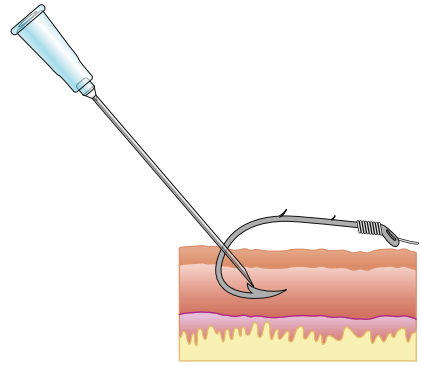

FIGURE 45-20. Needle-cover technique for fishhook removal. The area is anesthetized, and an 18-gauge needle is inserted into the entrance wound along the hook. The lumen of the needle is placed over the barb to cover it, and both the hook and needle are backed out of the wound.

are that failure can cause further pain to the patient and success can result in ripped tissue or a sharp, blood-contaminated object flying uncontrollably across the room.

The **needle-cover technique** is commonly described but rarely successful. The technique requires physician dexterity and is only useful if the hook is superficial. Insert an 18-gauge needle into the entrance wound alongside the shank of the hook. Have the needle follow the bend of the hook until the lumen of the needle can be placed over the barb to sheathe it. The hook and needle are then withdrawn from the wound as a unit (**Figure 45-20**).

The **advance-and-cut technique** is useful for deeply penetrated and larger fishhooks (**Figure 45-21**). Advance the tip of the hook through the skin surface. Once exposed, the point and barb are cut with wire cutters, and the remaining part of the hook is rotated back out of the original wound. If barbs along the shank are embedded beneath the dermis, the shank can be clipped near the hook's eye. The remaining part of the hook is then passed antegrade through the skin. The advance-and-cut method traumatizes and contaminates tissue but is an effective method in the ED if the barb has nearly or already penetrated the surface of the skin.

The **incision technique** is nearly always successful in removing fishhooks. Enlarge the entrance wound 2 to 3 mm with a #11 scalpel blade. Continue the incision along the bend of the hook to the barb until the barb is disengaged from the soft tissue. The hook can then be withdrawn easily through the larger entrance (**Figure 45-22**). If necessary, the barb can be grasped with a hemostat to prevent it from snagging tissue on the way out. There are two major benefits to enlarging puncture wounds containing foreign bodies. First, the wound is more easily inspected for additional foreign bodies. In the case of fishhook impalement, the wound may be harboring the bait that was on the hook. Second, the

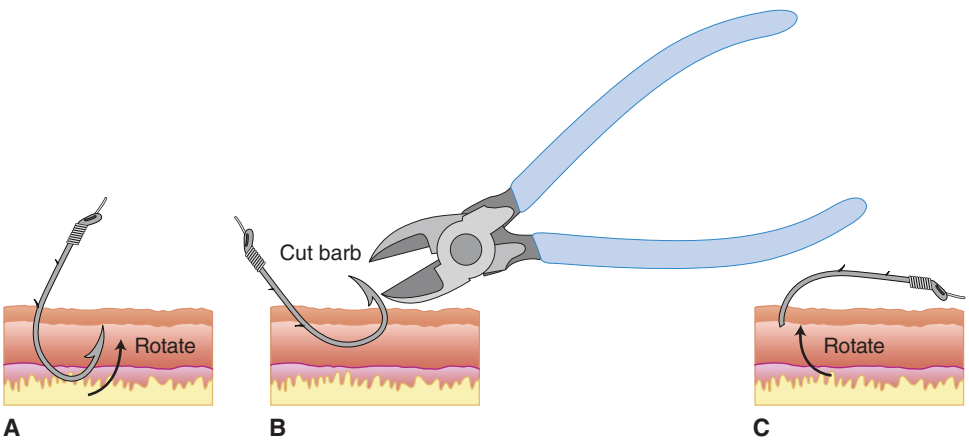

FIGURE 45-21. Advance-and-cut technique for fishhook removal. The area is anesthetized, and the tip of the hook is advanced through the skin surface (**A**), the barb is cut (**B**), and the hook is rotated back out of the original wound (**C**).

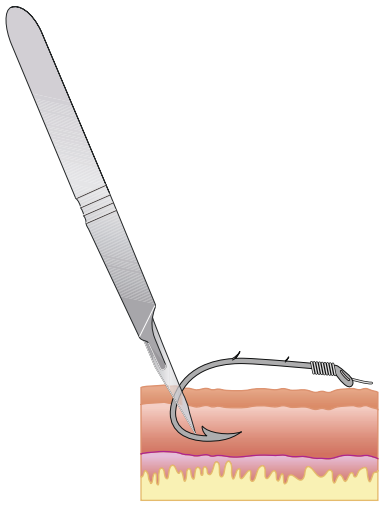

FIGURE 45-22. Incision technique for fishhook removal. The area is anesthetized, and a small incision is made along the shaft of the hook to the barb. The hook is withdrawn through the incision.

wound tract is more easily irrigated through a larger opening. However, the incising scalpel can easily injure tendons, nerves, and vessels.

TRAUMATIC DERMAL TATTOOING

Foreign particulates may be embedded in the epidermal and dermal layers of skin by an abrasion, which permanently stains or "tattoos" the surrounding tissue. If vigorous scrubbing does not remove the particulates, refer the patient to specialists for dermabrasion or block excision. The graphite from pencil lead can produce a pigmentation that may never dissolve; therefore, graphite should be excised in cosmetic areas (**Figure 45-23**).

CHAPTER 46

Puncture Wounds and Bites

James Quinn

PUNCTURE WOUNDS

A puncture wound is defined as a wound whose depth is greater than its width. These injuries most commonly occur on the plantar surface of the foot after stepping on a sharp object.[1,2] Despite the relatively innocuous-appearing skin wound, there is significant risk of infection and injury to underlying structures. Puncture wounds caused by high-pressure injection equipment and animal bites, and those involving exposure to body fluids have the potential for unique complications.

PATHOPHYSIOLOGY

With puncture wounds, shear forces between the penetrating object and tissue result in tissue disruption, producing hemorrhage and devitalization of skin and underlying tissues. Inoculation of infectious organisms into the deeper tissues can occur from the penetrating object (with or without leaving behind a foreign body from the object or material that has been pierced)[3] or from the skin surface. When the penetrating object is removed, closure of the small skin wound creates a favorable environment for the development of infection. The reported infection rate from plantar puncture wounds is approximately 6% to 11%.[4,5] Furthermore, exploration of infected plantar puncture wounds finds foreign material in about 25% of patients.[6]

Most soft tissue infections from puncture wounds are caused by gram-positive organisms. *Staphylococcus aureus* predominates, followed by other staphylococcal and streptococcal species.[4,7-10] Puncture wounds over joints can penetrate the joint capsule and produce septic arthritis. Those that penetrate cartilage, periosteum, and bone can lead to osteomyelitis. *Pseudomonas aeruginosa* is the most frequent pathogen isolated from plantar puncture wound–related osteomyelitis, particularly when the injury occurs through the rubber sole of an athletic shoe.[6,9-11] The source appears to be *Pseudomonas* that colonizes the foam lining of athletic shoes.

Difficulty in visualizing and cleaning to the full depth of the injury contributes to the higher risk for infection for puncture wounds compared with other traumatic lacerations. Other host and wound factors are associated with delayed healing and/or infection (**Table 46-1**).[12,13]

Plantar puncture wounds of the forefoot are at risk for foreign body deposition and infection,[6] and because most of the body weight is transmitted to the metatarsal heads during walking, a puncture in this area might penetrate more deeply than elsewhere on the sole and produce a higher rate of infection. However, case series of patients hospitalized with infected plantar puncture wounds both support[9,14] and refute[10] this theory.

TABLE 46-1 Risk Factors for Puncture Wound Complications

Patient characteristics
Elderly
Diabetes with or without microvascular complications
Immunocompromised (acquired immune deficiency syndrome, steroids, chemotherapy)
Peripheral vascular disease
Wound characteristics
Contaminated with soil or debris
Containing foreign body
Occurring outdoors
Occurring through a shoe and/or sock
Deeper penetration (jumping, falling, running)

RISK ASSESSMENT

The patient should be asked about the time of injury and circumstances involved. Wounds greater than 6 hours old with increasing pain and redness are likely infected. Falling or jumping onto an object suggests deeper penetration with potential for greater injury. Footwear (for plantar injuries) or clothing through which the object passed increases the potential for foreign body retention and infection. The patient should be asked to estimate the depth of penetration and about a foreign body sensation in the wound. Ask about postinjury care rendered before presentation and about host factors predisposing to infection.

Ask about the penetrating object. Materials such as wood, glass, or plastic are prone to break or splinter, leaving retained fragments in the wound and increasing the risk for infection. Thin objects, such as needles or pins, can break off cleanly beneath the skin surface, leaving a fragment behind.

Examine the puncture wound site and the function of underlying structures. Note the size and location of the wound, condition of surrounding skin, and presence of foreign matter or devitalized tissue. Assess the puncture wound for proximity to underlying structures. Assess distal function of tendons and nerves and the integrity of distal perfusion, especially with puncture wounds of the hand and wrist.[15]

Because the entire depth of a puncture wound cannot be reliably explored, assessment for a possible foreign body is complicated. Patient perception of a foreign body is modestly useful in predicting the presence of one.[16,17] The practice of probing the wound with a blunt instrument to assess depth and the presence of a foreign body is of unproven utility.

DIAGNOSIS

Plain-film radiographs using soft tissue visualization techniques are indicated in all infected puncture wounds, in wounds caused by materials prone to fragment, and whenever the patient reports a foreign body sensation (**Table 46-2**) (see chapter 45, Soft Tissue Foreign Bodies).[18]

TABLE 46-2 Indications for Imaging in Puncture Wounds

Plain radiographs
Suspicion of fracture
Infected wound
Wound caused by materials prone to fragment (wood, glass, etc.)
Foreign body sensation reported by patient
CT or MRI
Suspected deep-space infection
Persistent pain after injury
Failure to respond to treatment

A

B

FIGURE 46-1. Puncture wound to heel. **A.** Physician enlarged the wound in an unsuccessful attempt to locate and remove foreign body. **B.** Radiograph showing retained foreign body.

Plain radiographs will detect >90% of radiopaque foreign bodies >1 mm in diameter (**Figure 46-1**). Most organic substances, such as wood, thorns, and other plant matter, have radiodensities close to that of soft tissue and cannot reliably be detected in puncture wounds with plain radiographs.

US can identify soft tissue foreign bodies, but the ability to detect small objects that might have been introduced through a puncture wound is limited. US can be helpful in imaging puncture wounds with increasing pain when an abscess is suspected. CT can accurately detect most radiolucent foreign bodies and is the imaging modality to use when a retained foreign body is suspected but the plain radiograph does not show one. MRI provides excellent visualization of foreign bodies but cannot be used to image metallic objects or objects containing certain minerals due to the production of ferromagnetic artifacts. CT or MRI is indicated in patients with deep-space infection, persistent pain after a puncture wound, or when superficial infections fail to respond to therapy (**Table 46-2**). Rubber from athletic shoes is difficult to visualize with any imaging modality.[3]

TREATMENT

Treatment recommendations for puncture wounds are largely based on anecdotal evidence and reviews of uncontrolled case series.[4,7-12] Traditional wound cleaning techniques are largely ineffective as a result of the small entrance wound that has often spontaneously sealed by the time of presentation. The occurrence of serious infections after puncture wounds leads some clinicians to recommend more aggressive wound debridement and irrigation, although there is no evidence that this treatment reduces the rate or severity of post–puncture wound infections. The majority of puncture wounds have a benign course, and potentially catastrophic complications are uncommon.[1,4,5]

Wound Cleansing, Irrigation, and Debridement Uncomplicated clean punctures presenting <6 hours after injury require superficial wound cleansing and tetanus prophylaxis as indicated.[10] Soaking of the wound in an antiseptic solution has no proven benefit. Low-pressure (e.g., approximately 0.5 psi) irrigation of wounds will assist in surface cleansing and allow visualization of the entrance site, but will not penetrate the puncture tract. High-pressure (e.g., approximately 7 psi) injection of irrigation fluid into the wound might penetrate the tract, but has no proven benefit and theoretically could force foreign matter and bacteria deeper into the surrounding tissue.[19]

Debridement or coring of the wound tract in clean wounds does not reduce infection or facilitate accurate diagnosis of deeper structural injury. Adverse effects from debridement or coring include increased pain and a wound that is larger than the initial injury.

Antibiotics The role for prophylactic antibiotics in the management of puncture wounds is controversial, especially for plantar puncture wounds.[7-9] **There is no proven benefit of prophylactic antibiotics in any type of puncture, although antibiotic prophylaxis is recommended for use in high-risk patients with plantar puncture wounds.**[20] "High-risk" includes patients with diabetes[13] and impaired host defenses and may also include forefoot injuries and patients sustaining punctures through athletic shoes.[6] There is only one published study comparing patients receiving prophylactic antibiotics for plantar puncture wounds with untreated patients, and a variety of oral antibiotics were used.[21] There were many confounders with this observational study, and a subsequent review concluded that no evidence-based recommendations can be made regarding the use of prophylactic antibiotics for plantar puncture wounds.[22]

If prophylactic antibiotics are used, agents typically used for established wound infection are recommended—such as a first-generation oral cephalosporin, antistaphylococcal penicillin, or macrolide.[20] Although methicillin-resistant *S. aureus* has become a common cause of skin and soft tissue infections, postinjury antibiotic prophylaxis to cover this pathogen is not necessary.[20] **For plantar puncture wounds through athletic shoes, an oral fluoroquinolone with antipseudomonal activity, such as ciprofloxacin, seems sensible.** Agents such as trimethoprim-sulfamethoxazole and tetracycline can provide antistaphylococcal coverage but lack antipseudomonal activity. If antipseudomonal coverage is desired and oral fluoroquinolones are contraindicated, a combination of oral antistaphylococcal and parenteral antipseudomonal antibiotics (e.g., ticarcillin, ceftazidime, or cefepime) would be an acceptable albeit inconvenient choice.

COMPLICATIONS

Infectious complications of puncture wounds include cellulitis, localized abscess, deep soft tissue infection, and osteomyelitis. The hallmark of all complications is persistent pain. Patients with continued or increasing pain >48 hours postinjury should undergo an evaluation for retained foreign body or abscess.

Cellulitis Cellulitis usually presents within 4 days after injury. The patient typically notes pain with or without swelling and redness. Physical examination may demonstrate tenderness, erythema at the site of injury, warmth, and swelling. Postinjury cellulitis is an indication for imaging to evaluate for a retained foreign body. Cellulitis is generally caused by streptococcal and staphylococcal skin flora and usually responds to a 7- to 10-day course of a first-generation cephalosporin, antistaphylococcal penicillin, trimethoprim-sulfamethoxazole, or clindamycin.

Abscess Localized abscess is usually associated with a retained foreign body. Patients may note swelling and possibly drainage. A tender, warm, fluctuant mass can be palpated and further defined with US. Standard incision and drainage is generally curative. Where possible, the incision should be longitudinal or parallel to underlying tendons, vessels, or nerves. A short course of antibiotics is indicated if there is surrounding cellulitis.

Deep soft tissue infection is generally more painful than that of cellulitis or localized abscess. The key physical examination finding is tenderness, redness, or swelling remote from the puncture site. With plantar or palmar injuries, redness on the dorsum of the foot or hand, respectively, suggests a deep space infection. CT or MRI studies are indicated. Treatment requires parenteral antibiotics and surgical exploration with drainage, excision of necrotic tissue, and irrigation of infected areas.

Osteomyelitis Osteomyelitis is the most disastrous consequence of puncture wounds, occurring in 0.1% to 2.0% of all plantar puncture wounds and perhaps with a greater prevalence in forefoot punctures occurring through athletic shoes.[7-11] Patients with osteomyelitis present later than patients with other infections, often >7 days after injury and sometimes after a period of symptomatic improvement.[10] Pain is present in nearly every case, but the examination may be deceptively normal. Radiographs are normal in the early stages of osteomyelitis. Elevated erythrocyte sedimentation rate or C-reactive protein supports the diagnosis, but a normal value does not exclude osteomyelitis.[10,23,24] Imaging modalities most helpful in the diagnosis of osteomyelitis are nuclear medicine (either a triple-phase radionuclide bone scan with planar scintigraphy or with single-photon emission CT) or MRI.[25-27] Once the diagnosis is made, immediate surgical referral should be made. Antibiotic administration should be withheld pending discussion with the consultant, as pathogen identification is best done from cultures obtained during operative debridement. If antibiotics are administered before surgery, staphylococcal and pseudomonal coverage is recommended.

Disposition and Follow-Up of Complications Cellulitis and localized abscesses are almost always treated on an outpatient basis with incision and drainage, with oral antibiotics added in the case of surrounding cellulitis or fever. Follow-up is recommended in 48 hours to assess response.[10] Inpatient therapy is indicated when the patient has a significant systemic response to this localized infection, the infection is extensive, comorbidities or drug allergies preclude safe oral therapy, patients cannot tolerate oral medications, or patients cannot reliably care for the infection outside of the hospital setting. Deep soft tissue infection and osteomyelitis require admission, surgical intervention, and IV antibiotics.

SPECIAL CONSIDERATIONS FOR PUNCTURE WOUNDS

Needle-Stick Injuries **Needle-stick injuries** are common among healthcare professionals, especially in nurses and physicians who perform invasive procedures.[28,29] Mechanical damage from needle-stick injuries is essentially negligible. The major concerns are the risk of infection with hepatitis viruses and human immunodeficiency virus. **The risk of infection in a nonimmune recipient after an inadvertent needle stick contaminated from an infectious source has been estimated to be negligible for hepatitis A, 6% for hepatitis B, 2% for hepatitis C, and 0.3% for HIV.**[30]

Postexposure prophylaxis is available for hepatitis B and HIV, but is not for hepatitis C.[30] Recommendations for the assessment and management of occupational exposures to blood and body fluids (such as needle sticks) are complex and change frequently. Hospitals should have predetermined protocols endorsed by local infectious diseases specialists that are readily available and periodically reviewed. Consensus recommendations for postexposure prophylaxis of human immunodeficiency virus are updated regularly by the Centers for Disease Control and Prevention and are available from the National HIV/AIDS Clinicians' Consultation Center, accessible via the Internet at http://www.nccc.ucsf.edu/home/ or by phone at the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at

1-888-448-4911. When available, the use of rapid human immunodeficiency virus testing on the source (patient, blood, or fluid) can reduce the need for unnecessary prophylaxis on the exposed individual.

High-Pressure Injection Injuries **High-pressure injection injuries** are caused by industrial equipment designed to force grease, paint, or other liquids through a small-diameter nozzle at high pressures.[31-35] When the nozzle is applied close to or directly on the skin surface, the high pressure results in penetration of intact skin, forcing the material deep into the underlying structures and along fascial planes. The nozzle pressures for these devices are typically 5000 to 10,000 psi for grease guns, 2000 to 6000 psi for diesel fuel injectors, and up to 5000 psi for paint and water sprayers. Such extreme pressure can lacerate skin and fracture bones (**Figure 46-2**). The type, amount, and viscosity of material injected will determine the degree of tissue inflammatory response, and in less distensible tissue compartments, sudden pressure elevations can produce vascular injuries, ischemic necrosis, and gangrene.[32,35]

Most high-pressure injection injuries occur in the nondominant hand of an operator using a trigger-activated gun. The initial injury may cause little pain and appear relatively innocuous, leading to delays in presentation and under-appreciation of the extent of injury. Within hours, pain typically becomes severe, with evidence of ischemia or spreading inflammation. Delays in initial management increase the risk of amputation or disability.[32-35]

A

B

FIGURE 46-3. **A.** High-pressure injection paint injury to index finger. **B.** Radiograph showing radiopaque material. [Photo contributed by J. S. Stapczynski, MD.]

Despite an initial appearance that suggests only a minor injury (**Figure 46-3**), the history of high-pressure injection device use alone should prompt immediate consultation with a hand surgeon.[32-35]

ED evaluation includes assessment of neurovascular integrity and tendon function, pain management using IV opioids, prophylactic antibiotic coverage against skin flora, and tetanus prophylaxis as indicated. Radiographs will often demonstrate wide dissemination of radiopaque material as well as injected air along fascial planes (**Figures 46-2** and **44-3**). **Digital nerve blocks should be avoided, as they may further increase pressure in finger compartments. The risk of subsequent amputation is reduced if surgical debridement is performed within 6 hours of the injury, especially in cases of organic solvents.**[32,33,35] For patients with high-pressure injection of water only into the hand, it may be possible to forego exploration and manage with antibiotics, analgesics, and elevation, but that decision should be made in consultation with a hand specialist.[35,36]

Epinephrine Autoinjector Injuries **Epinephrine autoinjector injuries** occur most often to the finger (**Figure 46-4**). The typical scenario involves a patient who is unfamiliar with the proper use of the autoinjector or who errs as a result of the stress of the situation.[37,38] Patients present with pain due to the needle stick, paresthesias, and epinephrine-induced vasospasm to the injected area. In the extreme, the entire digit can be blanched and cold.[39,40] The intensity of digital ischemia and response to treatment can be assessed with digital pulse oximetry of the involved finger. The natural history of this injury is spontaneous resolution over several hours, with a reported range of resolution from 6 to 13 hours.[37-41] The published case reports sometimes express concern that the intense vasospasm can lead to tissue loss or gangrene, although the chance of this occurring appears rare.[42,43] Additionally, patients sustaining accidental injection without acute symptoms or signs of ischemia do well.[41,43] **There is no clear evidence that active treatment is better than observation alone**,[43] although patients and physicians may be uncomfortable with a prolonged ischemic and painful finger.

Attempts to increase blood flow to the ischemic digit with massage, warm water immersion, amyl nitrite inhalations, metacarpal nerve

FIGURE 46-4. Accidental epinephrine autoinjector injury to thumb. [Photo contributed by Sean Donahue, DO.]

block, or topical nitroglycerin paste application have no proven value.[37,42] Subcutaneous phentolamine injection into the affected area is the one treatment consistently described that rapidly reverses digital ischemia from accidental epinephrine injection.[37,39-42] Phentolamine doses described range from 1.5 to 3.0 milligrams, and response is usually seen within minutes. A mixture of 0.5 mL of standard phentolamine solution (5 milligrams/mL concentration) and 0.5 mL of 1% lidocaine solution will produce a 1 mL total volume containing 2.5 milligrams of phentolamine that can be subcutaneously injected directly through the site of autoinjector puncture. Once the ischemia is resolved, the patient can be discharged, as relapse appears very unlikely.

MAMMALIAN BITES

Most patients presenting for ED care of bite injuries have been bitten by domestic dogs or cats. In the United States, an estimated nearly 4 million people are bitten each year, approximately 800,000 seek medical attention, and 10 to 20 will die of their injuries.[44] Because of their size, children have greater potential for serious injuries and seek care for bites more often than adults.[45-47] Dogs that are specifically bred or trained for guard duty cause a disproportionate number of serious injuries and deaths.[45,47]

GENERAL PRINCIPLES OF BITE WOUND MANAGEMENT

Complications from bite wounds include the mechanical injury inflicted by the bite itself, local bacterial infection, and systemic infection or illness.[48] A large animal or multiple animals attacking a child or small adult can inflict severe injuries, including vascular damage and blunt or penetrating trauma. Standard assessment and resuscitation protocols for trauma victims should be employed if the patient is seriously injured. Take particular care when assessing children with facial and scalp bites from large dogs, as there are numerous case reports of innocuous-looking wounds associated with skull penetration resulting in brain abscess.[49,50] In most animal bite wounds, there is an isolated soft tissue injury and wound management and prevention of infection are the key issues.[48]

Meticulous examination and cleansing measures, including aggressive irrigation and debridement of devitalized tissue, are important.

TABLE 46-3 Indications for Primary Closure of Mammalian Bite Wounds

Location: face or scalp
Wound characteristics: simple and appropriate for single-layer closure, no devitalized tissue
Lack of underlying injury: no underlying fracture
Host: no systemic immunocompromising conditions

Determine the extent of underlying tissue damage, with special attention to the potential for penetration into joint spaces and tendon sheaths. Management of wounds involving the face, hands, or perineum can be challenging due to the close proximity of delicate structures. If there is suspicion of retained foreign material in the wound, such as animal teeth, imaging is needed.[51]

Some bite lacerations can safely undergo primary repair (**Table 46-3**). If desired for cosmetic or functional reasons, a skilled practitioner can primarily close the wound with percutaneous sutures with a risk of postrepair wound infection of less than 5%.[52-58] Delayed primary closure is applicable for the management of contaminated bite injuries, especially in areas other than the face (see chapter 41, Wound Closure).

Case reports have described the occurrence of bacteremia, sepsis, and death after dog bites in immunocompromised individuals, most often due to *Capnocytophaga canimorsus*.[59,60] **Wound closure is associated with a small increased risk of local wound infection but is unlikely to enhance the risk of serious systemic infection from *Capnocytophaga*, unless the patient is immunodeficient or the wound is at high risk of infection. The current practice is to avoid primary wound closure in patients with systemic immunodeficiencies and higher risk wounds (Table 46-4).**[61] High-risk wounds should be cleaned and debrided of devitalized tissue, closure avoided, and dressed with a nonadherent wound dressing to maintain a moist environment for epithelial regeneration, with re-evaluation in 24 to 48 hours. Prophylactic antibiotics are recommended for higher risk wounds, especially if primarily closed (**Table 46-5**).[61]

MICROBIOLOGY AND THERAPY OF INFECTIONS FROM CAT AND DOG BITES

Mammalian saliva contains large concentrations of microorganisms, and bite wounds should be considered to be contaminated with pathogenic bacteria.[62] The force of a bite, especially a clenching bite, can inoculate bacteria deep into the underlying tissue, leading to cellulitis, tenosynovitis, and septic arthritis. **Most dog bite wounds are relatively superficial, and despite the inoculation of bacteria, only approximately 5% of untreated dog bites will become infected.** Cats have narrower, sharper teeth than dogs, giving them the ability to deliver infectious agents deeper into a small-bore puncture wound. Thus **up to 80% of cat bites that present for care will become infected,** although the true rate of infection is unknown since most patients with cat bites do not present for care unless the bite appears infected (**Figure 46-5**).[62,63]

TABLE 46-4 Bite Wounds at Higher Risk of Infection

Diabetes

TABLE 46-5 Common Bites and First-Line Treatment

Animal	Organism	First-Line Antibiotic
Cat	*Pasteurella multocida* *Bartonella henselae* (cat-scratch fever)	Amoxicillin-clavulanate Azithromycin
Dog	*Pasteurella*, streptococci, staphylococci, *Capnocytophaga canimorsus*	Amoxicillin-clavulanate
Human	*Eikenella*, staphylococci, streptococci Herpes simplex (herpetic whitlow)	Amoxicillin-clavulanate Acyclovir or valacyclovir
Rats, mice, squirrels, gerbils	*Streptobacillus moniliformis* (North America) or *Spirillum minus/minor* (Asia)	Amoxicillin-clavulanate
Livestock, large game animals	Multiple organisms *Brucella, Leptospira, Francisella tularensis*	Amoxicillin-clavulanate or specific agent for disease
Bats, monkeys, dogs, skunks, raccoons, foxes (all carnivores and omnivores)	Rabies	Rabies immune globulin, rabies vaccine
Monkeys	Herpes B virus (*Cercopithecine herpesvirus*)	Acyclovir or valacyclovir
Freshwater fish	*Aeromonas*, staphylococci, streptococci	Fluoroquinolone or trimethoprim-sulfamethoxazole
Saltwater fish	*Vibrio*, staphylococci, streptococci	Fluoroquinolone

Infection after a cat bite is often due to *Pasteurella multocida*, particularly if the infection develops with 24 hours.[64-66] Infected dog bites are just as likely to contain *Pasteurella*, as well as anaerobes, streptococcal, and staphylococcal species.[64,66] Postexposure antibiotic prophylaxis of most bite wounds to prevent infection is controversial.[20,67] The only evidence-based benefit for prophylactic antibiotics is with dog or cat bites of the hands.[67,68]

A prudent approach is to use prophylactic antibiotics for higher-risk uninfected wounds. These include all cat bites, all bites in immunocompromised hosts, deep dog bite puncture wounds, hand wounds, and any injury undergoing surgical repair.[20] A 3- to 5-day course of an appropriate antimicrobial (**Table 46-5**) should be sufficient. Routine follow-up wound check is recommended in all but the most trivial cases. In lower-risk situations, counseling and advice regarding the lack of benefit from prophylactic antibiotics in addition to wound-care precautions are warranted.

Amoxicillin-clavulanate is the antibiotic most commonly recommended for prophylaxis of uninfected wounds and for treatment of local infections following dog, cat, or human bites.[20,48,54,63,67,68] However, penicillin V or ampicillin should be adequate for *Pasteurella multocida* infections and represent logical lower-cost alternatives for prophylaxis of cat bites.[68] Penicillin-allergic patients should receive doxycycline or cefuroxime for cat bites and clindamycin plus a fluoroquinolone for dog bites. **Cephalexin, dicloxacillin, erythromycin, or clindamycin should not be used alone for dog or cat bites, as they do not reliably cover *Pasteurella* species.**

FIGURE 46-5. Hand infection after a cat bite. Wound fluid culture grew *Pasteurella multocida*. [Photo contributed by J. S. Stapczynski, MD.]

SYSTEMIC BACTERIAL INFECTIONS AFTER DOG AND CAT BITES

Capnocytophaga Serious systemic infection after dog or cat bites is rare, but can develop days after the bite and is not necessarily accompanied by local bite wound infection.[60,69] *Capnocytophaga canimorsus* produces a rare but fulminant bacteremic illness after a dog bite, with fatal multiorgan failure, particularly in splenectomized patients and those with alcoholism or other immunosuppressive disorders.[59] Broad-spectrum therapy with penicillin and other agents is indicated in concert with aggressive resuscitation.[59] The virulence of this rare infection provides some justification for the prophylactic use of a penicillin-class agent in all immunocompromised patients bitten by dogs.

Cat-Scratch Disease **Cat-scratch disease** is a clinical syndrome of regional lymphadenopathy developing 7 to 12 days after a cat bite or scratch.[70-72] This chronic indolent infection caused by *Bartonella henselae* can result in painful, matted masses of lymph nodes.[71] Mild constitutional symptoms are common, and nonlymphoid organs may be affected in approximately 10% of cases (**Table 46-6**). The causative bacteria cannot be easily cultured from human lymph node tissue, so the diagnosis is usually made using a combination of epidemiologic, clinical, histologic, and/or serologic criteria.[70-72]

Most cases with only lymph node involvement resolve in 2 to 5 months, and therapy consists primarily of pain relief and reassurance. Large, painful, fluctuant nodes can be aspirated for symptomatic relief. Incision and drainage is to be avoided, as persistent fistula and scarring

TABLE 46-6 Organ Involvement in Cat Scratch Disease

Constitutional symptoms
Low-grade fever
Malaise and fatigue
Headache
Nausea and anorexia
Nonlymphoid organ involvement—often with prolonged fever
CNS: encephalopathy with headache, seizures, confusion, or altered mental status
Musculoskeletal: synovitis with joint pain and swelling
Lungs: pneumonitis with dyspnea and cough
Abdomen: granulomatous hepatitis or splenitis producing abdominal pain
Eyes: retinitis with vision loss

have been reported. Antibiotics are not indicated in most cases, but in patients with severe painful lymphadenopathy, a 5-day course of azithromycin may speed resolution of adenopathy.[73] Patients with systemic immunodeficiencies are susceptible to severe infection and bacteremia from *B. henselae*, so it is reasonable to treat immunodeficient patients with a 7- to 10-day course of trimethoprim-sulfamethoxazole, ciprofloxacin, or rifampin. Patients with nonlymphoid organ involvement usually require admission for definitive evaluation and parenteral antibiotic treatment. The vast majority of patients, even those with multiorgan involvement, recover without sequelae.

HUMAN BITES

Human bites tend to be more serious than bites from domestic animals.[74-76] The reasons are likely due to the nature of the event, location of the bite, and potential bacteria inoculated into the wound. Treatment recommendations are based on experience. All human bites should be treated as contaminated wounds. Patients with human bites often present for care late after injury.[75] The **closed-fist injury**, incurred when a flexed knuckle strikes a human tooth in the course of an altercation, is a common human bite injury (see chapter 43, Arm and Hand Lacerations). Most human bite wounds should not undergo primary closure, with the possible exception of wounds to the face, where primary closure is associated with a postrepair wound infection rate of approximately 10%.[56,76]

Human bite wound infections are usually polymicrobial, and the most common organisms isolated are staphylococcal and streptococcal species. Other pathogens include the species-specific gram-negative rod *Eikenella corrodens*. **Amoxicillin-clavulanate is recommended for prophylaxis after all but the most trivial human bites.[20,63]** For established infections, parenteral agents of choice include ampicillin-sulbactam, cefoxitin, or piperacillin-tazobactam.

Herpes simplex virus can cause local infection, termed **herpetic whitlow**, after a human bite or contact with infected saliva.[77] The appearance is usually a painful coalescence of vesicles, typically on the distal phalanx (**Figure 46-6**). Vesicles usually resolve in 3 to 4 weeks. Treatment with oral acyclovir for 7 to 10 days or topical acyclovir ointment for 7 to 14 days may shorten the duration of the symptoms.

RODENTS, LIVESTOCK, EXOTIC AND WILD ANIMALS

Rodents Patients often seek care or consultation after being bitten by a rodent. The injury is usually trivial, the risk of local wound infection is low, and rodents are not known to carry or transmit rabies, so standard wound care and reassurance should suffice. Of more concern is the potential zoonotic systemic infections carried by mice and rats.[78] **Rat-bite fever** consists of two similar febrile illnesses occurring after a small percentage of bites from rats, mice, squirrels, or gerbils due to either *Streptobacillus moniliformis* (more common in North America) or *Spirillum minus/minor* (more common in Asia).[79] Infection can also result from exposure to rat feces or urine. The incubation period for the streptobacillary form is typically 3 to 7 days, whereas it is usually longer than 10 days for the spirillary variety. Onset is typically with rigors and fevers and progresses to migratory polyarthralgia and a maculopapular petechial or purpuric rash. Infection can spread to the heart, brain, arteries, liver, kidneys, and lungs. The mortality rate for untreated infection is 10% to 15%. Treatment is with IV penicillin for 5 to 7 days followed by oral penicillin for an additional 7 days. Doxycycline or tetracycline is used for penicillin-allergic patients.

FIGURE 46-6. Herpes simplex virus infection: herpetic whitlow. Painful, grouped, confluent vesicles on an erythematous edematous base on the distal finger were the first (and presumed primary) symptomatic infection. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 6th ed*. New York. McGraw-Hill; 2009, p. 821.]

Livestock and Large Game Animals Livestock and large game animals can inflict serious tissue injury with their powerful jaws and grinding teeth.[80] The risk of wound infection is significant, and systemic illnesses, such as brucellosis, leptospirosis, or tularemia, can follow the injury. Aggressive wound care, imaging to detect fractures, and prophylactic broad-spectrum antibiotics are recommended. A febrile illness after such a bite usually requires inpatient antibiotic therapy guided by blood culture results.[60]

Fish Bites Freshwater fish bite infections can be due to *Aeromonas*, streptococci, and staphylococci, and treatment is with a fluoroquinolone or trimethoprim-sulfamethoxazole. Saltwater fish bite infections require coverage for *Vibrio*, usually with a fluoroquinolone.

SYSTEMIC INFECTIONS: SPIROCHETES, RABIES, AND OTHER VIRUSES

Disseminated spirochetal and viral illnesses resulting from mammalian bites include syphilis, rabies, hepatitis, herpes B virus, or human immunodeficiency virus. The risk of infection is variable depending on the amount of infectious organisms in the saliva of the biting animal.

Most human rabies cases identified in the United States were acquired from contact with domestic bats or from dog bites sustained while traveling abroad (see chapter 157, Rabies). In South Asia, monkeys are presumed to be at high risk for carriage and transmission of rabies. North American reservoirs of animal rabies exist in bats, skunks, raccoons, and foxes. **All carnivores and omnivores can transmit rabies, whereas rodents, hares, and rabbits are extremely unlikely to harbor the disease.** Local public health agencies or the state veterinarian are a good source of information regarding the rabies risk from contact with specific indigenous animals and recommended postexposure prophylaxis with immunoglobulin and vaccine.

B virus, also called herpes B, is caused by *Macacine herpesvirus* 1 and can be transmitted by bites from monkeys and other nonhuman primates.[81,82] Human infection with B virus causes myelitis and hemorrhagic encephalitis, with a case fatality rate of 70%. Immediate and thorough wound cleaning after a bite reduces the chance of infection, and acyclovir or valacyclovir given immediately after injury can prevent or ameliorate this illness.[83] Consultation with an infectious disease expert is strongly advised. The Centers for Disease Control and Prevention maintains a Web site with current B virus information at http://www.cdc.gov/herpesbvirus/index.html.

Viral hepatitis and human immunodeficiency virus can both be transmitted by a human bite, although human immunodeficiency virus concentration in nonbloody saliva is thought to be relatively low. **A protocol similar to that for an occupational needle-stick injury should be used when a patient sustains a bite from a high-risk source** (see chapter 154, Human Immunodeficiency Virus Infection).

CHAPTER 47

Postrepair Wound Care

Adam J. Singer
Judd E. Hollander

INTRODUCTION

Postoperative care begins immediately after laceration repair in the ED with gentle cleansing using normal saline or clean (tap) water to remove any residual blood products or contamination. Additional considerations include dressings, topical antibiotics, edema reduction techniques, prophylactic antibiotics, tetanus prophylaxis, and wound drains. Before ED release, give the patient instructions regarding wound care and cleansing, pain control, signs of infection, follow-up dates, and short-term and long-term cosmetic expectations.

WOUND DRESSINGS

Postoperative wound dressing should be tailored to both the type of wound and method of wound closure. Most sutured or stapled lacerations should be covered with a protective, nonadherent dressing for 24 to 48 hours. Maintaining a moist environment increases the rate of re-epithelialization, and occluded wounds heal faster than those exposed to air.[1-3] Conversely, leaving lacerations exposed to air may result in a slightly lower healing rate but does not result in an increased rate of infection.[4]

Useful dressings are semipermeable films manufactured from transparent polyurethane or similar synthetic films coated on one surface with a water-resistant hypoallergenic adhesive. They are highly elastic, conform easily to body parts, and are generally resistant to shear and tear. They are permeable to moisture vapor and oxygen but impermeable to water and bacteria. Common brands of semipermeable wound dressings are OpSite Post-Op® (Smith & Nephew PLC, London, UK), Bioclusive® (Johnson & Johnson, New Brunswick, NJ), and Tegaderm® (3M, St. Paul, MN). The disadvantages of these products are that they cannot absorb large amounts of fluid and exudate, and they do not adhere well to very moist wounds.

Topical antibiotic creams and ointments are an alternative to the use of commercial dressings to maintain a moist environment. As an added benefit, topical antibiotics may help reduce infection rates and may also prevent scab formation.[5-7] **However, patients whose lacerations are closed with tissue adhesives should not use topical ointments or creams because they will loosen the adhesive and may result in dehiscence.** Tissue adhesives serve as their own antimicrobial barrier and occlusive dressing; wounds closed with tissue adhesives do not require supplementary dressings.

EDEMA REDUCTION AFTER WOUND REPAIR

Wounds with associated soft tissue contusion should have the injury site elevated above the patient's heart for 24 to 48 hours to limit accumulation of fluid in the wound interstitial spaces. Wounds with little edema heal more rapidly than those with marked edema. Pressure dressings can be used to minimize the accumulation of intercellular fluid in the subcutaneous space. Pressure dressings are useful for ear and scalp lacerations (see chapter 42, "Face and Scalp Lacerations"). Pressure dressing applied to the ear can prevent auricular hematoma formation and reduce the subsequent likelihood of a cauliflower deformity. Vaseline gauze or Xeroform® (Kendall Healthcare, Mansfield, MA) dressings are easy to mold around the ear. For large scalp lacerations that have a tendency to bleed, short-term use of a pressure dressing will limit subcutaneous hematoma formation. However, excessive pressure should be avoided in all pressure dressings, especially in the extremities where they may compromise circulation. Consider a short period of splinting with large lacerations over joints to reduce pain, limit tension on the wound, minimize swelling, and promote healing.

PROPHYLACTIC ANTIBIOTICS

Prophylactic oral antibiotics are not recommended except for select circumstances[8-11] based on guiding principles: the degree of bacterial contamination, the presence of infection-potentiating factors (e.g., soil), the mechanism of injury, and the presence or absence of host predisposition to infection.[12-14] **Compulsive wound cleansing is far more important than antibiotics to reduce postrepair wound infection.**[15,16]

Prophylactic antibiotics are recommended for human bites, cat bites, deep dog bite puncture wounds, bite wounds to the hand, open fractures, and wounds with exposed joints or tendon.[12-17] Also, consider prophylactic antibiotics after wound closure in a lymphedematous area.[18,19]

The risk of bacteremia during care of grossly contaminated lacerations in the ED is unknown, but is likely to be small.[20] However, some patients who have structural heart disease, arteriovenous hemodialysis fistulas, prosthetic joints, cerebrospinal fluid shunts, vascular grafts, or other permanent indwelling "hardware" may trap bacteria from the blood stream and develop infections in the above-mentioned organs or devices. There is no evidence for preprocedure antibiotic prophylaxis to prevent bacteremic spread of infection from manipulation of a contaminated site. If the physician chooses to use antibiotic prophylaxis for the management of a heavily contaminated wound in a patient with these conditions or devices, give a single dose of an IV antibiotic before the wound is manipulated.

Antibiotics used for postrepair prophylaxis are similar to those used for treatment of established infections (**Table 47-1**).[8] For most patients, a first-generation cephalosporin or antistaphylococcal penicillin (e.g., dicloxacillin) is reasonable. Although methicillin-resistant *Staphylococcus aureus* has become a common cause of skin and soft tissue infections, postinjury antibiotic prophylaxis to cover this pathogen does not appear necessary.[8] Amoxicillin-clavulanate is the preferred prophylactic treatment for high-risk mammalian bite wounds.[12,13] For open fractures or joints, a parenteral antistaphylococcal agent and an aminoglycoside should be used.[17] There is no evidence that patients who receive antibiotic prophylaxis benefit from an initial IV dose. Antibiotic prophylaxis

TABLE 47-1 Postrepair Oral Antibiotic Prophylaxis

Situation	Primary Recommendation	Alternative Recommendation
Uncomplicated patient	First-generation cephalosporin or antistaphylococcal penicillin	Macrolide Clindamycin
Grossly contaminated wounds and/or retained foreign body	Amoxicillin/clavulanate or second-generation cephalosporin	Clindamycin plus a fluoroquinolone
Bite wounds	Amoxicillin/clavulanate	Clindamycin plus either a fluoroquinolone or trimethoprim-sulfamethoxazole
Plantar puncture wounds	Ciprofloxacin	First-generation cephalosporin or antistaphylococcal penicillin
Underlying systemic immunodeficiency (AIDS, chronic steroid use, poorly controlled diabetes mellitus)	Amoxicillin/clavulanate or second-generation cephalosporin	Clindamycin plus a fluoroquinolone
Impaired local defenses (peripheral arterial disease, lymphedema)	Amoxicillin/clavulanate	Clindamycin or erythromycin

TABLE 47-2 Recommendations for Tetanus Prophylaxis

	Clean Minor Wounds		All Other Wounds*	
History of Tetanus Immunization	Administer Tetanus Toxoid†	Administer TIG‡	Administer Tetanus Toxoid	Administer TIG
<3 or uncertain doses	Yes	No	Yes	Yes
≥3 doses				
Last dose within 5 y	No	No	No	No
Last dose within 5–10 y	No	No	Yes	No
Last dose >10 y	Yes	No	Yes	No

*Especially if wound care delayed (>6 h), deep (>1 cm), grossly contaminated, exposed to saliva or feces, stellate, ischemic or infected, avulsions, punctures, or crush injuries.

†Tetanus toxoid: Tdap if adult and no prior record of administration; otherwise, tetanus-diphtheria toxoid if >7 years and diphtheria-tetanus toxoid if <7 years, preferably administered into the deltoid.

‡Tetanus immune globulin: adult dose, 250–500 IU administered into deltoid opposite the tetanus-diphtheria toxoid immunization site.

continues for 3 to 5 days for nonbite injuries and 5 to 7 days for bite wounds. Patients at high risk for infection should be told to return for a wound check in 24 to 48 hours.

TETANUS PROPHYLAXIS

Two thirds of the recent tetanus cases in the United States follow lacerations, puncture wounds, and crush injuries (see chapter 156, "Tetanus"),[21] so, as part of wound care, ask about previous tetanus immunizations. Recommendations for tetanus prophylaxis are based on the condition of the wound and the patient's immunization history (**Table 47-2**). Consider passive immunization with tetanus immune globulin for those without a history of a primary series of three tetanus immunizations. Because of the emergence of pertussis infections, Tdap (containing the acellular pertussis vaccine) should replace a single dose of tetanus and diphtheria toxoids for adults who have not previously received a dose of Tdap (either in the primary series, as a booster, or for wound management).[22] The 2013 Advisory Committee on Immunization practices recommend either Tdap or Boostrix® for those >65 years old.

The only contraindication to tetanus toxoid is a history of neurologic or severe systemic reaction after a previous dose. Local self-limited reactions, such as erythema, induration, and pain at the injection site, are common after tetanus vaccination. These local side effects do not preclude future tetanus immunization. Exaggerated local reactions occur occasionally after tetanus toxoid and involve extensive pain and swelling of the entire extremity. Exaggerated local reactions occur most often in adults with high serum tetanus antitoxin levels who have received frequent doses of tetanus toxoid. Such patients should not receive tetanus toxoid more frequently than every 10 years. Severe systemic reactions to tetanus immunization include generalized urticaria, anaphylaxis, or neurologic complications, including peripheral neuropathy and Guillain-Barré syndrome. A severe allergic reaction, including acute respiratory distress or cardiovascular collapse after a dose of tetanus toxoid, is a contraindication to further immunization. A moderate or severe acute illness is also a reason to defer routine immunization, although a minor illness is not. If the use of a tetanus toxoid is contraindicated, consider passive immunization with tetanus immune globulin in a tetanus-prone wound.

WOUND CLEANSING

Sutured or stapled wounds can be gently washed and cleansed with tap water as early as 8 hours after closure without an increase in infection rate.[23,24] Using soap and tap water to cleanse lacerations will not increase the infection rate.[25] Use gentle blotting to dry the area; aggressive wiping could cause wound dehiscence. For routine wounds, tell patients to remove dressings after 24 hours, cleanse the wound, and examine it for signs of infections. In certain special situations, the dressing should remain undisturbed for 4 to 5 days until the patient is reevaluated by the physician.

Thereafter, daily cleansing ensures that the patient examines the laceration for early signs of infection. Patients should observe the wound for redness, warmth, swelling, and drainage, and contact a physician if such signs develop. Standardized wound-care instructions improve patient compliance and understanding.[26]

Reapplication of topical antibiotics for 3 to 5 days will decrease scab formation, thereby preventing wound edge separation. Patients with tissue adhesives may shower but should avoid bathing and swimming because prolonged moisture will loosen the adhesive bond and result in slightly earlier sloughing of the adhesive.[27]

WOUND DRAINS

Drains are placed in wounds and surgical incisions under three circumstances: (1) to drain interstitial fluid or blood and prevent accumulation into a seroma or hematoma, respectively; (2) to maintain a tract so pus can drain from an infected area; or (3) to allow for drainage from a contaminated location and prevent an abscess from forming.[28] Drains allow for near-complete wound closure in circumstances where closure would otherwise be impeded by fluid, pus, or blood accumulation. Drains can be categorized as (1) gauze packing to maintain open drainage and collect the exudate, (2) open systems using soft rubber (e.g., Penrose drain) or silicone tubing to direct drainage onto external gauze dressings, or (3) closed systems using silicone tubing and attached fluid collection reservoirs. Drains can be placed either through the suture line of the initial wound or incision or through an adjacent incision made specifically for drain access.

The most common type of wound drain placed in the ED is $^1/_4$- to 1-in. (0.6- to 2.5-cm) ribbon gauze used to pack an abscess cavity after incision and drainage. Dressings over draining abscesses may initially require frequent changes. **The internal packing should be replaced daily as long as the wound continues to produce exudate. Once the purulence stops, internal packing is no longer required, and daily cleaning with external dressing changes should continue until enough granulation tissue forms and the wound stops draining.** Maintaining a moist, clean environment promotes wound healing. Equivalent outcomes in otherwise healthy patients with subcutaneous abscesses can be obtained with alternatives to traditional packing: no packing,[29-31] incision and loop drainage,[32-35] modified Pezzar catheter,[36] and silver-containing hydrofiber dressing.[37]

Open drainage using soft rubber tubing (e.g., Penrose drains) has been used for years to drain infected or contaminated wounds that have been partially or completely closed. A safety pin placed through the tubing can prevent the drain from inappropriately advancing into the wound. As the exudate diminishes and the wound heals, the Penrose drain can be pulled out a portion each day to allow the wound to heal from the "bottom up." The disadvantage of open drains, such as the Penrose, is the access they provide for bacteria into the wound.

For many wounds, especially postsurgical wounds, closed drainage systems have replaced open wound drains. The collection reservoir for closed drainage systems often has a self-inflating ability so it can be squeezed before attachment to the tubing in order to place vacuum suction in the wound to enhance drainage (e.g., Jackson-Pratt®, Cardinal Health, Dublin, OH; Hemovac®, Zimmer, Inc., Warsaw, IN; ConstaVac®, Stryker Corp., Kalamazoo, MI). Assessment of the tubing and emptying of the reservoir should be done with sterile technique (similar to dressing changes for indwelling lines). The reservoir may require emptying several times per day, depending on the drainage volume. It is common practice to remove closed drains when the amount of fluid drained each day reaches low levels (typically 30 to 40 mL per day). If a drainage tube is accidentally pulled out, it should not be reinserted. In many surgical settings, the benefit of closed drainage systems is unproven.[38-47]

Vacuum-assisted closure or negative-pressure wound therapy is a method used to close difficult wounds.[48-51] The vacuum-assisted closure technique consists of insertion of an open-cell foam sponge into the wound, sealing with an adhesive drape, and subsequent application of negative, subatmospheric pressure, usually at 125 mm Hg.[50] Vacuum-assisted closure promotes wound healing by removing localized edema,

which improves vascular and lymphatic flow by reducing bacteria density, by promoting angiogenesis, and by increasing granulation tissue formation.[48-50] There is no proven role for vacuum-assisted closure in the management of lacerations closed in the ED.

PAIN CONTROL

Abrasions and some lacerations can be quite painful. Patients should be educated regarding the expected degree of pain and measures that may help reduce pain. Splints can be used to reduce swelling and pain for extremity lacerations. Appropriate analgesic medications and anti-inflammatory agents will help control pain. The pain from lacerations generally decreases after the initial 48 hours, and opioid analgesics are rarely necessary after that time. Patients with concurrent contusions (such as victims of motor vehicle crashes) will often report worsening pain 24 to 48 hours after the initial injury.

FOLLOW-UP

Tell patients when and with whom to follow up for suture removal or wound examination.[26] Sutures or staples in most locations should be removed after approximately 7 to 10 days (**Table 47-3**). Remove facial sutures in 3 to 5 days to avoid formation of unsightly sinus tracts and hatch marks.[52] Sutures over the joints or in the hands should be left in place for 10 to 14 days, as they may be subject to increased tension during movement. When removing sutures, avoid applying tension in a direction that would tend to cause dehiscence. Debride any scab or crusting over the sutures before suture removal by gently applying gauze soaked with hydrogen peroxide. Then, grasp the suture at the knot with the forceps for removal (**Figure 47-1**). Use scissors or a #12 blade to cut the sutures. Skin staples are removed with a specific device that deforms the center and extracts the legs from the skin (**Figure 47-2**).

Tissue adhesives will slough off, typically within 5 to 10 days of application, and do not usually require removal. Tell the patient to avoid picking at the tissue adhesive or scrubbing the area or exposing it to water for more than brief periods. If tissue adhesives remain on the skin for prolonged periods, antibiotic ointment, petroleum jelly, or bathing can accelerate removal. When adhesive tapes are used, they can be removed by gentle peeling away from the skin, starting at one end of the laceration and proceeding along and parallel to the wound, avoiding pulling across or perpendicular to the wound.

Scheduled "wound checks" might be useful in high-risk patients, high-risk wounds, or patients unable to identify signs of infection. Because many healing wounds may develop erythema and patients are not able to correctly identify wound infections, do not prescribe antibiotics

TABLE 47-3 Suture and Staple Removal Recommendations

Location	Days
Face	3–4 (child), 3–5 (adult)
Neck	2–3 (child), 3–4 (adult)
Upper extremity	7–10
Hand	10–14
Chest	7–10
Back	10–14
Buttocks	10–14
Legs	8–10
Foot	10–14
Delayed closure	8–12
Retention sutures	14–30
Overlying joints	10–14

New York, McGraw-Hill, 2004, p. 735.]

without a reevaluation.[53] Patients who require further tetanus immunization to complete their primary series should have the second dose 1 to 2 months after the first dose, and the third dose 6 to 12 months after the second dose.

LONG-TERM COSMETIC OUTCOME

Educate patients about the expected outcome before wound closure. Re-enforce the message at the time of suture or staple removal or wound follow-up. Tell patients that all traumatic lacerations result in some scarring and that short-term cosmetic appearance is not highly predictive of the ultimate cosmetic outcome.[54] Healing lacerations and abrasions should not be exposed to direct sunlight, because sun exposure can result in permanent hyperpigmentation.[55] Protect injured skin with a sun-blocking agent for 6 to 12 months after injury.

Cardiovascular Disease

CHAPTER 48

Chest Pain

Simon A. Mahler

INTRODUCTION AND EPIDEMIOLOGY

About 8 million patients with chest pain present to a U.S. ED each year.[1] Of these, 50% to 70% are placed into an observation unit or admitted to the hospital, yet only about 10% are eventually diagnosed with an acute coronary syndrome.[2-5] Still, 2% to 5% of patients with acute myocardial infarctions are missed on initial presentation and discharged from the ED.[2] We discuss the features and approach that help differentiate acute coronary syndrome from other causes of chest pain. The chapters titled "Acute Coronary Syndromes" and "Low Probability Acute Coronary Syndromes" discuss management of these specific syndromes.

Acute chest pain is the recent onset of pain, pressure, or tightness in the anterior thorax between the xiphoid, suprasternal notch, and both midaxillary lines. **Acute coronary syndrome** includes **acute myocardial infarction** and acute ischemia (unstable angina). Acute myocardial infarction is defined by myocardial necrosis with elevation of cardiac biomarkers and is classified by ECG findings as **ST-segment elevation myocardial infarction** or **non-ST-segment elevation myocardial infarction**. Unstable angina is a clinical diagnosis defined by chest pain or an equivalent (neck or upper extremity pain) from inadequate myocardial perfusion that is new, occurring with greater frequency, less activity, or at rest. Patients with unstable angina do not have pathologic ST-segment elevation on ECG or cardiac biomarker elevation, but they are at risk of eventual myocardial damage absent recognition and treatment.

PATHOPHYSIOLOGY

The chest wall, from the dermis to the parietal pleura, is innervated by somatic pain fibers. Neurons enter the spinal cord at specific levels corresponding to the skin dermatomes. Visceral pain fibers are found in internal organs, such as the heart, blood vessels, esophagus, and visceral pleura. Visceral pain fibers enter the spinal cord and map to areas on the parietal cortex corresponding to cord levels shared with somatic fibers. Stimulation of visceral or somatic afferent pain fibers results in two distinct pain syndromes. Pain from somatic fibers is usually easily described, precisely located, and often experienced as a sharp sensation. Pain from visceral fibers is generally more difficult to describe and imprecisely localized. Patients with visceral pain are more likely to use terms such as *discomfort*, *heaviness*, *pressure*, *tightness*, or *aching*. Visceral pain is often referred to an area of the body corresponding to adjacent somatic nerves, which explains why pain from an acute myocardial infarction may radiate to the neck, jaw, or arms. Factors such as age, sex, comorbid illnesses, medications, drugs, and alcohol may interact with psychological and cultural factors to alter pain perception and communication.

CLINICAL FEATURES

RISK ASSESSMENT

Patients with abnormal vital signs, concerning ECG findings (if available initially), a history of prior coronary artery disease, multiple atherosclerotic risk factors, or any abrupt, new, or severe chest pain or dyspnea should be quickly placed into a treatment bed. Initiate cardiac monitoring and IV access, and obtain an ECG, ideally within 10 minutes of arrival. Identify and treat immediate life needs like supporting the airway, breathing, and circulation. Measure vital signs promptly and at regular intervals. Administer oxygen if ambient saturation is <95%.

Once the patient is stable, focus on history, physical exam, and laboratory findings associated with cardiac (acute coronary syndrome) versus noncardiac chest pain causes. Obtain a focused history that includes symptoms, abridged past medical history, and review of systems, seeking features of life-threatening causes of chest pain, such as acute coronary syndrome, aortic dissection, pulmonary embolism, severe pneumonia, and esophageal rupture. Ask about the onset, timing, severity, radiation, and character of the chest pain; alleviating and exacerbating factors; and presence of associated symptoms, such as diaphoresis, dyspnea, nausea, vomiting, palpitations, and dizziness.

Focus the physical examination on findings pertinent to life-threatening causes of chest pain. Inspect the thorax for prior surgical incisions, chest wall deformities, and symmetric rise and fall with respiration. Palpate the chest wall for tenderness, masses, or crepitus. Auscultate to identify chest consolidation or pneumothorax, murmurs, gallops, or friction rubs, and obtain a chest x-ray immediately to identify immediate life-threatening processes.

HISTORY

Patients with serious and life-threatening intrathoracic disorders, including acute coronary syndrome, may report pain outside the chest, such as in the epigastrium, neck, jaw, shoulders, or arms. Some patients never experience chest pain or have migratory pain that is no longer in the chest at the time of medical evaluation. Patients with acute myocardial infarction who present without chest pain have diagnostic and treatment delays and have an in-hospital mortality rate more than twice that of acute myocardial infarction patients with chest pain.[6]

Classic Chest Pain Terms such as "typical" and "atypical" symptoms are misleading because symptoms among patients with acute coronary syndrome vary and may not include classic findings. **Classic cardiac chest pain** is retrosternal left anterior chest crushing, squeezing, tightness, or pressure. Cardiac chest pain is often brought on or exacerbated by exertion and relieved by rest. Traditional teaching is that anginal pain lasts 2 to 10 minutes, unstable angina pain lasts 10 to 30 minutes, and pain from acute myocardial infarction often lasts longer than 30 minutes, but great overlap exists. Other classic features of acute coronary syndrome presentation include radiation of the pain to the arms, neck, or jaw; diaphoresis; dyspnea; and nausea or vomiting.[7]

Nonclassic Chest Pain Patients with acute coronary syndrome frequently present without a "classic" chest pain story. The absence of classic symptoms contributes to delays in seeking care and in evaluation once they reach the ED.

Nonclassic presentations include chest pain lasting for seconds, constant pains lasting for 12 to 24 hours or more without waxing and waning intensity, or pain worsened by specific body movements or positions, such as twisting and turning of the thorax. Reports of stabbing, well-localized, positional, or pleuritic chest pain are uncommon with acute coronary syndrome but do not exclude it with certainty. The Multicenter Chest Pain Study reported that 22% of patients with acute myocardial infarction described their chest pain as sharp or stabbing.[8] **Nonclassic presentations of acute coronary syndrome occur more frequently in women, racial minorities, diabetics, the elderly, and patients with**

TABLE 48-1 Acute Myocardial Infarction Symptoms: Positive Likelihood Ratios[22,24,25]

Pain Descriptor	Study	No. of Patients Studied	Positive Likelihood Ratio (95% Confidence Interval)
Radiation to right arm or shoulder	Chun et al.	770	4.7 (1.9–12.0)
Radiation to both arms or shoulders	Goodacre et al.	893	4.1 (2.5–6.5)
Associated with exertion	Goodacre et al.	893	2.4 (1.5–3.8)
Radiation to left arm	Panju et al.	278	2.3 (1.7–3.1)
Associated with diaphoresis	Panju et al.	8426	2.0 (1.9–2.2)
Associated with nausea or vomiting	Panju et al.	970	1.9 (1.7–2.3)
Worse than previous angina or similar to previous myocardial infarction	Chun et al.	7734	1.8 (1.6–2.0)
Described as pressure	Chun et al.	11,504	1.3 (1.2–1.5)

psychiatric disease or altered mental status than in other patient groups.[6,9,10] Multiple prescription medications, drugs, alcohol, patient or provider sex, and cultural differences can impact the pain perception or reporting of symptoms.[11-13] For example, the term "sharp" in some cultures is interpreted to mean "severe," rather than knife-like.[14]

Premenopausal and early menopausal women with acute coronary syndrome are more likely to present with pain unrelated to exercise, pain not relieved by rest or nitroglycerin, pain relieved by antacids, palpitations without chest pain, or a chief complaint of fatigue.[15] Associated symptoms of nausea, emesis, jaw pain, neck pain, and back pain are more common in women with acute coronary syndrome, while diaphoresis is more common among men.[15]

Anginal Equivalents One large public hospital reported that 47% of 721 consecutive patients with myocardial infarction presented complaining of symptoms other than chest pain.[10] This means ED physicians must consider potential **anginal-equivalent symptoms** like dyspnea at rest or with exertion, nausea, light-headedness, generalized weakness, acute changes in mental status, diaphoresis, or shoulder, arm, or jaw discomfort. Patients with dyspnea alone have a fourfold increased risk of sudden death from cardiac causes compared with asymptomatic patients, and a twofold increased risk compared with patients with classic angina.[16]

Epigastric or upper abdominal discomfort, even when relieved with antacids, should raise suspicion for acute coronary syndrome, especially for patients >50 years old and those with known coronary artery disease. In these two high-risk groups, include an ECG in routine evaluation of abdominal pain. Consider acute coronary syndrome in patients presenting with palpitations, because myocardial ischemia may increase automaticity and irritability, leading to dysrhythmias. Furthermore, tachycardia can cause an increase in myocardial oxygen demand, triggering myocardial ischemia.

Risk Factors Major risk factors for coronary artery disease include age >40 years old, male or postmenopausal female, hypertension, tobacco use, hypercholesterolemia, diabetes, truncal obesity, family history, and a sedentary lifestyle.[17,18] **Cocaine** use is associated with acute myocardial infarction even in young people with minimal or no coronary artery disease. Chronic cocaine use may accelerate atherosclerosis and severe coronary artery disease,[19] although some suggest no relationship once controlling for other cardiovascular risk factors.[20] **Human immunodeficiency virus** infection and treatment with highly active antiretroviral therapy can accelerate atherosclerosis.[21]

Although cardiac risk factors are useful in predicting coronary artery disease risk within a given population, they are less useful for diagnosing the presence or absence of acute coronary syndrome in an individual patient.[7,22,23] Patients with known coronary artery disease and prior acute coronary syndrome are at risk for another acute coronary syndrome event. So, identify previous episodes of chest pain, prior echocardiography, stress testing or coronary angiography, or prior revascularization (stent placement or coronary artery bypass graft surgery).

ACUTE MYOCARDIAL INFARCTION SIGNS AND SYMPTOMS: LIKELIHOOD RATIOS

There are no historical features with sufficient sensitivity and specificity to either diagnose or exclude acute coronary syndrome. Radiation to the arms and shoulders, particularly to the right arm or both arms, is the historical feature most strongly associated with acute coronary syndrome (likelihood ratio range of 2.3–4.7).[22,24,25] Chest pain with exertion or associated symptoms of dyspnea, diaphoresis, nausea, or vomiting are associated with twofold likelihood of acute coronary syndrome.[24,25] Pressure-like chest sensation has limited value in the prediction of acute coronary syndrome.[22] Sharp, pleuritic, positional chest pain is associated with a decreased likelihood of acute coronary syndrome but cannot eliminate the diagnosis.[22] Lack of exertional pain or pain radiation has no diagnostic value for exclusion of acute coronary syndrome.[22,25] Since classic cardiac ischemic pain is not universal and men and women both present with nonclassic symptoms, the diagnostic utility of specific chest pain descriptions does not differ significantly between men and women.[26] **Tables 48-1** and **48-2** summarize the chest pain characteristics associated with increased or decreased likelihood ratios of acute myocardial infarction.

TABLE 48-2 AMI Symptoms: Negative Likelihood Ratios[22,25,27]

Pain Descriptor	Study	No. of Patients Studied	Positive Likelihood Ratio (95% Confidence Interval)
Described as pleuritic	Chun et al.	8822	0.2 (0.1–0.3)
Described as positional	Chun et al.	8330	0.3 (0.2–0.5)
Described as sharp	Chun et al.	1088	0.3 (0.2–0.5)
Reproducible with palpation	Chun et al.	8822	0.3 (0.2–0.4)
Reproducible with positioning	Chun et al.	8330	0.3 (0.2–0.5)
Inframammary location	Everts et al.	903	0.8 (0.7–0.9)
Not associated with exertion	Goodacre et al.	893	0.8 (0.6–0.9)

PHYSICAL EXAMINATION

The examination of patients with acute coronary syndrome is often normal, and there are no exam findings that are sensitive or specific enough to exclude or diagnose acute coronary syndrome. Use the exam in conjunction with history to identify or exclude other causes of chest pain and to guide therapy.

Vital sign abnormalities from acute coronary syndrome may include hyper- or hypotension, tachycardia, or bradycardia. Tachycardia may result from increased sympathetic tone and decreased left ventricular stroke volume. Bradycardia may occur due to ischemia or infarction involving the conduction system or alterations in sympathetic and parasympathetic activation of the sinoatrial or atrioventricular nodes. Patients with acute myocardial ischemia or infarction may have abnormal heart sounds due to changes in ventricular function or compliance, such as an S_3 or S_4 gallop, diminished S_1, or a paradoxically split S_2. New murmurs in patients with chest pain may be associated with acute myocardial infarction with chordae tendineae rupture or aortic root dissection. Ischemia-induced congestive heart failure may produce crackles on auscultation of the lungs.

Physical examination findings most strongly associated with acute myocardial infarction in patients presenting with acute chest pain are hypotension, S_3 gallop, and diaphoresis, although the frequency, interrater reliability, and added diagnostic value are limited.[22] Reproducible chest wall tenderness is suggestive of a musculoskeletal etiology but is reported in up to 15% of patients with confirmed acute myocardial infarction and cannot alone exclude the diagnosis of acute coronary syndrome.[28]

RESPONSE TO THERAPY

Response to medications poorly discriminates between cardiac and noncardiac chest pain. While nitroglycerin reduces anginal pain, it may also relieve the pain from noncardiac conditions such as esophageal spasm.[22,29-31] Similarly, relief from antacid or combination "GI cocktail" therapy does not represent a noncardiac cause of chest pain.[32,33] Combine the above responses with other features to best assess the likely presence or absence of acute coronary syndrome.

DIAGNOSIS

Life-threatening concerns in acute chest pain are acute coronary syndrome, aortic dissection, pulmonary embolism, pneumonia, tension pneumothorax, and esophageal rupture. Other diagnoses with the potential for morbidity and mortality include simple pneumothorax, myocarditis, pericarditis, aortic stenosis, perforated ulcer, and cholecystitis. Benign causes of chest pain include anxiety, musculoskeletal pain, esophagitis, and gastritis. Common causes of chest pain are listed in **Table 48-3**. **Table 48-4** summarizes the classic symptoms of the life-threatening causes of acute chest pain.

TABLE 48-3 Common Causes of Acute Chest Pain

Visceral Pain	Pleuritic Pain	Chest Wall Pain
Typical angina	**Pulmonary embolism**	Costosternal syndrome
Unstable angina	**Pneumonia**	Costochondritis (Tietze's syndrome)
Acute myocardial infarction	Spontaneous pneumothorax	Precordial catch syndrome
Aortic dissection	Pericarditis	Xiphodynia
Esophageal rupture	Pleurisy	Radicular syndromes
Esophageal reflux or spasm		Intercostal nerve syndromes
Mitral valve prolapse		Fibromyalgia

PULMONARY EMBOLISM

Symptoms of pulmonary embolism include sharp chest pain (may worsen with inspiration, called "pleuritic"), dyspnea, hypoxemia, syncope, or shock. There may be associated cough or hemoptysis. Patients with pulmonary embolism may be febrile and have leg swelling or pain, and some patients will report chest wall tenderness. Common physical examination findings include tachypnea, tachycardia, and hypoxemia. Pulmonary embolism risk factors include recent surgery, trauma, prolonged immobility, active cancer, estrogens from birth control pills or hormone replacement therapy (particularly when combined with smoking), procoagulant syndromes, or a history of prior pulmonary embolism or deep venous thrombosis.[34,35]

Clinical decision aids, such as the **Wells and Revised Geneva Scores,** can risk stratify patients with possible pulmonary embolism.[36,37] The **Pulmonary Embolism Rule-Out Criteria** exclude pulmonary embolism in patients with a low pretest probability without further diagnostic testing.[38] Normal **D-dimer** testing, measured by a sensitive enzyme-linked immunosorbent assay, in a hemodynamically stable low- to intermediate-risk patient (with a Revised Geneva Criteria Score of 0 to 10) makes pulmonary embolism exceptionally unlikely; in those with higher risk assessment, a negative D-dimer has limited value.[39,40] In patients with pulmonary embolism, elevated cardiac troponin (cTn) indicates ventricular dysfunction and identifies patients with an elevated risk of death and complications.[41]

In pulmonary embolism, ECG findings are nonspecific, with the most common finding being sinus tachycardia. Chest radiographs are usually normal, but in rare cases may show signs of pulmonary infarction. CT pulmonary angiography is the test of choice and is highly sensitive for the detection of large to medium-sized pulmonary emboli. See more details on pulmonary embolism in the chapter 46, "Venous Thromboembolism."

AORTIC DISSECTION

Pain from aortic dissection is classically described as a ripping or tearing sensation radiating to the interscapular area of the back. The pain is often sudden in onset, maximal at the time of symptom onset, and may migrate or be noted above and below the diaphragm. Lack of sudden-onset pain decreases the probability of aortic dissection but cannot exclude it.[42] Secondary symptoms of aortic dissection result from arterial branch occlusions and include stroke, acute myocardial infarction, or limb ischemia. Risk factors include male sex, age over 50 years, poorly controlled hypertension, cocaine or amphetamine use, a bicuspid aortic valve or prior aortic valve replacement, connective tissue disorders (Marfan's syndrome and Ehlers-Danlos syndrome), and pregnancy.[43]

Physical exam findings for aortic dissection lack sensitivity and specificity. A unilateral pulse deficit of the carotid, radial, or femoral arteries is suggestive of aortic dissection (likelihood ratio 5.7; 95% confidence interval, 1.4–23).[42] Focal neurologic deficits are rare, occurring in only 17% of patients with aortic dissection, but the combination of chest pain and a focal neurologic deficit greatly increase the likelihood of aortic dissection.[42] While a completely normal chest radiograph lowers the likelihood of aortic dissection being present, it does not exclude dissection. A negative **D-dimer** lowers the probability of aortic dissection (detecting the clotting/declotting expected), but it also cannot exclude the disease.[44] ECG changes are common among patients with aortic dissection, with up to 40% to 50% presenting with ST-segment or T-wave changes.[45,46] Elevated cTn among patients with aortic dissection is associated with increased mortality.[47] If aortic dissection is suspected, obtain a CT aortogram or transesophageal echocardiogram. See chapter 59, "Aortic Dissection and Related Aortic Syndromes."

PNEUMONIA

Pneumonia is potentially life threatening in the elderly, immunocompromised, or patients with multiple comorbid conditions. Chest pain from pneumonia is usually described as sharp, pleuritic, and associated

TABLE 48-4 Classic Symptoms of Potentially Life-Threatening Causes of Chest Pain*

Disorder	Pain Location	Pain Character	Radiation	Associated Signs and Symptoms
Acute coronary syndrome	Retrosternal, L chest, or epigastric	Crushing, tightness, squeezing, pressure	R or L shoulder, R or L arm/hand, jaw	Dyspnea, diaphoresis, nausea
Pulmonary embolism	Focal chest	Pleuritic	None	Tachycardia, tachypnea, hypoxia, may have hemoptysis
Aortic dissection	Midline, substernal	Ripping, tearing	Intrascapular area of back	Secondary arterial branch occlusion
Pneumonia	Focal chest	Sharp, pleuritic	None	Fever, hypoxia, may see signs of sepsis
Esophageal rupture	Substernal	Sudden, sharp, after forceful vomiting	Back	Dyspnea, diaphoresis, may see signs of sepsis
Pneumothorax	One side of chest	Sudden, sharp, lancinating, pleuritic	Shoulder, back	Dyspnea
Pericarditis	Substernal	Sharp, constant or pleuritic	Back, neck, shoulder	Fever, pericardial friction rub
Perforated peptic ulcer	Epigastric	Severe, sharp	Back, up into chest	Acute distress, diaphoresis

Abbreviations: L = left; R = right.

*Atypical presentations are common.

with fever, cough, sputum production, and possibly hypoxemia.[48] Auscultation may reveal decreased breath sounds, rales, or bronchial breath sounds over the affected areas of consolidation. A chest radiograph usually confirms the diagnosis. See chapter 65, "Pneumonia and Pulmonary Infiltrates."

ESOPHAGEAL RUPTURE (BOERHAAVE'S SYNDROME)

Patients classically present with a history of sudden-onset, sharp, substernal chest pain following forceful vomiting. Patients with esophageal rupture are usually ill-appearing and may be tachycardic, febrile, dyspneic, or diaphoretic. Physical examination may reveal crepitus in the neck or chest from subcutaneous emphysema. **Hamman's crunch**, audible crepitus that varies with the heartbeat on auscultation of the precordium, is a rare finding associated with pneumomediastinum. Chest radiography may demonstrate a pleural effusion (left more common than right), pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous air, although a normal x-ray cannot exclude esophageal rupture. If esophageal rupture is suspected, obtain a CT with oral water-soluble contrast. See chapter 77, "Esophageal Emergencies."

SPONTANEOUS PNEUMOTHORAX

The symptoms of spontaneous pneumothorax are sudden-onset, sharp, pleuritic chest pain with dyspnea. Classically, spontaneous pneumothorax occurs in tall, slender males. Risk factors for spontaneous pneumothorax include smoking and chronic lung diseases such as asthma and chronic obstructive pulmonary disease. Approximately 1% to 3% of patients with a spontaneous pneumothorax progress to develop a tension pneumothorax.[49] Auscultation may reveal decreased breath sounds and hyperresonance to percussion on the ipsilateral side. However, the physical exam findings of a simple pneumothorax are inconstant and cannot be used to exclude presence, with the diagnosis made by chest radiography. See chapter 68, "Pneumothorax."

ACUTE PERICARDITIS

Pain from acute pericarditis is classically described as a sharp, severe, constant pain with a substernal location. The pain may radiate to the back, neck, or shoulders; worsens by lying flat and by inspiration; and is relieved by sitting up and leaning forward. A pericardial friction rub is the most specific physical exam finding but is not always evident. The classic ECG findings are diffuse ST-segment elevation with PR depression.[50] See chapter 55, "Cardiomyopathies and Pericardial Disease."

MITRAL VALVE PROLAPSE

Symptoms attributed to mitral valve prolapse include sharp chest pain, palpitations, fatigue, anxiety, and dyspnea unrelated to exertion. A midsystolic click may be heard on auscultation. However, most patients are asymptomatic and have no consistent association of chest pain, dyspnea, or anxiety with the disorder.[51,52] See chapter 54, "Valvular Emergencies."

CHEST WALL PAIN

Musculoskeletal or chest wall pain is characterized by sharp, highly localized, and positional pain. The pain should be completely reproducible by light to moderate palpation or by specific movements and may be increased by inspiration or coughing. However, chest wall tenderness is also reported by some patients with acute coronary syndrome and pulmonary embolism. **Costochondritis (Tietze's syndrome)** is an inflammation of the costal cartilages or their sternal articulations and causes chest pain that is variably sharp, dull, and often increased with respirations. **Xiphodynia** is inflammation of the xiphoid process that causes sharp, pleuritic chest pain reproduced by light palpation. **Precordial catch syndrome** is a short, lancinating chest pain occurring in bunches lasting 1 to 2 minutes near the cardiac apex and is associated with inspiration, poor posture, and inactivity. *Pleurisy* is inflammation of the parietal pleura resulting in sharp pleuritic chest pain.

GI PAIN

GI disorders often cannot be reliably differentiated from acute coronary syndrome by history and physical examination alone.[25,53] **Gastritis** and **esophageal reflux** typically produce burning or gnawing pain in the lower half of the chest, with a brackish or acidic taste in the back of the mouth. The pain may be lessened with antacids and exacerbated by recumbency. **Peptic ulcer disease** is classically described as a postprandial, dull, boring pain in the epigastric region. Patients often describe being awakened from sleep by discomfort. Duodenal ulcer pain may be relieved after eating food, whereas gastric ulcer pain is often exacerbated by eating. Antacid medications usually provide symptomatic relief. **Acute pancreatitis** and **biliary disease** typically present with right upper quadrant or epigastric pain and tenderness but can also cause chest pain. *Esophageal spasm* is often associated with reflux disease and is characterized by a sudden onset of dull or

tight substernal chest pain. The pain is frequently precipitated by consumption of hot or cold liquids or a large food bolus and may be relieved by nitroglycerin. See chapter 77, "Esophageal Emergencies" and 78, "Peptic Ulcer Disease and Gastritis."

PANIC DISORDER

Panic disorder is characterized by recurrent, unexpected, and discrete periods of intense fear or discomfort (panic attacks) with at least four of the following symptoms: chest pain, dyspnea, palpitations, diaphoresis, nausea, tremor, choking, dizziness, fear of losing control or dying, paresthesias, chills, or hot flashes. In one study, 25% of ED patients with chest pain met diagnostic criteria for panic disorder. Conversely, 9% of the patients identified as having panic disorder were ultimately diagnosed with acute coronary syndrome on hospital discharge.[54] This means panic disorder is at best a diagnosis of exclusion or a co-diagnosis with acute coronary syndrome (or another cause). Do not assume panic disorder in a patient with chest pain in the ED until further testing allows better risk stratification. See chapter 289, "Mood and Anxiety Disorders."

DIAGNOSTIC TESTING

Focus initial diagnostic testing for patients with chest pain on the exclusion or confirmation of serious pathology based on the differential diagnosis drawn from the history and physical examination. When history and exam make acute coronary syndrome a potential cause, testing commonly includes an ECG, chest x-ray, and cardiac biomarkers. Stress testing, advanced cardiac imaging, serial or continuous ECG monitoring, and serial cardiac biomarker measurements are discussed in chapter 49, "Acute Coronary Syndromes."

IMAGING

Chest radiography is commonly performed in the evaluation of ED patients with chest pain. Most patients with acute coronary syndrome have a normal chest x-ray, but the images are useful to diagnose or exclude other conditions such as pneumonia and pneumothorax.[55] Other imaging modalities such as CT help evaluate conditions such as aortic dissection or pulmonary embolism.

ECG

Guidelines recommend a screening ECG within 10 minutes of ED arrival on patients with chest pain or other symptoms concerning for acute coronary syndrome.[56] Rapid ECG screening is essential because delay in identification of an ST-segment elevation myocardial infarction is associated with increased mortality.[57] Routine triage ECG testing and prehospital ECG transmission reduce delays to ST-segment elevation myocardial infarction identification, decrease door-to-balloon or door-to-needle time, and improve patient outcomes.[58-61]

Less than 5% of patients presenting to the ED with chest pain have evidence of an ST-segment elevation myocardial infarction on ECG.[62,63] However, new ST-segment elevation of ≥1 mm in at least two contiguous leads represents an acute myocardial infarction that will benefit from rapid reperfusion interventions.[22,64] ST-segment elevation also occurs in patients with pericarditis, myocarditis, early repolarization, left ventricular hypertrophy, and ventricular aneurysms. ST-segment depression and T-wave inversions are also associated with an increase in risk of acute myocardial infarction.[22,65]

A normal ECG lacks the sensitivity to exclude acute coronary syndrome, notably unstable angina, or non-ST-segment elevation myocardial infarction. In a large multicenter observational study of 391,208 patients with an evaluable ECG and diagnosis of acute myocardial infarction, 57% had "diagnostic" ECG changes, 35% had nonspecific changes, and 8% had normal ECGs. Diagnostic changes were defined as ST-segment elevation, ST-segment depression, or left bundle-branch block.[66] Other studies document normal or near normal ECGs in 5% to 10% of patients with acute myocardial infarction.[67-70] A normal ECG is also an independent risk factor for missed acute myocardial infarction and inappropriate ED discharge (odds ratio 7.7; 95% confidence interval, 2.9–20.2).[2] However, among young patients (<40 years old) without known coronary artery disease, a normal ECG is associated with a cardiovascular event rate of less than 1% at 30 days.[71]

Misinterpretation of ECGs (i.e., failure to detect ischemic changes that are present) occurs in up to 40% of missed acute myocardial infarction cases.[70] In addition, the initial ECG represents only a single time point in a dynamic pathophysiologic process; the diagnostic value of an ECG is improved by comparing it to a prior ECG or repeating it.[72]

CARDIAC BIOMARKERS

Cardiac Troponins Cardiac cTns are proteins essential to cardiac muscle contraction, which are complexed with actin and myosin filaments within cardiac myofibrils and are present within cardiac myocyte cytoplasm.[73] Myocardial injury resulting in the disruption of myocyte cell membrane integrity or myofibril destruction results in extracellular cTn leak, which can be detected in the patient's peripheral blood and used to identify and quantify myocardial damage.[74] Due to its high sensitivity and nearly complete cardiac specificity, cTn is the biomarker of choice for the detection of myocardial injury.[75]

Although cTn elevation is specific for myocardial necrosis, elevation does not indicate the mechanism of injury, nor does it necessarily indicate acute myocardial infarction. There are numerous nonischemic causes of cTn elevations, which are summarized in **Table 48-5**. Acute myocardial infarction can be differentiated from nonischemic cTn elevations based on the pattern of cTn elevation and the clinical context. The diagnostic criteria for acute myocardial infarction include a gradual rise and fall of cTn with a maximum value above the 99th percentile of a reference population (the upper reference limit), combined with any of the following: symptoms consistent with ischemia, characteristic acute ECG changes (ST- and T-wave changes, new left bundle-branch block, or new Q waves), or imaging evidence of a new regional wall motion abnormality or new loss of viable myocardium.[76]

Immunoassays have been developed for the isoforms of cTnI and cTnT. Isoforms I and T provide nearly identical information, and selection between them is driven mainly by central laboratory vendor and equipment preference.[77] A single manufacturer produces the cTnT assay;

TABLE 48-5 Conditions Associated with Elevated Cardiac Troponin Levels in the Absence of Ischemic Heart Disease

Cardiac contusion
Cardiac procedures (surgery, ablation, pacing, stenting)
Acute or chronic congestive heart failure
Aortic dissection
Aortic valve disease
Hypertrophic cardiomyopathy
Arrhythmias (tachyarrhythmia or bradyarrhythmia)
Apical ballooning syndrome
Rhabdomyolysis with cardiac injury
Pulmonary hypertension
Pulmonary embolism
Acute neurologic disease (e.g., stroke, subarachnoid hemorrhage)
Myocardial infiltrative diseases (amyloid, sarcoid, hemochromatosis, scleroderma)
Inflammatory cardiac diseases (myocarditis, endocarditis, pericarditis)
Drug toxicity
Respiratory failure
Sepsis
Burns
Extreme exertion (e.g., endurance athletes)

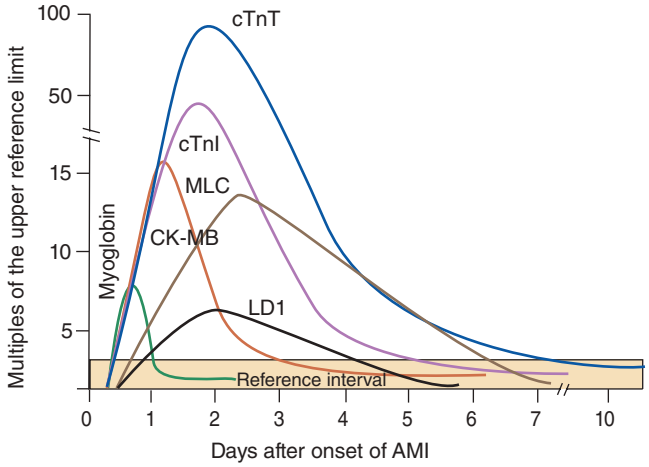

FIGURE 48-1. Typical pattern of contemporary serum marker elevation after acute myocardial infarction (AMI). CK-MB = MB fraction of creatine kinase; cTnI = cardiac troponin I; cTnT = cardiac troponin T; LD1 = lactate dehydrogenase isoenzyme 1; MLC = myosin light chain.

however, multiple manufacturers produce cTnI assays, which differ in their upper reference limits (the cTn value above the 99th percentile of a reference population), coefficients of variability, and lower limits of detection.

Over the past 25 years, cTn assays have become more analytically sensitive, pushing down the upper reference limits (URLs) and limits of detection. For example, a "first-generation" assay, available in 1995, had a URL of 0.4 nanograms/mL, whereas a commonly used contemporary (current-generation) assay has a 10-fold lower URL (0.04 nanograms/mL).[78,79] Current commercially available contemporary cTn assays have URLs ranging from 0.023 to 0.20 nanograms/mL and lower limits of detection ranging from 0.006 to 0.15 nanograms/mL.[80] Point-of-care assays offer a shorter turnaround time but with slightly lower analytic sensitivities than conventional assays.[76,81]

With contemporary assays, cTn is detected in serum as early as 2 hours after symptom onset of an acute myocardial infarction, but elevations are not reliably present until 6 hours or more.[82] Elevations peak at approximately 48 hours from symptom onset unless repeat injury occurs, and cTns remain elevated for up to 10 days (**Figure 48-1**). This persistence makes cTn a good tool in diagnosing acute myocardial infarction in patients with delayed presentations. However, in patients with intermittent symptoms over a period of days, an elevated cTn could represent a remote or new infarct. In this rare setting, the concomitant use of creatine kinase-MB fraction, which returns to normal sooner, can help differentiate acute from remote infarction.

Obtain cardiac cTn levels in all patients with suspected acute coronary syndrome.[55] Contemporary cTn assays will identify most patients (approximately 80%) with acute myocardial infarction within 2 to 3 hours of ED arrival.[82-84] Patients with early presentations (within 6 hours of symptom onset) or those with intermittent symptoms should have serial measurements of cTn over time. In patients with constant symptoms for >8 to 12 hours, a single cTn may be sufficient to exclude acute myocardial infarction.[56,85] Measurement of cTn at short time intervals, such as 2 to 4 hours, to evaluate for serial change (delta cTn) is more sensitive for acute myocardial infarction than a single cTn approach.[55]

Newer high-sensitivity cTn assays have a 10-fold higher analytical sensitivity compared to contemporary assays; these are currently pending U.S. Food and Drug Administration approval.[80,87,88] Compared with contemporary assays, high-sensitivity cTn assays are more sensitive for the detection of acute myocardial infarction in all patients (94% to 96% vs. 85% to 90%) and increase the early detection of myocardial injury.[83,84] Among patients presenting within 3 hours of chest pain onset, high-sensitivity cTn assays are 92% to 94% sensitive for acute myocardial infarction compared to 76% for a contemporary assay.[83] However, the increased sensitivity of high-sensitivity cTn assays for acute myocardial infarction is balanced by the detection of more patients with non–acute myocardial infarction cTn elevations.[83,88] The overall impact on ED decision making and ultimate outcome is not yet defined or shown to be clearly superior to previous assay use.

An elevated cTn is associated with an increased risk of cardiac death or acute myocardial infarction at 30 days (odds ratio 3.4; 95% confidence interval, 2.9–4.0).[89] This elevated risk of death or cardiovascular complications is independent of ECG findings or creatine kinase-MB levels.[90] Higher cTn elevations also are associated with more adverse events, even with minimal elevations.[91]

Patients with **renal disease** often have an elevated cTnT (15% to 50%), whereas cTnI elevations are less common (<10%). After dialysis, serum levels of cTnT generally increase while cTnI levels decrease.[92] Despite these features, cTnT and cTnI assays remain highly sensitive for acute myocardial infarction in patients with renal failure, particularly when new measures can be compared with baseline measures. Furthermore, renal failure patients with elevated cTn levels are at higher risk for death and adverse events than patients with normal cTn levels.[93]

Creatine Kinase-MB and Myoglobin Troponin testing has made these markers almost obsolete in acute coronary syndrome care. **Creatine kinase-MB** fraction levels elevate within 4 to 8 hours after acute myocardial infarction, peak between 12 and 24 hours, and return to normal between 36 and 72 hours (Figure 48-1). When used with cTn, creatine kinase-MB provides little additional information.[94] Creatine kinase-MB testing may be useful in a small subset of patients in whom the timing of infarction is unclear. Elevated creatine kinase-MB and cTn indicate an acute infarct, whereas a negative creatine kinase-MB with an elevated cTn suggests a remote or subacute infarction.

Myoglobin is a small heme-containing protein found in skeletal and cardiac muscle. After acute myocardial infarction, serum myoglobin levels rise within 3 hours of symptoms, peak at 4 to 9 hours, and return to baseline within 24 hours (Figure 48-1). False-positive results are common, and false-negative results may occur in patients with delayed presentations. Due to the improved sensitivity of contemporary cTn assays, myoglobin does not appear to have added value in the early detection of acute myocardial infarction.[95]

B-Type Natriuretic Peptide Natriuretic peptide elevations are not specific to myocardial ischemia or infarction and will rise with any ventricular dysfunction. Patients with acute coronary syndrome and an elevated natriuretic peptide level have higher short-term mortality, although the lab test does not aid in specific patient management actions.

Other Biomarkers High-sensitivity C-reactive protein aids long-term cardiac event prediction, but this test is not recommended for ED care.[54] A variety of other assays have been studied as cardiac biomarkers, such as ischemia-modified albumin, interleukin-6, vascular cell adhesion molecule, intercellular adhesion molecule, E-selectin, P-selectin, pregnancy-associated plasma protein A, and myeloperoxidase. Current evidence does not support the use of these novel biomarkers for ED chest pain evaluations.

CLINICAL RISK SCORES AND DECISION AIDS

The **Thrombosis in Myocardial Infarction** risk score or **Global Registry of Acute Coronary Events** score can aid acute coronary syndrome risk stratification (**Figure 48-2**).[56] The Thrombosis in Myocardial Infarction and Global Registry of Acute Coronary Events scores were drawn from groups with acute coronary syndrome present or strongly suspected, and then were applied to a wider population. Each stratifies patients into low-, intermediate-, or high-risk groups for acute coronary syndrome. However, a low-risk score is not sensitive enough to exclude acute coronary syndrome or identify patients for early discharge without further evaluation.[96,97]

The **HEART** score, **ADAPT**, and the **North American Chest Pain Rule** (**Figure 48-3**) combine clinical information to risk stratify patients and guide key decisions, notably discharge with follow-up for the lowest

TIMI Score	Yes 1 point	No 0 points
Age ≥65		
≥3 Risk factors for ACS; hypertension, hyperlipidemia, smoking, diabetes, family history		
Use of aspirin in last 7 days		
Prior coronary stenosis >50%		
≥2 angina events in 24 hours or persisting discomfort		
ST-segment deviation of ≥0.05 mV on initial ECG		
Elevated cardiac biomarkers		
Total Score		

Low Risk	0-2
Intermediate Risk	3-4
High Risk	5-7

North American Chest Pain Rule		
High risk criteria	**Yes**	**No**
Age ≥50		
Acute ischemic ECG changes		
Known coronary artery disease		
Pain typical for ACS		
Any troponin >99th percentile		

FIGURE 48-3. ADAPT, the North American Chest Pain Rule (NACPR), and the HEART score. With ADAPT and NACPR, a patient is considered low risk if the patient has none of the high-risk criteria. For ADAPT, risk factors include family history of coronary disease, hypertension, hypercholesterolemia, diabetes mellitus, and current smoker. With the HEART score, low risk is a score of 0 to 3, and high risk is a score of 4 or greater. Risk factors include currently treated diabetes mellitus, current or recent (<90 days) smoker, diagnosed and/or treated hypertension, diagnosed hypercholesterolemia, family history of coronary artery disease, obesity (body mass index >30), or a history of significant atherosclerosis (coronary revascularization, myocardial infarction, stroke, or peripheral arterial disease). ACS = acute coronary syndrome; TIMI = Thrombosis in Myocardial Infarction score.

risk patients or observation/admission for the remaining patients. Although these decision support tools may improve the quality and efficiency of chest pain care in the ED, they require further impact assessment before routine use.[98-100]

CHAPTER 49

Acute Coronary Syndromes

Judd E. Hollander
Deborah B. Diercks

EPIDEMIOLOGY

Ischemic heart disease is the leading cause of death among adults in the United States, with more than 405,000 people dying annually. Atherosclerotic disease of the epicardial coronary arteries—termed *coronary artery disease* (CAD)—accounts for the vast majority of patients with ischemic heart disease. The predominant symptom of CAD is chest pain, and patient concern over potential acute heart disease contributes to the >8 million visits each year to U.S. EDs. In a typical adult ED population with acute chest pain, about 15% of patients will have an acute coronary syndrome (ACS). ACS encompasses unstable angina through acute myocardial infarction (AMI). Of patients with an ACS, approximately one third have an AMI, and the remainder have unstable angina.

TABLE 49-1 Three Principal Presentations of Unstable Angina

Class	Presentation
Rest angina*	Angina occurring at rest and that is prolonged, usually >20 min
New-onset angina	New-onset angina that markedly limits ordinary physical activity, such as walking 1–2 blocks or climbing 1 flight of stairs or performing lighter activity
Increasing angina	Previously diagnosed angina that has become distinctly more frequent, has a longer duration, or is lower in threshold, limiting ability to walk 1–2 blocks or climb 1 flight of stairs or perform lighter activity

*Patients with non-ST-elevated myocardial infarction usually present with angina at rest.

The three principal presentations of unstable angina are listed in **Table 49-1**.[1] These definitions assume that the anginal chest pain is due to ischemia, and this categorization does not apply to patients presenting to the ED with chest pain from other causes. During the initial ED assessment, it may not be possible to determine whether the patient has or will sustain permanent damage to the myocardium, has reversible ischemia (injury or unstable angina), or has a noncardiac cause of symptoms.

The American College of Cardiology and American Heart Association have a tool for estimating the short-term risk for death or AMI in patients with unstable angina (**Table 49-2**).[1]

ANATOMY

The left coronary artery divides into the left circumflex and the left anterior descending branches (**Figure 49-1**). The left anterior descending branch courses down the anterior aspect of the heart providing the

TABLE 49-2 Short-Term Risk of Death or Nonfatal Myocardial Infarction by Risk Stratification in Patients with Unstable Angina

Feature	High Likelihood (at least one of the following features must be present)	Intermediate Likelihood (no high-risk feature, but must have one of the following)	Low Likelihood (no high- or intermediate-risk feature, but may have any of the following)
History	Accelerating tempo of ischemic symptoms in preceding 48 h	Prior myocardial infarction, peripheral or cerebrovascular disease, or coronary artery bypass grafting; prior aspirin use	
Character of the pain	Prolonged, ongoing (>20 min) rest pain	Prolonged (>20 min) rest angina, now resolved, with moderate or high likelihood of CAD Rest angina (>20 min) or relieved with rest or sublingual nitroglycerin Nocturnal angina New-onset or progressive angina in the past 2 wk without prolonged (>20 min) rest pain but with intermediate or high likelihood of CAD (see Table 49-3)	Increased angina frequency, severity, or duration Angina provoked at a lower threshold New-onset angina with onset 2 wk to 2 mo before presentation
Clinical findings	Pulmonary edema, most likely due to ischemia New or worsening mitral regurgitation murmur S_3 or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 y old	Age >70 y old	Chest discomfort reproduced by palpation
ECG	Angina at rest with transient ST-segment changes >0.5 mm Bundle-branch block, new or presumed new Sustained ventricular tachycardia	T-wave changes, pathologic Q waves, or resting ST depression <1 mm in multiple lead groups (anterior, inferior, lateral)	Normal or unchanged ECG
Cardiac markers	Elevated cardiac TnT, TnI (e.g., TnT or TnI >0.1 nanogram/mL)	Slightly elevated cardiac TnT, TnI (e.g., TnT >0.01 but <0.1 nanogram/mL)	Normal

Abbreviations: CAD = coronary artery disease; TnI = troponin I; TnT = troponin T.

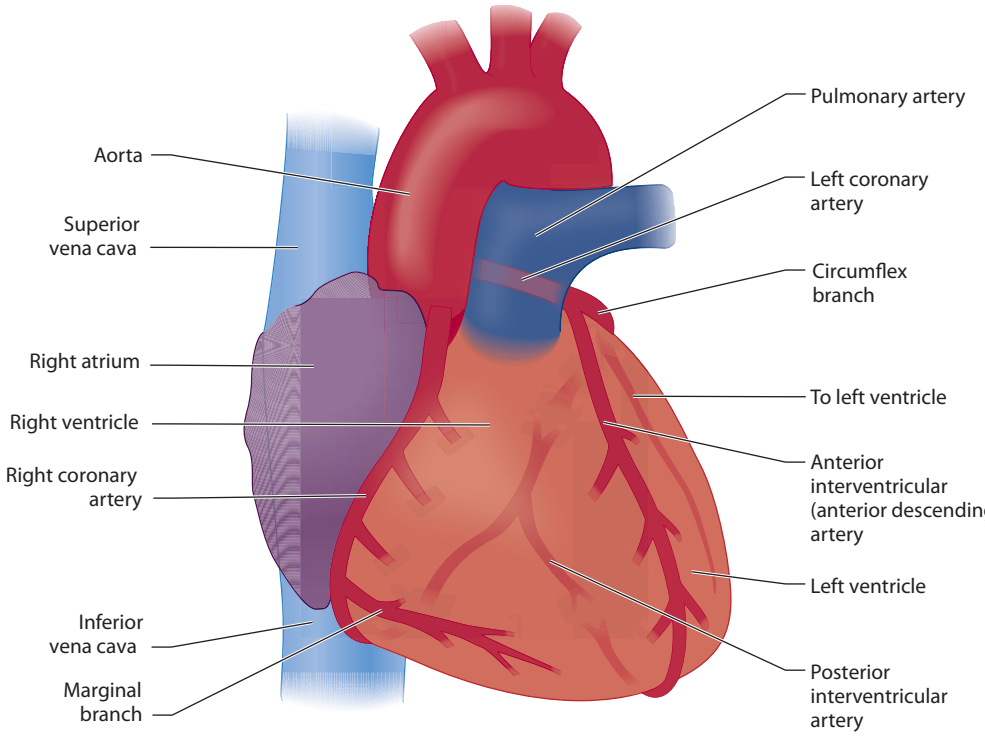

FIGURE 49-1. Schematic diagram of the coronary arteries.

main blood supply to the anterior and septal regions of the heart. The circumflex branch supplies blood to some of the anterior wall and a large portion of the lateral wall of the heart. The right coronary artery supplies the right side of the heart and provides some perfusion to the inferior aspect of the left ventricle through its continuation as the right posterior descending artery.

The atrioventricular conduction system receives blood supply from the atrioventricular branch of the right coronary artery and the septal perforating branch of the left anterior descending coronary artery. Similarly, the right bundle branch and the posterior division of the left bundle branch each obtain blood flow from both the left anterior descending and right coronary arteries. The posteromedial papillary muscle receives blood supply from one coronary artery, usually the right coronary artery.

PATHOPHYSIOLOGY

Ischemia occurs when there is an imbalance between oxygen (O_2) demand and O_2 supply. O_2 supply is influenced by the O_2-carrying capacity of the blood and the coronary artery blood flow. The O_2-carrying capacity of the blood is determined by the amount of hemoglobin present and O_2 saturation. Coronary artery blood flow is determined by the duration of diastolic relaxation of the heart and peripheral vascular resistance. Humoral, neural, metabolic, and extravascular compressive forces and local autoregulation mechanisms determine the coronary vascular resistance.

Exercise-induced myocardial ischemia and its sequelae usually occur as a result of fixed atherosclerotic lesions. ACS may be caused by secondary reduction in myocardial blood flow due to coronary arterial spasm, disruption or erosion of atherosclerotic plaques, and platelet aggregation or thrombus formation at the site of an atherosclerotic lesion. Secondary causes of myocardial ischemia are less common and prompted by factors extrinsic to the coronary arteries such as increased myocardial O_2 demand (i.e., fever, tachycardia, thyrotoxicosis), reduced blood flow (i.e., hypotension), or reduced O_2 delivery (i.e., anemia, hypoxemia). In the event of a secondary cause, global ischemia may occur widely or focally.

Atherosclerotic plaque forms through repetitive injury to the vessel wall. Macrophages and smooth muscle cells are the main cellular elements in plaque development, whereas lipids are predominant in the extracellular milieu. Plaque fissuring and rupture are affected by features inherent to the plaque, such as its composition and shape; local factors, such as shear forces, coronary arterial tone, and coronary arterial perfusion pressure; and movements of the artery in response to myocardial contractions. When plaque rupture occurs, potent thrombogenic substances activate circulating platelets.

The platelet response involves adhesion, activation, and aggregation. Platelet adhesion occurs through the weak platelet interactions with subendothelial adhesion molecules, such as collagen, fibronectin, and laminin, and the binding of the glycoprotein IIb receptor to the subendothelial form of von Willebrand factor. Adherent platelets are strongly thrombogenic. Lipid-laden macrophages in the plaque core and adventitia of the vessel wall release tissue factor, which stimulates the conversion of prothrombin to thrombin. Thrombin and the local shear forces are also potent platelet activators. Platelet secretion of adenosine diphosphate, thromboxane A_2, and serotonin are autostimulatory agonists of platelet activation. Activated platelet glycoprotein IIb/IIIa receptors become cross-linked by fibrinogen or von Willebrand factor in the final common pathway of platelet aggregation.

The extent of O_2 deprivation and the clinical presentation of ACS depend on the limitation of O_2 delivery imposed by thrombus adhering to a plaque. In stable angina, ischemia occurs only when activity induces O_2 demands beyond the supply restrictions imposed by a partially occluded coronary vessel. Ischemia occurs at a relatively fixed point and changes slowly over time. In this scenario, the atherosclerotic plaque has not ruptured, and there is little or no superimposed thrombus. In ACS, atherosclerotic plaque rupture and platelet-rich thrombus develop. Coronary blood flow is reduced suddenly, and myocardial ischemia occurs. The degree and duration of the O_2 supply–demand mismatch determines whether the patient develops reversible myocardial ischemia without necrosis (unstable angina) or myocardial ischemia with necrosis (AMI). More severe and prolonged obstruction increases the likelihood of infarction.

AMI may inhibit myocardial contractility and impair both central and peripheral perfusion. When an area of the myocardium does not receive adequate O_2, the functional deterioration progresses; as the size of the infarcted myocardium increases, left ventricular pump function decreases. This creates increased left ventricular end-diastolic pressure and end-systolic volume. Cardiac output, stroke volume, and blood pressure may decrease. When left atrial and pulmonary capillary pressures increase, heart failure or pulmonary edema may develop.

Poor perfusion to the brain and kidneys can result in altered mental status and impaired renal function, respectively.

CLINICAL FEATURES

HISTORY AND ASSOCIATED SYMPTOMS

The main symptom of ischemic heart disease is chest discomfort or pain, and the history should characterize its severity, location, radiation, duration, and quality. In addition, the presence of associated symptoms such as nausea, vomiting, diaphoresis, dyspnea, light-headedness, syncope, and palpitations may help detect myocardial ischemia (see Tables 48-1 and 48-2 in chapter 48 "Chest Pain"). Obtain information regarding the onset and duration of symptoms, activities that precipitate symptoms, and prior evaluations for similar symptoms to assess the possibility of acute myocardial ischemia.

Symptoms of acute myocardial ischemia often will be described as *discomfort* rather than pain; look for descriptions of chest pressure, heaviness, tightness, fullness, or squeezing. Less commonly, patients will describe their symptoms as knife-like, sharp, or stabbing. The classic pain or discomfort location is substernal or in the left chest, with radiation to the arm (either), neck, or jaw. Reproducible chest wall tenderness is noted in some.

Exercise, stress, and a cold environment classically precipitate angina. Angina typically has a duration of symptoms of <10 minutes, occasionally lasting up to 10 to 20 minutes, and usually improves within 2 to 5 minutes after rest or nitroglycerin. In contrast, acute myocardial ischemia is usually accompanied by more prolonged and severe chest discomfort, more prominent associated symptoms (e.g., nausea, diaphoresis, shortness of breath), and little response to initial sublingual nitroglycerin. Easy fatigability may be a prominent symptom of ACS, especially in women.[2]

Ask about the frequency of anginal episodes and any change in frequency of episodes over the past months. Determine if there is any increase in severity or duration of symptoms, or whether less effort is required to precipitate symptoms.

Advanced age, female gender, and a history of diabetes mellitus are associated with more nonclassic ACS presentations. Presentations with nonclassic features or silent myocardial ischemia are common; for example, as many as 37.5% of women and 27.4% of men present without chest pain.[3] Up to 30% of patients with acute myocardial ischemia identified in large longitudinal studies are clinically unrecognized, often not seeking medical care or not recalling any symptoms. The prognosis for patients with nonclassic symptoms (e.g., fatigue, weakness, not feeling well, vague discomfort) at the time of infarction is worse than that of patients with more classic symptoms. Women and the elderly are more likely to have presentations that differ from classic ones in the younger patients; across all age groups, those with unstable angina have nonclassic features nearly half the time. This is why the term *atypical chest pain* is misleading, because nonclassic presentations are common despite being often called atypical.

Cardiac risk factors are poor predictors of risk for AMI or other ACSs.[4] Traditional cardiac risk factors for CAD, such as hypertension, diabetes mellitus, tobacco use, family history at an early age, and hypercholesterolemia, are not helpful to predict ACS in ED patients >40 years old.[4] The cardiac risk factors predict risk of CAD over time, not likelihood of presence at one moment.

PHYSICAL EXAMINATION

Patients with ACS may appear well, without any clinical signs of distress, or may be uncomfortable, pale, cyanotic, or in respiratory distress. The pulse rate may be normal or display bradycardia, tachycardia, or irregular pulses. Bradycardic rhythms are more common with inferior wall myocardial ischemia; in the setting of an acute anterior wall infarction, bradycardia or new heart block is a poor prognostic sign. Blood pressure can be normal, elevated (due to baseline hypertension, sympathetic stimulation, and anxiety), or decreased (due to pump failure or inadequate preload), although extremes of blood pressure are associated with a worse prognosis.

An S_3 is present in 15% to 20% of patients with AMI; if detected, an S_3 may indicate a failing myocardium. **The presence of a new systolic murmur is an ominous sign, because it may signify papillary muscle dysfunction, a flail leaflet of the mitral valve with resultant mitral regurgitation, or a ventricular septal defect.**

The presence of rales, with or without an S_3 gallop, indicates left ventricular dysfunction and left-sided heart failure. Jugular venous distention, hepatojugular reflex, and peripheral edema suggest right-sided heart failure.

DIAGNOSIS

The diagnosis of ST-segment elevation myocardial infarction (**STEMI**) depends on the ECG in the setting of symptoms suggestive of myocardial infarction. The diagnosis of non-ST-segment elevation myocardial infarction (**NSTEMI**) depends on abnormal elevation of cardiac biomarkers but may include ECG changes not meeting criteria for STEMI. The diagnosis of **unstable angina** is based on history (Table 49-1) because the ECG and cardiac injury biomarkers are nondiagnostic. Early risk assessment for the likelihood of myocardial infarction uses all of these data to aid decision making (**Tables 49-3** and **49-4**).

TABLE 49-3 Likelihood That Signs and Symptoms Represent Acute Coronary Syndrome Secondary to Coronary Artery Disease

Feature	High Likelihood (any of the following)	Intermediate Likelihood (absence of high-likelihood features and presence of any of the following)	Low Likelihood (absence of high- or intermediate-likelihood features but may have the following)
History	Chest or left arm pain or discomfort as chief symptom reproducing prior documented angina Known history of coronary artery disease, including myocardial infarction	Chest or left arm pain or discomfort as chief symptom Age >70 y old Male sex Diabetes mellitus	Probable ischemic symptoms in absence of any of the intermediate-likelihood characteristics Recent cocaine use
Examination	Transient mitral regurgitation murmur, hypotension, diaphoresis, pulmonary edema, or rales	Extracardiac vascular disease	Chest discomfort reproduced by palpation
ECG	New, or presumably new, transient ST-segment deviation (≥1 mm) or T-wave inversion in multiple precordial leads	Fixed Q waves ST depression 0.5–1.0 mm or T-wave inversion >1 mm	T-wave flattening or inversion <1 mm in leads with dominant R waves Normal ECG
Cardiac markers	Elevated cardiac troponin I, troponin T, or MB fraction of creatine kinase	Normal	Normal

Note: Estimation of the likelihood of significant coronary artery disease is a complex, multivariable problem that cannot be fully specified in a table such as this. Therefore, the table is meant to illustrate major relationships rather than offer rigid algorithms.

TABLE 49-4 Thrombosis in Myocardial Infarction (TIMI) Score for Unstable Angina

Age 65 y or older
3 or more traditional risk factors for coronary artery disease
Prior coronary stenosis of 50% or more
ST-segment deviation on presenting electrocardiogram
2 or more anginal events in prior 24 h
Aspirin use within the 7 d prior to presentation
Elevated cardiac markers
The presence of each of the above is assigned 1 point. The maximum possible score is 7.

The **Thrombosis in Myocardial Infarction (TIMI) score** is a seven-item tool that helps stratify patients with potential ACSs in the ED. Patients with a score of 0 to 2 have a 2% to 9% 30-day risk of death, myocardial infarction, or revascularization. Patients with higher scores have higher risks.

ELECTROCARDIOGRAPHY

The standard 12-lead ECG is the single best test—although it can be fallible—to identify patients with AMI upon ED presentation.[1] **Obtain the initial 12-lead ECG and interpret the tracing quickly, ideally within 10 minutes of presentation in those patients with symptoms suggestive of myocardial ischemia.** Prehospital ECGs reduce the time from symptom onset to reperfusion therapy in STEMI patients and are an optimal tool when possible.[5,6]

ST-segment–based diagnostic ECG criteria for AMI are shown in **Table 49-5**. STEMI in the listed distributions suggests acute transmural injury. ST-segment depressions in these distributions suggest ischemia. **Inferior wall AMIs should have a right-sided lead V_4 (V_4R) obtained**, because ST-segment elevation in V_4R is highly suggestive of right ventricular infarction. For patients with a nondiagnostic tracing and persistent symptoms who have a high risk of ACS, repeat the ECG to detect developing changes.[1,5,7] Early studies of fibrinolytic therapy identified an increased risk of mortality in patients with new bundle-branch block; this led to interpreting a new left bundle-branch block as being a "STEMI equivalent." However, <10% of patients with new or possibly new left bundle-branch block have AMI.[8]

TABLE 49-5 Electrocardiographic ST-Segment–Based Criteria for Acute Myocardial Infarction

Location	Electrocardiographic Findings
Anteroseptal	ST-segment elevations in V_1, V_2, and possibly, V_3
Anterior	ST-segment elevations in V_1, V_2, V_3, and V_4
Anterolateral	ST-segment elevations in V_1–V_6, I, and aVL
Lateral	ST-segment elevations in I and aVL
Inferior	ST-segment elevations in II, III, and aVF
Inferolateral	ST-segment elevations in II, III, aVF, and V_5 and V_6
True posterior*	Initial R waves in V_1 and V_2 >0.04 s and R/S ratio ≥1
Right ventricular	ST-segment elevations in II, III, and aVF and ST elevation in right-side V_4

*Posterior wall infarction does not produce Q-wave abnormalities in conventional leads and is diagnosed in the presence of tall R waves in V_1 and V_2.

Reciprocal ST-segment changes—those in leads away from or opposite the elevation area—are from subendocardial ischemia and denote a larger area of injury risk, an increased severity of underlying CAD, more severe pump failure, a higher likelihood of cardiovascular complications, and increased mortality. In general, **the more elevated the ST segments and the more ST segments that are elevated, the more extensive is the injury.**

The ECG changes correlate often with the infarct-related vessel (**Table 49-6**). Inferior wall AMIs can result from occlusion of the left circumflex artery or the right coronary artery. In the setting of an inferior wall AMI, ST-segment elevation in at least one lateral lead (V_5, V_6, or aVL) with an isoelectric or elevated ST segment in lead I is strongly suggestive of a left circumflex lesion (**Figure 49-2**). The presence of ST-segment elevation in lead III greater than that in lead II predicts a right coronary artery occlusion (**Figure 49-3**). When accompanied by ST-segment elevation in V_1 or a V_4R, it predicts a proximal right coronary artery lesion with accompanying right ventricular infarction (**Figure 49-4**). Reciprocal anterior ST-segment depressions in V_1 through V_4 are equally prevalent in right coronary and left circumflex inferior wall AMIs. **Figure 49-5** shows anterior myocardial infarction from distal left anterior descending artery

TABLE 49-6 ECG Findings and Culprit Coronary Artery[9–13]

ECG Findings	Culprit Artery	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
ECG findings for inferior ST-segment elevation myocardial infarction					
ST-segment elevation in lead III greater than in lead II plus ST-segment depression of >1 mm in lead I, lead aVL, or both	Right coronary artery	90	71	94	70
In addition to the findings immediately above, ST-segment elevation on V_1, V_4R, or both	Proximal right coronary artery	79	100	100	88
Absence of the above findings plus ST-segment elevation in leads I, aVL, V_5, and V_6 and ST-segment depression in leads V_1, V_2, and V_3	Left circumflex coronary artery	83	96	91	93
ECG findings for anterior ST-segment elevation myocardial infarction					
ST-segment elevation in leads V_1, V_2, and V_3 plus any of the features below:					
ST-segment elevation of >2.5 mm in lead V_1, or right bundle-branch block with Q wave, or both	Proximal left anterior descending coronary artery	12	100	100	61
ST-segment depression of >1 mm in leads II, III, and aVF	Proximal left anterior descending coronary artery	34	98	93	68
ST-segment depression of ≤1 mm, or ST-segment elevation in leads II, III, and aVF	Distal left anterior descending coronary artery	66	73	78	62

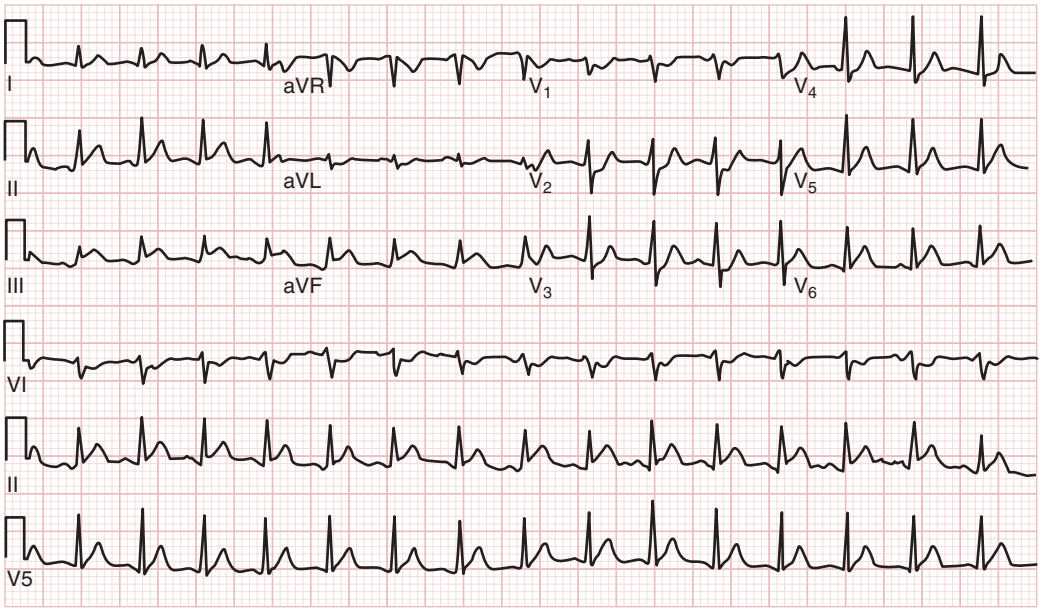

FIGURE 49-2. ECG showing inferior-lateral myocardial infarction from left circumflex coronary artery occlusion. ECG from a 42-year-old man presenting with chest pain. ECG shows ST-segment elevation in limb leads II, III (inferior), and aVF, as well as lead V_6 (lateral). ST-segment depression is evident in leads V_1, V_2, and V_3, reflecting reciprocal changes in the anterior leads. The patient was found to have 100% occlusion of the left circumflex coronary artery at cardiac catheterization. [Used with permission of David M. Cline, MD, Wake Forest University.]

occlusion, whereas **Figure 49-6** shows anterior myocardial infarction from proximal left anterior descending artery occlusion.

ECGs are frequently misinterpreted, with a low of 5.9% to as many as 29% being misinterpreted.[14] False-positive interpretations of the ECG, indicating STEMI when no injury exists, occur between 11% and 14% of the time.[13] Balancing this is the observation that **even patients with normal or nonspecific ECGs have a 1% to 5% incidence of AMI and a 4% to 23% incidence of unstable angina**. Patients with nondiagnostic ECGs or evidence of ischemia that is age-indeterminate have a 4% to 7% incidence of AMI and a 21% to 48% incidence of unstable angina. Demonstration of new ischemia in ECG increases the risk of AMI from 25% to 73% and the unstable angina risk from 14% to 43%. Thus, the standard 12-lead ECG is useful for cardiovascular risk stratification of patients with ACSs. The only guideline-recommended addition to the standard 12-lead ECG is the use of right-sided precordial lead, V_4R, in the setting of acute inferior myocardial infarction to detect right ventricular involvement.[1,5,6]

There are several clinical conditions in which ECG interpretation is difficult (**Table 49-7**). In the setting of paced rhythms or left bundle-branch block, acute myocardial ischemia can be identified (**Figure 49-7**) with select findings. **In those with a preexisting left bundle-branch block, the following patterns are indicative of AMI:** (1) ST-segment elevation of 1 mm or greater and concordant (in the same direction as the main deflection) with the QRS complex (odds ratio, 25.2; 95% confidence interval [CI], 11.6% to 54.7%) seen in Figure 49-7C; (2) ST-segment depression of 1 mm or more in leads V_1, V_2, or V_3 (odds ratio, 6.0; 95% CI, 1.9% to 19.3%) seen in Figure 49-7D; and (3) ST-segment elevation of 5 mm or greater and discordant (in the opposite direction) with the QRS complex (odds ratio, 4.3; 95% CI, 1.8% to 10.6%) seen in Figure 49-7E.[14]
